p*K*. A measurement of the completeness of an incomplete chemical reaction. It is defined as the negative logarithm (to the base 10) of the equilibrium constant K for the reaction in question. The pK is most frequently used to express the extent of dissociation or the strength of weak acids, particularly fatty acids, amino acids, and also complex ions, or similar substances. The weaker an electrolyte, the larger its pK. Thus, at 25°C for sulfuric acid (strong acid), pK is about −3.0; acetic acid (weak acid), p$K = 4.76$; boric acid (very weak acid), p$K = 9.24$. In a solution of a weak acid, if the concentration of undissociated acid is equal to the concentration of the anion of the acid, the pK will be equal to the pH.

PLANT GROWTH MODIFICATION AND REGULATION. Those chemical substances having the most to do with plant growth and form are given the general term *plant hormones*. A plant hormone, or *phytohormone*, may be defined as an organic compound produced naturally in plants, which controls growth or other functions at a site remote from its place of production, and which is very active in minute amounts. Three chemically quite different types of compounds apparently act as plant hormones: the *auxins*, the *gibberellins*, and the *kinetins*. In addition, the growth of roots is dependent upon vitamins of the B group which are synthesized in leaves and transported thence to the roots, thus qualifying as hormones.

Auxins

The best-studied hormones are those belonging to the class of auxins. These are defined as organic substances which promote growth along the longitudinal axis, when applied in low concentrations to shoots of plants freed as far as practical from their own inherent growth-promoting substances. Auxins generally have additional properties, but this one is critical.

Natural auxins have been identified in a number of instances. Indole-3-acetaldehyde occurs in a number of etiolated seedlings and in pineapple leaves; indole-3-acetonitrile has been isolated from cabbage and its presence indicated in a number of plants. One of the most widely occurring auxins is indole-3-acetic acid, which has been isolated in pure form from fungi and from corn (maize) grains. Its presence has been conclusively demonstrated by biochemical and chromatographic tests in a wide variety of flowering plants, including mono- and dicotyledons.

Many synthetic auxins have been produced, including 2,4-dichlorophenoxyacetic acid or 2,4-D; naphthalene-1-acetic acid; and 2,3,6-trichlorobenzoic acid, among others. Used as a herbicide, 2,4-D is described in **Herbicides**.

By definition, these synthetic compounds are not hormones, although they are sometimes loosely referred to as hormone-type compounds.

An auxin is formed in fruits, seeds, pollen, root tips, coleoptile tips, young leaves, and especially in developing buds. The auxin travels away from the site of production in shoots by a special transporting system, depending on oxygen, which moves it in a predominantly polar direction from apex toward base. Movement in the opposite direction, i.e., from base toward apex, takes place to a variable extent depending upon the tissue and the plant. In the course of the polar transport, a large part of the auxin becomes bound and is no longer transportable. The transport is rather specifically inhibited by related compounds, particularly 2,3,5-triiodobenzoic acid, 2,4-D, and other synthetic auxins, which are transported either more slowly or to a much lesser extent in the polar system. Auxin applied artificially to intact plants can travel rapidly upward by penetrating into the conducting tissues of the wood, where it is carried upward in the transpiration stream.

In its normal polar, downward movement, the auxin stimulates the cells below the tip to elongate and sometimes to divide. Specific tissues, notably the cambium, are caused to divide laterally by auxin coming from the developing buds, which accounts for the wave of cell division occurring in tree trunks in the spring. Stimulation of other stem cells to divide

leads to the production of root initials, which grow out as lateral roots. Cells of the young ovary are commonly caused to multiply and enlarge so that an apparently normal fruit is produced without requiring pollination (*parthenocarpic fruit*). This latter phenomenon indicates that the growing seeds normally secrete an auxin to which enlargement of the fruit is due, a conclusion which has been directly confirmed by bioassay in several fruit types.

Gibberellins can also cause enlargement of fruit. On reaching the lateral buds, however, auxin inhibits their elongation into shoots, and this accounts for *apical dominance*, i.e., suppression of the growth of lateral buds by the terminal bud of a shoot. Auxin also inhibits the falling off of leaves or fruits, which normally occurs when they are mature or aged by the formation of an *abscission layer* of special cells whose walls come apart. That the leaves or fruits do not absciss earlier is due to their steady production of auxin, which prevents formation of these cells. In the root, auxin inhibits elongation except in very low concentrations, but its level therein is usually low. Auxin can be transported for a short distance from the root apex toward the base, but the transport is not fully polar and in the more basal parts of the root the transport is slight.

When the shoot is placed horizontal, auxin is transported toward the lower side, causing accelerated growth there and hence upward curvature (*geotropism*); in the root, this causes decreased growth on the lower side and hence downward curvature. However, in the downward geotropic curvature of roots, other phenomena appear to enter in, and the complexities are not yet fully resolved. When shoots are illuminated from one side, auxins accumulate on the shaded side and, therefore, the plant curves toward the light (*phototropism*). Both geotropic and phototropic auxin movements have been confirmed with carboxyl-^{14}C-labeled compounds. The first observed effect when auxin is applied is the acceleration of the streaming of cytoplasm, but acceleration of growth begins in 7 to 14 minutes at about 23°C.

In plants that flower on short days, auxin may inhibit flowering; in plants that flower on long days, however, if close to the transition from the vegetative to the flowering state, auxin may promote flowering. In hemp and some of the squashes, auxin modifies the sexuality of the flowers toward femaleness. In the special case of pineapple, auxin directly causes flowering in an unusually clear-cut and quantitative response.

The principal uses of synthetic auxins are to promote the formation of roots on stem cuttings, to prevent abscission, especially of apples and pears, to induce flowering in pineapples, and occasionally to produce seedless fruits. The largest use, however, is that of weed killing. This action depends upon the fact that, at concentrations from 100 to 1000 times those concentrations occurring naturally, the auxins are highly toxic. Monocotyledonous plants, however, are usually resistant. In years past, 2,4-D has been favored in North and South America, whereas 2-methyl-4-chlorophenoxyacetic acid (*methoxone*) has been popular in Europe. However, as of the early 1980s, the regulatory status of these compounds in various countries is under study and may be subject to change.

Some chemically related compounds antagonize the action of auxins, for example, relieving the inhibition of root growth caused by 2,4-D. In contrast, 2,3,5-triiodbenzoic acid synergizes the action.

Gibberellins

These compounds were originally isolated from a parasitic fungus that causes excessive leaf elongation in rice plants. The mechanisms and applications of this group of compounds are described in **Gibberellic Acid and Gibberellin Plant Growth Hormones**.

Kinetins

Considerably less is known about this class of compounds. The first one to be discovered, produced by autoclaving yeast nucleic acid, was 6-furfurylaminopurine. Somewhat later, zeatin was isolated from immature corn (maize) kernels. The kinetins promote cytokinesis and protein synthesis, thus causing amino acids to accumulate where kinetins are synthesized (or externally applied) and maintaining the chlorophyll content of yellowing leaves. The kinetins antagonize auxin in apical dominance, releasing lateral buds from inhibition by a terminal bud or by applied auxin. It is believed that through the same mechanism, the kinetins promote the development of buds and leaves on tissue cultures. Their action is primarily local, and if there is transport *in vivo*, it probably occurs mainly in the transpiration stream (where amino acids are also often found).

Ethylene

The production of ethylene in fruit tissue and in small amounts in leaves may justify its consideration as a hormone, functioning in the gaseous state. Cherimoyas and some varieties of pear produce 1000 times the effective physiological concentration. Ethylene formation is closely linked to oxidation and may be centered in the mitochondria. Its effects are to promote cell-wall softening, starch hydrolysis, and organic acid disappearance in fruits—the syndrome known as *ripening*. Ethylene also decreases the geotropic responses of stems and petioles.

Daminozide Growth Modifier

Daminozide, the chemical name of which is 2,2-dimethyldrazide, was developed in the early 1960s as a modifying or regulating agent for the growth process of several food plants. The action varies with each plant. For example, on apple, the compound accelerates the start of flower budding, restricts nonproductive vegetative growth, and assist in fruit drop control. It is also claimed that the compound accelerates fruit coloring and helps to retain the firmness of the fruit. For some of these and other similar reasons, the compound has been used effectively for certain varieties of grape (particularly Concord), for peanuts (groundnuts), for tomatoes, nectarines (except Cherokee), and peaches. Other commercial designations are Alar, B-Nine, Kylar, and Sadh.

Ethephon Growth Modifier

This compound, (2-chloroethyl)phosphonic acid was developed in the United States in the mid-1960s and is used effectively on a number of fruit and vegetable crops for controlling a variety of factors. These include loosening fruit and causing earlier ripening of the fruit (apple, blackberry, blueberry, cherry, cranberry, filbert, tangerine, and walnuts); for encouraging uniform ripening and increasing yield (pepper and tomato); to improve color as well as accelerate maturity (cranberry); and to decrease time required for degreening in citrus fruits, particularly lemon. Other commercial designations for this compound include Cepha, Ethrel, and Florel.

Maleic Hydrazide

This compound, 1,2-dihydro-3,6-pyridazinedione, is also used as a growth regulator, herbicide, and plant modifier. It is used in the treatment of tobacco plants; as a post-harvest sprouting inhibitor; and as a sugar content stabilizer in sugar beets.

PLANT HORMONES (Gibberellins). See **Gibberellic Acid and Gibberellin Plant Growth Hormones**.

PLASMA. The portion of the blood remaining after removal of the white and red cells and the platelets; it differs from serum in that it contains fibrinogen, which induces clotting by conversion into fibrin by activity of the enzyme thrombin. Plasma is made up of more than 40 proteins and also contains acids, lipids, and metal ions. It is an amber, opalescent solution in which the proteins are in colloidal suspension and the solutes (electrolytes and nonelectrolytes) are either emulsified or in true solution. The proteins can be separated from each other and from the other solutes by ultrafiltration, ultracentrifugation, electrophoresis, and immuno-chemical techniques. See also **Blood**.

PLASMA FREQUENCY. The oscillation frequency of plasma electrons about an equilibrium charge distribution is called the plasma or Langmuir frequency and is

$$\omega_p = \sqrt{\frac{4\pi n_e q^2}{m}} = 5.7 \times 10^5\ n_e^{1/2}\ \text{(radians/sec)}$$

where n_e is the electron density, m is the electron mass, and q is the electronic charge in esu. Its value is

$$(5.7 \times 10^{-5}\ \text{radian cm}^{-3/2}\ \text{sec}^{-1})n_e^{1/2}$$

PLASMA (Particle). 1. An assembly of ions, electrons, neutral atoms and molecules in which the motion of the particles is dominated by electromagnetic interactions. This condition occurs when the macroscopic electrostatic shielding distance (Debye length) is small compared to the dimensions of the plasma. Because of the large electrostatic potentials

which would result from an inhomogeneous distribution of unlike charges, a plasma is effectively neutral. Thus there are equal numbers of positive and negative charges in every macroscopic volume of a plasma. Also, because a plasma is a conductor, it interacts with electromagnetic fields. The study of these interactions is called *hydromagnetics* or *magnetohydrodynamics*.

2. A collection of electrons and ions, usually at a high enough temperature so that the ionization level is about 5% and at densities such that the Debye shielding distance is much smaller than the macroscopic dimensions of the system. See also **Fusion Energy**.

PLASMID. A strand or fragment of genetic material existing outside the chromosomes in certain types of bacteria. R-type plasmids, which are present in *E. coli*, impart resistance to antibiotics in organisms that are exposed to them. The plasmids can be transferred from animals to humans, as well as to other, harmful bacteria that also become resistant to antibiotics. Feeding of traces of antibiotics to animals is believed to promote the growth of E. *coli* and, thus, to produce strains of pathogenic bacteria that are not amenable to antibiotic treatment. For this reason FDA has recommended elimination of certain antibiotics from animal feeds, e.g., penicillin, oxytetracycline, and chlortetracycline. Synthetic plasmids have been used successfully in recombinant DNA research.

PLASTIC DEFORMATION. When a metal or other solid is plastically deformed it suffers a permanent change of shape. The theory of plastic deformation in crystalline solids such as metals is complicated but well advanced. Metals are unique among solids in their ability to undergo severe plastic deformation. The observed yield stresses of single crystals are often 10^{-4} times smaller than the theoretical strengths of perfect crystals. The fact that actual metal crystals are so easily deformed has been attributed to the presence of lattice defects inside the crystals. The most important type of defect is the dislocation. See also **Creep (Metals)**; **Crystal**; and **Hot Working**.

PLASTIC FILM. A thermoplastic film less than 0.022 cm (0.010 inch) in thickness.

PLASTIC FLOW. A type of rheological behavior in which a given material shows no deformation until the applied stress reaches a critical value called the *yield value*. Most of the so-called plastics do not exhibit plastic flow. Common putty is an example of a material having plastic flow.

PLASTICITY. A rheological property of solid or semisolid materials expressed as the degree to which they will flow or deform under applied stress and retain the shape so induced, either permanently of for a definite time interval. It may be considered the reverse of elasticity. Application of heat and/or special additives is usually required for optimum results.

See also **Plasticizers**; and **Thermoplastic**.

PLASTICIZERS. High-boiling solvents or softening agents, usually liquid, added to a polymer to facilitate processing or to increase flexibility or toughness. (Where these effects are achieved by chemical modification of the polymer molecule, e.g., through copolymerization, the resin is said to be "internally plasticized.")

Thermoplastic polymers are composed of long-chain molecules held together by secondary valence bonds. When incorporated in the polymer with the aid of heat or a volatile solvent, plasticizers replace some of these polymer-to-polymer bonds with plasticizer-to-polymer bonds, thereby facilitating movement of the polymer chain segments and producing the physical changes described. Thermosetting polymers, which consist of three-dimensional networks connected through primary valence bonds, are not usually amenable to such softening by external plasticizers. Not all the thermoplastics can be plasticized satisfactorily. Polyvinyl chloride polymers and copolymers, and cellulose esters respond particularly well to plasticizing and represent the major outlets for plasticizers.

The results obtained by addition of plasticizer vary with different polymers. In polyvinyl chloride, for example, plasticizer concentrations of 30–50% convert the hard, rigid resin to rubber-like products having remarkably high elastic recovery, while similar plasticizer concentrations in cellulose acetate produce tough but essentially rigid products.

The plasticizer field has grown tremendously since camphor was patented as plasticizer for nitrocellulose in 1870. The reported U.S. production of plasticizers in 1968 exceeded 1.3 billion pounds. Close to two-thirds of this production volume is used in vinyl chloride polymers and copolymers. Plasticized polyvinyl chloride is fabricated at elevated temperature into film and sheeting, and into molded and extruded articles; it is also processed in the form of dispersions, which may be applied as coatings and subsequently baked to form continuous films. These dispersions include plastisols, in which the plasticizer is the continuous phase; organosols, in which a volatile solvent is added; and water dispersions. Plastisols are also used in molding.

Compatibility

Where the polymer-to-plasticizer attraction is strong, the plasticizer has high compatibility with the resin and is said to be of the "primary" or "solvent" type. With polyvinyl chloride this attraction is furnished particularly well by ester groups. Where the polymer-to-plasticizer attraction is low the plasticizer is of the "secondary" or "nonsolvent" type; it functions as a spacer between polymer chains but cannot be used alone because of limited compatibility. This is manifested by exudation of the plasticizer from the resin. Secondary plasticizers are often employed to take advantage of other desirable properties which they may impart. Where they are used merely to cheapen the formulation, they are usually referred to as "extenders."

Plasticizing Efficiency

It is customary when evaluating plasticizers in polyvinyl chloride to compare them at concentrations which produce a standard apparent modulus in tension, as measured at room temperature. Since the stress-strain relationship is generally nonlinear it is necessary to specify a given point on the stress-strain curve as well as the rate of loading or straining. The efficiency may be expressed as the concentration of a given plasticizer necessary to produce this standard modulus. Other properties, e.g., indentation hardness, may take the place of tensile modulus.

Such tests, while they constitute an adequate basis for routine evaluation of plasticizers, furnish only a rudimentary picture of the elastic properties of the plasticized resin. More complete studies supply valuable information. For example, tensile creep tests have shown that polyvinyl chloride resin plasticized with trioctyl phosphate will deform more in response to stresses of short duration than will resin plasticized with tricresyl phosphate; the reverse is true for stresses of long duration.

For many applications low-temperature flexibility of the plasticized composition is also important. Plasticizers of low viscosity and low viscosity-temperature gradient are usually effective at low temperature. There is also a close relationship between rate of oil extraction and low-temperature flexibility: plasticizers effective at low temperature are usually rather readily extracted from the resin. Plasticizers containing linear alkyl chains are generally more effective at low temperature than those containing rings. Low-temperature performance is evaluated by measurement of stiffness in flexure or torsion or by measurement of second-order transition point, brittle point or peak dielectric loss factor.

Permanence

Where a plasticizer is used in thin films it is important that it have low vapor pressure. For polyvinyl chloride a plasticizer vapor pressure of no more than 4 mm at 225°C has been suggested as a rough criterion, although much higher vapor pressures are tolerated in plasticizers for cellulose acetate. Volatile losses are determined, not only by the plasticizer vapor pressure, but also by the plasticizer-resin interaction; plasticizers of limited compatibility may exhibit unexpectedly high volatile loss. Comparisons are usually made by heating a plasticized sample in contact with activated carbon and measuring the weight loss of the sample. Resistance of the plasticizer to migration determines whether the plasticized composition will mar or soften varnished surfaces with which it comes in contact. Stability and water-and oil resistance are further factors in plasticizer permanence. Plasticizers which have poor oil resistance are usually also the worst offenders with respect to marring.

Commercial Plasticizers

Phthalates. These esters, prepared from *o*-phthalic anhydride, constitute the most important group of plasticizers from the stand-point of production and sales volume. Among these the dioctyl phthalates are the most widely used in vinyl chloride resins, where they are preferred because they offer a good compromise with respect to a wide range of properties: satisfactory volatility, good compatibility, fair low-temperature flexibility,

and moderately low cost. Most popular of the group is the 2-ethylhexyl ester, known as DOP, but the isoctyl, n-octyl, and capryl esters also find use. Increased emphasis on low volatility and plastisol viscosity stability has in recent years led to use of octyl decyl and didecyl phthalates. The lower alkyl phthalates are generally employed in resins other than polyvinyl chloride. Dibutyl phthalate is used chiefly in nitrocellulose lacquers and polyvinyl acetate adhesives; diethyl, dimethyl, and di(methoxyethyl) phthalates are used in cellulose acetate. For low toxicity, methyl and ethyl phthalyl ethyl glycolates are favored for cellulose acetate, and butyl phthalyl butyl glycolate for vinyl chloride polymers and nitrocellulose.

Phosphates. The phosphates, second only to phthalates in production volume, are favored for flame resistance and low volatility. Tricresyl phosphate (mixed meta and para isomers) is the most popular; it is used in polyvinyl chloride and in nitrocellulose lacquers. Resins plasticized with tricresyl phosphate are deficient in low-temperature flexibility. Diphenyl cresyl phosphate and triphenyl phosphate are other examples, the former for polyvinyl chloride, the latter for cellulose acetate. Diphenyl-2-ethylhexylphosphate is preferred to tricresyl phosphate in polyvinyl chloride where its low toxicity and improved low-temperature flexibility are required. Tri(2-ethylhexyl)-phosphate is outstanding among phosphates used in polyvinyl chloride with respect to low-temperature flexibility; in flame- and oil resistance, however, it is inferior to tricresyl phosphate. Tri(butoxyethyl)phosphate finds some use in synthetic rubber.

Esters of Aliphatic Dibasic Acids. This group consists of the adipates, sebacates, and azelates. These esters lead the field for low-temperature flexibility and efficiency in vinyls: they are useful in the preparation of low-viscosity stable plastisols. The principal disadvantages are high cost and poor solvent resistance. They are generally incompatible with cellulose acetate. Cheapest but most volatile are the adipates. Among the sebacates, the 2-ethylehexyl ester is outstanding in polyvinyl chlorides for low-temperature flexibility and low volatility; the butyl ester is used in polyvinyl butyral. The 2-ethylexyl ester of azelaic acid falls between the corresponding adipate and sebacate in price and properties.

Fatty Acid Esters. Monohydric alcohol esters of fatty acids usually have limited compatibility with vinyl chloride polymers. However, small amounts of these esters are useful for imparting low-temperature flexibility and softness and for their lubricant action during processing. Butyl oleate and stearate are leaders in this group. Methyl and butyl acetyl ricinoleates are used in nitrocellulose. Various glycol and glycerol esters of fatty acids have properties similar to the monohydric alcohol esters. Castor oil (glyceryl triricinoleate) and its derivatives are used in nitrocellulose. Triethylene glycol (di(2-ethylbutyrate) is the leading polyvinyl butyral plasticizer.

Epoxidized esters of fatty acids are similar in their plasticizing properties to other fatty acid esters, with the added advantage that they improve heat and light stability of vinyl resins by acting as hydrogen chloride scavengers. Although generally used together with conventional stabilizers, they can also be used as the sole stabilizer.

Polymeric Plasticizers. Polyesters prepared from dicarboxylic acids and diols enjoy some use in polyvinyl chloride resins for specialized applications. Ranging in properties from somewhat viscous liquids to soft resins, these plasticizers have outstanding permanence: they are of very low volatility and generally show good resistance to extraction and migration. The acids used commercially in preparing them include adipic, sebacic and azelaic; among the diols employed are propylene glycol and 2-ethyl-1,3-hexanediol; monobasic acids may be included in the preparation to limit molecular weight. Reported molecular weights of commercial polyester plasticizers range from 850 to 8000. Those of highest molecular weight are the most permanent but are somewhat difficult to process because of high viscosity and slow solvation of the resin. Other disadvantages include poor low-temperature properties and high cost. Most polyesters are rated as secondary plasticizers and are blended with the more efficient monomeric types.

Butadiene-acrylonitrile copolymers may also be used in polyvinyl chlorides and are rated as primary plasticizers for these resins. Like polyesters, they are favored for permanence, particularly oil resistance, and because they permit high loading with filler without serious impairment of physical properties. They are difficult to incorporate in vinyl resin and are often used together with conventional plasticizers. GRS rubber and polyisobutylene are also blended with certain polymers for plasticizer-like action. Other addition polymers have been studied as plasticizers, among them a series of promising liquid polymers of dibutyl itaconate.

Other Plasticizers. Acetyl tributyl citrate is an outstanding nontoxic plasticizer for polyvinyl chloride in food packaging. Plastisol formulations containing this ester have exceptional viscosity stability. Acetyl triethyl citrate is a good plasticizer for the cellulosics and acetyl trioctyl citrate shows promise with vinylidene chloride polymers. Other compounds of diverse nature find application as plasticizers. These include tetra-*n*-butyl thiodisuccinate, camphor, *o*-nitrobiphenyl and partially hydrogenated isomeric terphenyls.

New York

PLASTIC PIPE. Tubes, cylinders, conduits, and continuous length piping made (1) from thermoplastic polymers unreinforced (polyethylene, polyvinyl chloride, ABS polymers, polypropylene) or (2) from thermosetting polymers (polyesters, phenolics, epoxies) blended with 60–80% of such reinforcing materials as chopped asbestos or glass fibers to increase strength. The latter type is a reinforced plastic. In general the properties of plastic tubing or pipe are those of the polymers that comprise it. Most have good resistance to chemicals, corrosion, weathering, etc., combined with flexibility, light weight, and high strength. They are combustible but generally slow burning. The reinforced type is widely used as underground conduit for transportation of gases and fluids, including city water services, sewage disposal systems, etc. Its use in buildings is subject to local building codes. For additional information contact Plastic Pipe Institute, 1825 Connecticut Ave., NW, Suite 680, Washington, DC 20009. http://www.plasticpipe.org/applications/productinfo03_1_1.php

PLASTICS. These are materials formed from resins through the application of heat, pressure, or both. Most starting materials prior to the final fabrication of plastic products exhibit more or less plasticity—hence the term plastic. However, the great majority of plastic end-products are quite *nonplastic*, i.e., they are nonflowing, relatively stable dimensionally, and are hard. There are scores of different kinds of plastics. They fall into two broad categories: (1) *thermoplastic resins*, which can be heated and softened innumerable times without suffering any basic alteration in characteristics; and (2) *thermosetting resins*, which once set at a temperature critical to a given material cannot be resoftened and reworked. Since most plastic fabrication methods, such as casting, molding, or extruding, involve heat, the thermosetting materials must be properly and accurately formed during any thermal cycling that exceeds the critical temperature.

The principal kinds of thermoplastic resins include: (1) acrylonitrile-butadiene-styrene (ABS) resins; (2) acetals; (3) acrylics; (4) cellulosics; (5) chlorinated polyethers; (6) fluorocarbons, such as polytetra-fluorethy lene (TFE), polychlorotrifluoroethylene (CTFE), and fluorinated ethylene propylene (FEP); (7) nylons (polyamides); (8) polycarbonates; (9) poly ethylenes (including copolymers); (10) polypropylenes (including copolymers); (11) polystyrenes; and (12) vinyls (polyvinyl chloride). The principal kinds of thermosetting resins include: (1) alkyds; (2) allylics; (3) the aminos (melamine and urea); (4) epoxies; (5) phenolics; (6) polyesters; (7) silicones; and (8) urethanes.

The development of electrically conductive plastics is reviewed by R.B. Kaner and A.G. MacDiarmid (*Sci. Amer.*, 106–111, February 1988).

Numerous plastics are described in terms of manufacture and chemical and physical properties throughout this volume. Consult the alphabetical index.

PLASTIDS. Pigments in plants are often located in special bodies called plastids. There are many kinds of plastids: leucoplasts, those which contain no pigment and which are therefore colorless; chloroplasts, those which contain chlorophyll (by far the commonest kind); and chromoplasts, colored plastids that do not contain chlorophyll.

Leucoplasts occur in parts of stems and roots where light fails to penetrate. They absorb glucose and change it to starch.

Chloroplasts occur in cells exposed to light. They are indispensable to photosynthesis. In the algae the shapes of these bodies are many; in a large number of cases the plastid is a thick cup-shaped body occupying the greater part of the volume of the cell; in other algae the plastids have a central mass from which radiating plates of arms extend outward to the cell wall; spiral, net-shaped and ring-shaped plastids are not uncommon in this group of plants. In some algae and in nearly all higher plants, the chloroplasts are small subspherical or lens-shaped bodies, varying in number from one to many in a single cell. Always the chloroplasts are found embedded in the cytoplasm of the cell. In many plants the continuous movement of the cytoplasm in the cell carries the plastids along with it; in others these bodies have a fixed position. In certain algae and in many cells in higher plants, as for example in the palisade layer of leaves, the chloroplasts may change their position so that they will receive the most favorable amount of light. If the light intensity is low, they will present their flat surface to it; whereas if the light intensity is high, the plastid rotates so that it is placed edgewise to the light. Chloroplasts contain chlorophyll and other pigments. See also **Pigmentation (Plants)**.

PLASTISOL. A dispersion of finely divided resin in a plasticizer. Atypical composition is 100 parts resin and 50 parts plasticizer, forming a paste that gels when heated to 150C as a result of solvation of the resin particles by the plasticizer. If a volatile solvent is included, the plastisol is called an *organosol*.

Plastisols are used for molding thermoplastic resins, chiefly polyvinyl chloride. See also **Plasticizers**.

PLATFORMING. The process in which octane ratings of gasoline are raised by dehydrogenating naphthenes to aromatics, cracking high-boiling paraffins, and isomerizing paraffins to form products of greater chain branching. Desulfurization also takes place in this process.

PLATINUM AND PLATINUM GROUP. [CAS: 7440-06-4]. Chemical element, symbol Pt, at. no. 78, at. wt. 195.09, periodic table group 10 (formerly 8—transition metals), mp 1,772°C, bp 3,727 to 3, 927°C, density 21.37 g/cm^3 (solid), 21.5 g/cm^3 (single crystal) (20°C). Elemental platinum has a face-centered cubic crystal structure. The five stable isotopes of platinum are ^{192}Pt, ^{194}Pt through ^{196}Pt, and ^{198}Pt. The seven unstable isotopes are ^{188}Pt through ^{191}Pt, ^{193}Pt, ^{197}Pt, and ^{199}Pt. In terms of earthly abundance, platinum is one of the scarce elements. Also, in terms of cosmic abundance, the investigations by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for platinum at 0.016. No notable presence of platinum in seawater has been found.

Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^9 6s^1$$

Ionic radius Pt^{2+} 0.52 Å. Metallic radius 1.3873 Å. First ionization potential 8.96 eV. Oxidation potentials $Pt \longrightarrow Pt^{2+} + 2e^-$, ca. −1.2 V; $Pt + 2OH^- \longrightarrow Pt(OH)_2 + 2e^-$, −0.16 V.

Platinum is one member of a family of six elements, called the *platinum metals*, which almost always occur together. Before the discovery of the sister elements, the term *platinum* was applied to an alloy with Pt as the dominant metal, a practice that persists to some degree even today. The major properties of the platinum metals are given in Table 1. See also **Iridium Osmium**; **Palladium**; **Rhodium**; and **Ruthenium**.

Occurrence

These metals occur in both primary and secondary deposits. The primary deposits are generally associated with Ni-Cu sulfide ores. The Sudbury ores of Canada and the deposits of the Bushveld complex of South Africa are of this type. Native platinum occurs as a primary deposit in the Ural Mountains of the former U.S.S.R. and also in the Choco district of Colombia. Weathering and erosion of these deposits have resulted in the formation of secondary, or placer, deposits of native Pt in riverbeds and streams. One nugget of Pt found in the Urals weighed over 25 pounds (11.3 kilograms). Most of the world's platinum comes from Canada, the former U.S.S.R., and South Africa. Minor amounts have been found in Alaska, Colombia, Ethiopia, Japan, Australia, and Sierra Leone.

TABLE 1. REPRESENTATIVE PROPERTIES OF PLATINUM GROUP METALS

Property	Iridium	Osmium	Palladium	Platinum	Rhodium	Ruthenium
Atomic volume, cm^3/g-atom	8.54	8.43	8.88	9.09	8.27	8.29
Atomic radius	1.355	1.350	1.373	1.335	1.342	1.336
Crystalline form	fcc	hcp	fcc	fcc	fcc	hcp
Lattice parameters, Å, *a*	3.8389	2.7341	3.8902	3.9310	3.804	2.7041
B	—	4.3197	—	—	—	4.2814
Thermal conductivity at 20°C, (cal)(cm)/(s)(cm^3)(°C)	0.14	—	0.168	0.166	0.21	—
Electrical resistivity at 0°C, micro-ohm-cm	5.3	9.5	10.8	10.6	4.5	7.2
Thermal expansivity, °C × 10^6 at 20°C	6.6	6.6	12.4	9.0	8.3	9.6
Hardness, Mohs scale	6.5	7.0	4.8	4.3	—	6.5
Specific heat, cal/g-atom at 20°C	0.031	0.031	0.0584	0.031	0.059	0.057
Heat of fusion, kcal/mole	6.3	7.0	4.0	4.7	5.2	6.1
Heat of vaporization, kcal/mole	134.7	150	90	122	118.4	135.7

fcc = face-centered cubic
hcp = hexagonal close-packed

Because of their unique properties and in spite of their high initial cost, the platinum metals find many applications in industry. Since used platinum metals retain a large portion of their initial value, many scrap materials are a major source of recoverable platinum metals. Practically every application of platinum generates scrap in some form, which is eventually returned to the platinum refiner for recycling. Although there are ample mine reserves, they soon would be depleted without constant scrap recycling.

Refining Processes

The refining procedures are a good introduction to the complex chemistry of the platinum metals. Some of these methods are still the best analytical techniques available for the separation of the metals. South African ore is smelted to form a Cu-Ni matte containing small amounts of the platinum metals (0.18%). The matte is melted, cast into anodes, and electrolytically dissolved. The contained Cu is deposited at the cathode, the Ni remains in the H_2SO_4 electrolyte, and the Pt metals are contained in the anode slimes. The resulting Cu is refined and the $NiSO_4$ solution purified and crystallized. The anode slimes are treated by roasting to remove sulfur and leached with dilute H_2SO_4 and air to remove Cu and Ni. The leached slimes are treated with aqua regia. The aqua regia solution is evaporated to concentrate the solutions and expel the excess HNO_3. The residue from this treatment contains Rh, Ir, Ru, Os, and Ag. The solution contains Pt, Pd, and Au.

Platinum is first removed by precipitating as ammonium hexachloroplatinate(IV) $[(NH_4)_2PtCl_6]$ by the addition of a saturated solution of NH_4Cl. The precipitate is washed, dried, and calcined to form platinum sponge about 98% pure. The sponge is purified by redissolving in aqua regia and evaporating the solution to dryness with NaCl. The resulting sodium hexachloroplatinate is dissolved in H_2O and boiled with $NaBrO_3$ to convert impurities, such as Ir, Rh, Pd, and base metals, to valence states which produce readily filterable hydroxides. The Pt left in solution is free of impurities. It is then treated with NH_4Cl, and the pure ammonium hexachloroplatinate precipitate is calcined at 1000°C to pure Pt sponge.

The first aqua regia solution is treated with $FeSO_4$ to precipitate the gold. Pd is precipitated by oxidizing the solution with HNO_3 and adding NH_4Cl. Ammonium hexachloropalladate(IV) is formed (analogous to the Pt compound). This salt is purified by dissolving in NH_4OH, filtering off the impurities, and reprecipitating the Pd by the addition of HCl. The insoluble complex $Pd(NH_3)_2Cl_2$ is formed, which when calcined and reduced in H_2 yields pure Pd sponge.

The insolubles from the first aqua regia treatment are fused with a flux of litharge, soda ash, borax, and carbon in a gas-fired furnace at 1000°C for 1 hour. This procedure converts silica, alumina, and some base metals to slag. The precious metals are retained in the lead phase. The lead portion is heated with HNO_3, which dissolves the Pb and Ag. The Pb is precipitated as a sulfate and then the Ag as a chloride. The residue is treated with concentrated H_2SO_4 at 300°C. Rh will dissolve, leaving Ir, Ru, and Os as insolubles. The Rh solution is treated with Zn powder, precipitating an impure Rh. The impure Rh is heated in an atmosphere of Cl_2. Many impurities form volatile chlorides at this temperature and are expelled. Rh forms a polymeric trichloride, which is insoluble in aqua regia. The rhodium trichloride is digested in aqua regia for several hours, then filtered, dried, and calcined, yielding a commercial grade of Rh sponge.

The residue insoluble in H_2SO_4 is fused with Na_2O_2, poured into thin slabs and cooled. Ir is oxidized in the fusion of IrO_2, which is insoluble in H_2O. Ru and Os form soluble sodium salts and are separated from the Ir by filtration. The insoluble IrO_2 is dissolved in aqua regia, and ammonium hexachloroiridate(IV) is precipitated by the addition of NH_4Cl. Calcining yields pure Ir sponge.

The filtrate from the dissolution of the Na_2O_2 fusion contains $NaRuO_4$ and $NaOsO_4$. Ethyl alcohol is added to the solution, causing the precipitation of RuO_2, which is separated by filtration.

The Ru is purified by distilling with Cl_2. Volatile ruthenium tetroxide is collected. A saturated solution of NH_4Cl is added, causing the precipitation of ammonium hexachlororuthenate(III). The precipitated salt is calcined in H_2, yielding commercial Ru sponge.

The filtrate from the alcohol precipitation of Ru contains the Os. The solution is neutralized with HCl and is treated with powdered Zn, reducing the Os to the metallic state. Osmium tetroxide is formed by roasting the impure Zn in a current of O_2. The volatile OsO_4 is trapped in an aqueous solution of KOH. Ethanol is added to the solution, precipitating potassium osmate(VI), which is mixed with an excess of NH_4Cl and calcined in an atmosphere of H_2. The resulting Os sponge is leached to remove KCl, leaving a commercial-grade Os sponge.

The refining of secondary scrap follows much the same procedures with minor variations. For example, solid metallic Pt and especially the Rh and Ir alloys of Pt are very difficult to dissolve in aqua regia. Therefore the scrap generally is alloyed with Cu, Ni, Pb, or Zn before dissolution with acids.

Uses

These metals, in various forms, currently are used as catalysts for a wide variety of reactions. Products include high-octane gasoline, HNO_3, H_2SO_4, HCN, vitamins, antibiotics, H_2O_2, cortisone, alkaloids, and fuel-cell chemicals. These catalysts also are used to remove trace impurities, e.g., acetylene in ethylene or O_2 in H_2, or noxious constituents of partial combustion, e.g., automobile exhausts. Although substitutes are being sought, Pt is by far the best catalyst for pollution control of auto exhausts. In the future, the catalytic converters currently installed in automobiles will become a significant source of platinum metals. See also **Catalysis**.

The corrosion resistance of the Pt metals has made the Pt crucible and the Pt electrodes commonplace laboratory tools. The glass industry makes use of large amounts of Pt and its alloys for manufacturing very pure glass. Synthetic fibers often are extruded through spinnerettes made of Pt alloys. The large use of Pt metals in dental and medical devices, in jewelry, and for decorative purposes is based on the corrosion resistance and general appearance of these metals.

Because of their high melting points and stability, Pt alloys have found applications in thermocouples, resistance thermometers, potentiometer windings, electrodes, insoluble anodes, high-temperature furnace winding, crucibles that can withstand corrosive materials at high temperature, and generally as materials of construction that will not contaminate products at very high temperatures. Often Pt and Pd are alloyed with Rh, Ir, Ru, or Os to increase their strength, hardness, and corrosion resistance.

Platinum metals, in particular Pd, find extensive use in the electrical industry. Most of these metals are used as contacts, particularly in telephone relays, where their resistance to oxidation and sulfidization results in circuits of reliability and stability. Alloys of Pt find use as grids for electronic tubes, in electrodes for aircraft spark plugs, for contact metal in printed and solid-state circuits, and in pressure-rupture disks.

In the medical field, *cis*-dichlorodiammineplatinum(II) has been available for cancer therapy (*Science*, **192**, 774–775, 1976).

Platinum Compounds

Platinum forms many di- and tetravalent compounds. The latter valence is more common and more stable. Pt in compact form is inert to all mineral acids except aqua regia. Under oxidizing conditions, fused alkalies will attack Pt to some extent. Molten halides, carbonates, and sulfates have little effect on the metal. Concentrated boiling H_2SO_4, fused cyanides, and fused alkaline sulfides will attack the finely divided metal. Pt is vigorously attacked by Cl_2 at elevated temperatures. In hot aqua regia or HCl containing chlorate ion or H_2O_2, the metal slowly dissolves, yielding a solution of hexachloroplatinic acid, H_2PtCl_6.

Platinum(II) hydroxide is made by adding KOH to a solution of platinum(II) chloride. The unstable black powder is easily oxidized by air and must therefore be handled in an inert atmosphere. In hot alkali or HCl, it disproportionates into the platinum(IV) compound and the metal. Very careful dehydration results in the formation of a gray powder that approaches the composition of platinum(II) oxide. Platinum(II) oxide can also be made by combining the elements at 420–440°C at an O_2 pressure of 8 atm.

When a solution of hexachloroplatinic(IV) acid is boiled for some time with NaOH, all the chloride ions are replaced by hydroxide ions. The resulting sodium hexahydroxoplatinate(IV), $Na_2Pt(OH)_6$, is soluble in the basic solution, but it can be precipitated as hexahydroxoplatinic(IV) acid, $H_2Pt(OH)_6$, by the addition of acetic acid. The hydroxide ions of the salt are replaced by the corresponding ions of mineral acids when the compound is dissolved in acid. Hexahydroxoplatinic acid can be dehydrated to yield compounds corresponding to the tri-, di-, and monohydrate of platinum(IV) oxide. The last water molecule cannot be removed without some destruction of the dioxide.

Brown-black, insoluble, anhydrous, platinum(IV) oxide is made by fusing hexachloroplatinic(IV) acid with $NaNO_3$ at about 500°C. The alkali salts are washed out with H_2O to free the fine insoluble residue of platinum(IV) oxide. This compound is known as *Adam's catalyst*.

When Pt is heated to 500°C in the presence of Cl_2, yellow-green, insoluble platinum(II) chloride is formed. At a pressure of 1 atm of Cl_2, the compound is stable from 435 to 581°C. It can also be made by heating hexachloroplatinic(IV) acid in Cl_2 at about 500°C. Platinum(II) chloride is soluble in HCl as tetrachloroplatinic(II) acid. It forms many salts that are water-soluble. These salts can be made by reducing a hot sol7ution of the corresponding hexachloroplatinate(IV) with oxalic acid or SO_2. Platinum(III) chloride has a narrow range of stability. It can be made by contacting Pt or a platinum chloride with 1 atm of Cl_2 at 364–374°C. This dark-green to black compound is practically insoluble in cold concentrated HCl but does dissolve on warming, forming a mixture of tetrachloroplatinic(II) and hexachloroplatinic(IV) acids. Anhydrous platinum(IV) chloride is very difficult to prepare. This brown soluble solid can be made by heating hexachloroplatinic(IV) acid in Cl_2 at 360°C. The most common Pt compound, hexachloroplatinic(IV) acid, is readily made by dissolving Pt in aqua regia, followed by several evaporations with additional HCl to destroy nitrosyl compounds. The acid crystallizes as a hexahydrate. It is difficult to stop the evaporation at just this point, and slight local overheating causes excess loss of water. The sodium salt is quite soluble, and the compound is resistant to hydrolysis in basic solution, allowing the bromate hydrolysis to precipitate base metals and other Pt metals as their hydroxides. The Pt remains in solution. The insolubility of ammonium hexachloroplatinate(IV) often is used in refining Pt. Its slight solubility can be overcome sufficiently by mass action to allow its use as a gravimetric procedure for the determination of Pt. This yellow compound decomposes at red heat, yielding pure Pt sponge. The insolubility of the potassium salt is used for the gravimetric determination of potassium.

A series of di-, tri-, and tetrabromides is well known. Platinum(II) iodide is precipitated as a black insoluble compound by the addition of 2 equiv of iodide to a hot solution of platinum(II) chloride. The black, insoluble, graphitelike substance, platinum(III) iodide, is made by combining the elements in a sealed tube at 350°C.

In contrast with Pd, Pt does form a Pt(IV) iodide. When a concentrated solution of hexachloroplatinic(IV) acid is treated with a hot solution of KI, this brown-black substance is precipitated. The compound is somewhat

unstable and light-sensitive. It dissolves in excess KI to form the complex salt, also rather unstable.

Pt forms a nonvolatile tetrafluoride, a pentafluoride, and a volatile hexafluoride. The dark-red PtF_6 melts at 56.7°C and is very reactive. It even reacts with O_2 at 21°C to form dioxygenylhexafluoroplatinate(V), O_2PtF_6.

When sulfur and Pt sponge are ignited, some platinum(II) sulfide is formed. The naturally occurring mineral is called cooperite. When heated in air or H_2, the products are metallic Pt and S. Platinum(IV) sulfide can be made by heating ammonium hexachloroplatinate(IV) or Pt and S at 650°C. When precipitated by H_2S from chloroplatinic acid, the compound may exist as $PtS_2 \cdot H_2S$.

Divalent and tetravalent Pt probably form as many complexes as any other metal. The platinum(II) complexes are numerous with N_2, S, halogens, and C. The tetranitritoplatinum complexes are soluble in basic solution. Tetranitritoplatinum(II) ion is formed when a solution of platinum(II) chloride is boiled, at about neutral pH, with an excess of $NaNO_3$. The ammonium salt may explode when heated. Generally, platinum-metal nitrites should be destroyed in solution. They never should be heated in the dry form. Platinum(II) complexes most often have a coordination number of 4. Many compounds have been prepared with olefins, cyanides, nitriles, halides, isonitriles, amines, phosphines, arsines, and nitro compounds.

Platinum(IV) has a coordination number of 6. It forms complexes with halides, nitrogen and sulfur compounds, and other donors but to a lesser extent than platinum(II).

Health and Safety Factors

In bulk metallic form, the PGMs are not hazardous to health. However, like many other metals in finely divided form, PGM powders can be hazardous to handle. Powdered platinum is a powerful catalyst and is liable to ignite combustible materials. Powdered iridium can ignite in air and palladium dust is combustible.

PLUTONIUM. [CAS 7440-07-5]. Actinide radioactive metal. Atomic number 94. Symbol Pu. This element does not occur in nature except in minute quantities as a result of the thermal neutron capture and subsequent beta decay of ^{238}U; all isotopes are radioactive; atomic weight tables list the atomic weight as [242]; the mass number of the second-most-stable isotope ($t_{1/2} = 3.8 \times 10^5$ years). The most stable isotope is ^{244}Pu ($t_{1/2} = 7.6 \times 10^7$ years). Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^6 6s^2 6p^6 7s^2$. Ionic radii Pu^{4+} 0.86 Å; Pu^{3+} 1.01 Å (Zachariasen). Oxidation potentials in acid solution $Pu \longrightarrow Pu^{3+} + 3e^-$, 2.03 V; $Pu^{3+} \longrightarrow Pu^{4+} + e^-$, −0.982 V; $Pu^{4+} + O_2 + 3e^- \longrightarrow PuO_2{}^+$, −1.17 V; $PuO_2{}^+ \longrightarrow PuO_2{}^{2+} + e^-$, −0.91 V. Oxidation potential in alkaline solution $Pu^{3+} + 4H_2O \longrightarrow Pu(OH)_4 + 4H^+ + e^-$, 0.4 V; $Pu(OH)_4 \longrightarrow PuO_2{}^+ + 2H_2O + e^-$, −1.0 V; $PuO_2{}^+ + 2OH^- \longrightarrow PuO_2(OH)_2 + e^-$, −0.8 V.

The isotope of major importance is ^{239}Pu ($t_{1/2} = 2.44 \times 10^4$ years). The importance of this isotope stems from its property of being fissionable with slow neutrons, together with the fact that the problem of its mass production has been solved. The first isotope to be produced was ^{238}Pu ($t_{1/2} = 86.4$ years).

Processes for the isolation and purification of plutonium, including the enrichment of spent nuclear reactor fuels, are described in the entry on **Nuclear Power Technology**. These processes take advantage of Pu's several oxidation states, each of which has different chemical properties. The processes may involve carrier precipitation, solvent extraction, and ion exchange.

Plutonium is of major importance because of its successful use as an explosive ingredient in nuclear weapons and the role it plays in the industrial applications of nuclear power. Exemplary of the energy available from plutonium: (1) One pound (0.45 kilogram) ≅ 10 million kilowatts; (2) one kilogram (2.2 pounds) = 22 million kilowatts; (3) one kilogram (2.2 pounds) = 20, 000 tons of chemical explosive. Plutonium has the important nuclear property of being readily fissionable with neutrons. ^{238}Pu was used in the Apollo lunar missions to power seismic and other experimental instruments placed on the lunar surface. Because comparatively large quantities of plutonium are produced in reactors, the amount available for various applications has increased considerably during recent years. It is estimated that as of the late 1980s, nuclear reactors throughout the world are producing in excess of 20,000 kilograms of Pu per year. Within a few years, there will be an accumulation of some 300,000 kilograms of Pu or more. The element is available for purchase by qualified potential users.

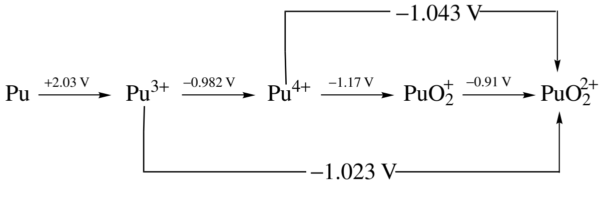
In a typical fast breeder nuclear reactor, most of the fuel is ^{238}U (90 to 93%). The remainder of the fuel is in the form of fissile isotopes, which sustain the fission process. The majority of these fissile isotopes are in the form of ^{239}Pu and ^{241}Pu, although a small portion of ^{235}U can also be present. Because the fast breeder converts the fertile isotope ^{238}U into the fissile isotope ^{239}Pu, no enrichment plant is necessary. The fast breeder serves as its own enrichment plant. The need for electricity for supplemental uses in the fuel cycle process is thus reduced. Several of the early liquid-metal-cooled fast reactors used plutonium fuels. The reactor "Clementine," first operated in the United States in 1949, utilized plutonium metal, as did the BR-1 and BR-2 reactors in the former Soviet Union in 1955 and 1956, respectively. The BR-5 in the former Soviet Union, put into operation in 1959, utilized plutonium oxide and carbide. The reactor "Rapsodie" first operated in France in 1967 utilized uranium and plutonium oxides.

Plutonium was the second transuranium element to be discovered. The isotope ^{238}Pu was produced in 1940 by Seaborg, McMillan, Kennedy, and Wahl at Berkeley, California by deuteron bombardment of uranium in a 150-cm cyclotron. Plutonium exists in trace quantities in naturally occurring uranium ores. The metal is silvery in appearance, but tarnishes to a yellow color when only slightly oxidized. A relatively large piece will give off sensible heat as the result of alpha decay. Large pieces are capable of boiling water.

Chemical Properties

Plutonium has the oxidation states (III), (IV), (V), and (VI), and a complex chemistry in aqueous solutions, as can be judged from such a multiplicity of states. A large number of solid compounds corresponding to these states have been made, and they are in general similar in formulas and properties to the corresponding compounds of uranium and neptunium. An important difference, especially as regards ranges of stability of these compounds, arises as a result of the much greater stability of the (III) and (IV) states of plutonium. This also leads to differences in the aqueous solution chemistry of plutonium as compared to uranium and neptunium. The pentavalent state, like that of uranium, but unlike that of neptunium, is unstable in aqueous solution with respect to disproportionation.

The ionic species corresponding to the four oxidation states of plutonium vary with the acidity of the solution. In moderately strong (one-molar) acid the species are Pu^{3+}, Pu^{4+}, $PuO_2{}^+$, and $PuO_2{}^{2+}$. The ions are hydrated but it is not possible at present to assign a definite hydration to each ion. The potential scheme of these ions in one-molar perchloric acid is the following:



The potentials are in volts relative to the hydrogen–hydrogen-ion couple as zero.

The values given for the potential scheme in one-molar acid may be altered extensively by a change in hydrogen ion concentration (pH) or as a result of the addition of substances capable of forming complex ions with the plutonium species. Among such substances are sulfate, phosphate, fluoride, and oxalate ions, and various organic compounds, especially those known as chelating agents. The tetrapositive and hexapositive ions are complexed appreciably even by nitrate and chloride ions. The stability of the complex formed with a specified anion increases in the order: $PuO_2{}^+$, Pu^{3+}, $PuO_2{}^{2+}$, Pu^{4+}.

The hydrolysis of the ions follows a similar order; Pu^{4+} begins to hydrolyze even in tenth-molar acid and in hundredth-molar acid forms partly the hydroxide, $Pu(OH)_4$, and partly a colloidal polymer of variable but approximate composition $Pu(OH)_{3.85}X_{0.15}$, where X is an anion present in the solution. Further reduction of the acidity results in the hydrolysis of $PuO_2{}^{2+}$ near pH 5, of Pu^{3+} at about pH 7, and of $PuO_2{}^+$ at about pH 9.

The plutonium ions in aqueous solution possess characteristic colors: blue-lavender for Pu^{3+}, yellow-brown to green for Pu^{4+}, and pink-orange for $PuO_2{}^{2+}$.

Plutonium monoxide occasionally appears on the surface of metal exposed to atmospheric oxidation, but is prepared more conveniently by treating the oxychloride with barium vapor at about 1,250°C. The oxide is classified with the interstitial compounds rather than with the typical metal oxides.

The so-called sesquioxide ($PuO_{1.5-1.75}$) is a typical mixed oxidation state oxide, similar to those formed by uranium, praseodymium, terbium, titanium, and many other metals. Its composition shows continuous variation with changes in temperature and pressure of oxygen above the oxide.

Plutonium dioxide (yellow-green to brown, cubic) is the most important oxide of the element. Almost all compounds of plutonium are converted to the dioxide upon ignition in air at about 1,000°C.

The important halides and oxyhalides of plutonium are PuF_3 (purple, hexagonal), PuF_4 (brown, monoclinic), PuF_6 (red-brown, orthorhombic), $PuCl_3$ (green, hexagonal), $PuCl_4$ (green-yellow, tetragonal), $PuBr_3$ (green, orthorhombic), PuI_3, PuOF, PuOCl, PuOBr, PuOI.

All of the halides except the hexafluoride and the triiodide may be prepared by the hydrohalogenation of the dioxide or of the oxalate of plutonium(III) at a temperature of about 700°C. With hydrogen fluoride the reaction product is PuF_4, unless hydrogen is added to the gas stream, in which case the trifluoride is produced. With hydrogen iodide the reaction product is PuOI, and the other oxyhalides may be formed by the addition of appropriate quantities of water vapor to the hydrogen halide gas. Plutonium triiodide is produced by the reaction of the metal with hydrogen iodide at about 400°C. The hexafluoride is produced by direct combination of the elements or by the reaction $2PuF_4 + O_2 \longrightarrow PuF_6 + PuO_2F_2$ at high temperature. The hydrides of plutonium include PuH_2 (black, cubic) and PuH_3 (black, hexagonal).

Plutonium forms several binary compounds that are of interest because of their refractory character and stability at high temperatures. These include the carbide, nitride, silicide, and sulfide of the element.

The monocarbide is formed by reacting the dioxide in intimate mixture with carbon at about 1,600°C. The mononitride may be obtained by heating the trichloride in a stream of anhydrous ammonia at 900°C; it is prepared more easily, however, by reacting finely divided metal with ammonia at 650°C. Although the lower temperatures are favorable to the production of higher nitrides, none are obtained, in contrast to the uranium-nitrogen system in which compositions up to $UN_{1.75}$ are easily realized.

The disilicide is formed when a slight stoichiometric excess of calcium disilicide is heated with plutonium dioxide in vacuum at about 1,550°C. The disilicide is only moderately stable in air and burns slowly to the dioxide when heated to about 700°C.

Plutonium "sesquisulfide" may be prepared by prolonged treatment of the dioxide in a graphite crucible with anhydrous hydrogen sulfide at 1,340°–1,400°C, or by the reaction of the trichloride with hydrogen sulfide at 900°C.

Handling Precautions. Care must be taken in the handling of plutonium to avoid unintentional formation of a critical mass. Plutonium in liquid solutions is more apt to become critical than solid plutonium. The shape of the mass also determines criticality. Plutonium's chemical properties also increase handling difficulty. Metallic plutonium is pyrophoric, particularly in finely divided form. Because of the high rate of emission of alpha particles, and the physiological fact that the element is specifically absorbed by bone marrow, plutonium, like all of the transuranium elements, is a radiological poison and must be handled with special equipment and precautions. To assure the safety of personnel, plutonium operations are normally handled in an essentially closed system, such as a *glovebox*. In addition, shielding is required when certain isotopes, including ^{240}Pu and ^{241}Pu, are present in appreciable quantity. Because research continues on the hazards and toxicity of plutonium, specific toxicity data should be sought from current authoritative literature, including government (U.S., UK, France, etc.) publications. As of the early 1980s, permissible body burden was established at 0.6 microgram; lung burden at 0.25 microgram. Chemical toxicity is trivial compared with radiation effects. The permissible levels for plutonium are the lowest for any of the radioactive elements.

The behavior of actinides in natural waters has great relevancy to the safe long-term storage of radioactive wastes. The enhanced solubility of plutonium and other actinides in the water of Mono Lake, California was studied by a group of scientists with the U.S. Geological Survey (Denver, Colorado). J.M. Cleveland and associates found that the solubility of plutonium in Mono Lake water is enhanced by the presence of large concentrations of indigenous carbonate ions and moderate concentrations of fluoride ions. In spite of the complex chemical composition of this water, only a few ions govern the behavior of plutonium, as demonstrated by the fact that it was possible to duplicate plutonium speciation in a synthetic water containing only the principal components of Mono Lake water. See reference listed.

Practical Utilization. Since the potential reserves of ^{235}U are limited, some point will be reached where this power source no longer will be competitive with fossil fuels, synthetic fuels, solar power plants, etc.—unless the development of means for the practical utilization of plutonium can be achieved. An important element of nuclear fuel cost is the credit received from the sale or future utilization of plutonium after its recovery from spent fuel. The plutonium credit is realistic only if the plutonium is used for power production, since, at present, there are few commercial uses envisioned where it would yield a similar economic return.

PNEUMOKONIOSES. Diseases of the lungs produced by inhalation of dusts, particularly those containing silica, asbestos and other inorganic material, or certain vegetable substances, notably sugar cane waste and raw cotton dust (brown lung).

Silicosis occurs in industries in which the air is polluted by silica dust, e.g., pottery, metal grinding, sandblasting and mining in rock. The inhaled silica gives rise to the production of diffuse fibrosis in the lungs; moreover it facilitates the growth of the tubercle bacillus so that tuberculosis is a possible complication. A special form of silicosis, called anthracosis (black lung), occurs in coal miners who are exposed to a mixed dust, mainly of coal, with a small proportion of silica.

Asbestosis is much less common but more serious than silicosis, since once contracted it is more rapidly fatal, and is associated with a liability to lung cancer.

Another form of pneumokoniosis is an acute and often fatal form which results from inhalation of beryllium, much used in the manufacture of fluorescent lamps.

Corticosteroid therapy has had encouraging results but the primary consideration in these diseases is the environmental protection of exposed workers.

POISON. (1) Any substance that is harmful to living tissues when applied in relatively small doses. The most important factors involved in effective dosage are (a) quantity or concentration, (b) duration of exposure, (c) particle size or physical state of the substance, (d) its affinity for living tissue, (e) its solubility in tissue fluids, and (f) the sensitivity of the tissues or organs. Sharp distinction between poisons and non-poisons is not always possible, because many variables must be taken into consideration in each case. Poisons are divided into four classes by the shipping regulatory agencies, as follows:

- *Poison A:* A gas or liquid so toxic that and extremely small amount of the gas of the vapor formed by the liquid is dangerous to life.
- *Poison B:* Less toxic liquids and solids that are hazardous either by contact with the body (skin adsorption) or by ingestion.
- *Poison C:* Liquids or solids that evolve toxic or strongly irritating fumes heated or when exposed to air (excluding class A poisons).
- *Poison D:* Radioactive materials.

See also **Toxicity**; and **Toxic Substances**.

Note: A computerized poison information center is operated by the FDA in Washington, DC. The National Clearinghouse for Poison Information Centers is located at 5401 Westbard Ave., Bethesda, MD 20016.

(2) In nuclear technology, any material with a high capture probability for neutrons that may divert an undesirable number of neutron from the fission chain reaction. (3) A substance that reduces or destroys the activity of a catalyst. Carbon monoxide and phosphorus arsenic, or sulfur compounds have this effect on the formation of ammonia from hydrogen and nitrogen gases, and the gases must be highly purified to avoid this. Another example is the poisoning of the platinum catalyst used in emission-control devices by organic lead compounds.

POLANYI, JOHN C. (1929–). Awarded the Nobel prize in chemistry in 1986 jointly with Dudley R. Herschbach and Yuan T. Lee. Herschbach reported that the energies of reactions of colliding beams of isolated alkali metal atoms and alkyl halide molecules appeared mostly as vibrational excited states of products. Polanyi characterized the excited states by the infrared light emitted by product molecules. His work also led to the development of lasers. Born in Germany, Polanyi studied in England and later became a Canadian citizen. Doctorate awarded by Manchester University, England, in 1952.

POLAR. Descriptive of a molecule in which the positive and negative electrical charges are permanently separated, as opposed to non-polar molecules in which the charges coincide. Polar molecules ionize in solution and impart electrical conductivity. Water, alcohol, and sulfuric acid are polar in nature; most hydrocarbon liquids are not. Carboxyl and hydroxyl groups often exhibit an electric charge. The formation of emulsions and the action of detergents are dependent on this behavior.

See also **Dipole Moment**.

POLAR COMPOUND. See **Compound (Chemical)**.

POLARIMETER. An instrument for measuring the amount by which the plane of polarization of plane polarized light is rotated in passing through a medium (usually a liquid).

See also **Polarimetry**.

POLARIMETRY. The basic principles of polarimetry as a method of quantitative chemical analysis were established over 150 years ago. The method is simple and nondestructive. A polarimeter measures the angle of rotation of linearly polarized light upon passage of the light from the unknown sample. Saccharimetry represents the polarimetric analysis of sugar and is a specialized area with its own form of instrumentation and well-established procedures of international acceptance. Polarimetry in other fields is less standardized, but is extensively used for the qualitative determination of numerous alkaloids, steroids, pharmaceutical, and organic chemical products. See also **Saccharimeter**.

Polarimetric instruments are operative with asymmetric molecules in the direct measurement of circular dichrosm (i.e., the difference of absorption of the left and right circularly polarized light as it passes through the sample). The technique is analogous to absorptiometry.

When plane polarized light passes through an anisotropic medium, the refractive indices of the two beams which emerge, which are right-hand and left-hand polarized, respectively, are not the same. This causes a phase difference between the two component beams and the resultant beam is rotated in its plane of polarization as it emerges from the medium.

Molecules of inherent structural asymmetry are anisotropic; they are *optically active* and exhibit *optical rotation* in solution. The typical optically active center is a carbon atom with four different substituents. In addition, any structural dissymmetry that results in a spatial left- and right-handedness will cause optical activity. Compounds of these types of come in a right-hand (R) and left-hand (L) form. When equal amounts of these two forms are mixed (racemic mixtures) there is no optical rotation because the activity of the two forms exactly cancel. Internal compensation of optically active centers in complex molecules is also found. Left- and right-handed optical isomers were first studied by Pasteur well over 100 years ago, and extensive surveys are found in most organic chemical texts.

Visual Polarimeters

A typical visual polarimeter is shown in Fig. 1. Light source may be a sodium or a mercury arc (less usual is the cadmium arc for the 509-millimicron and 644-millimicron lines). A filter isolates the emission line for monochromatic illumination. (While an instrument does not produce absolutely monochromatic light, the term is used by spectroscopists to describe light within a very narrow wavelength range, such as 0.2 millimicron.) The light then passes a polarizer prism system. This is usually a Nicol prism (a prism made of calcite that is cut and recemented in such a way that the incident light is split into a linear polarized beam which is transmitted, while the second beam is reflected and absorbed). The polarized beam is then passed through the analyzer, which is essentially identical with the polarizer. One of these two elements (usually the analyzer) can be rotated, and it is provided with a graduated circle for the precise read-out in angular degrees. By using a large circular scale and a vernier, a precision of 0.002° can be obtained in research-type polarimeters.

The principle of measurement is straightforward. If the two "Nicols" are oriented identically with respect to their optic axes, maximum light is passed. When they are crossed (90°), the intensity is at minimum (following a $\sin^2$ law). A refinement in all commercial visual polarimeters is that the observation of the crossed analyzer position is made easier by a half-shade field. See Fig. 2. Because the human eye is a comparative, rather than absolute, light-measuring device, very much better precision can be obtained by comparing two adjacent fields, rather than attempting to evaluate the brightness of a single field. The half-shade fields are created by an auxiliary prism, and the details of the optical arrangement can be found in the literature. Here we are only concerned with the operational features. The zero position of the instrument is that angle at which the two (or three) segments of the observed field are *equally* dim. Between the polarizer and the analyzer, a space is provided to accept the sample. The sample is placed in a tube that has precisely ground ends corresponding to the light path. End windows are held to the tube by gasketed fittings.

Routine polarimetric determinations are simple enough. First the polarimeter is balanced to zero degrees with the solvent. Then the solution is placed into the instrument, the instrument is rebalanced, and the angle α read off the scale. Nevertheless, when many measurements are taken, this becomes somewhat tedious. For the assessment of the half-shade field, the operator's eyes must be dark-adapted. Extended work in a darkened room peering through the eyepiece at an almost black field is tiring. The precision of visual polarimetric measurements will tend to increase rapidly at first, as the observer's eyes become adapted, but then it will decrease gradually

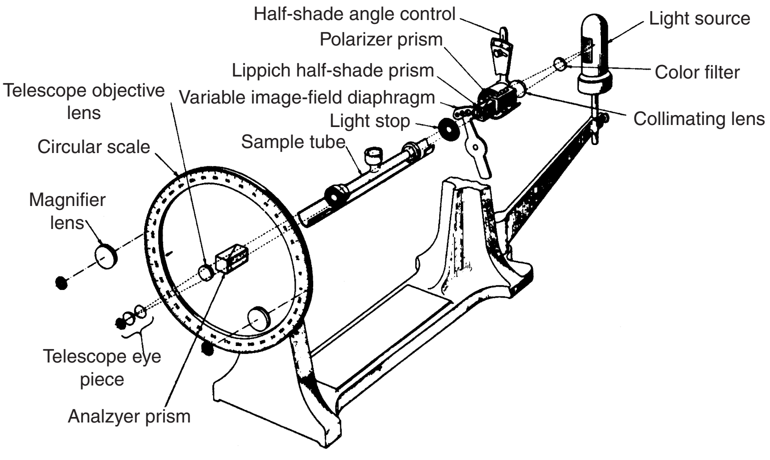

Fig. 1. Schematic diagram of a visual polarimeter

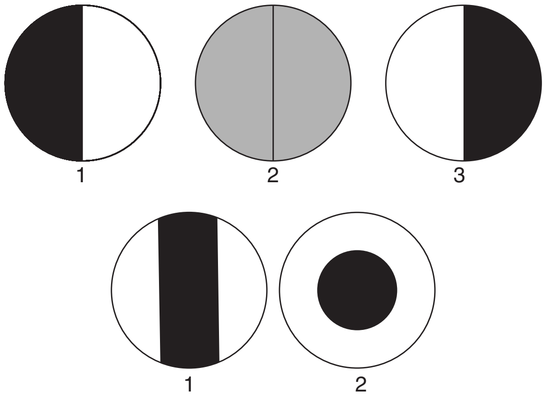

Fig. 2. Aspect of half-shade fields. Top diagram shows conventional split fields with (2) at the balance point. Bottom diagrams show special field configurations when at the off-balance point

because of fatigue. These facts justified the introduction of photoelectric polarimeters.

Photoelectric Polarimeters

In one design, there is no split half-shade field, but rather the analyzer is mechanically flip-flopped over an adjustable angle. At balance (and only at balance), the two extreme positions of the analyzer yield equal (low) intensity. A sensitive photomultiplier-photometer serves as a null indicator. The analyzer prism is manually rotated until a minimum deflection results on the large photometer scale and then the angle of rotation is read visually. In another design, Faraday cells are used. In the Faraday effect, a magnetic field induces optical rotatory power in liquids and solids by its influence on the atomic electron configuration. By using an electromagnet surrounding a glass rod, or a suitable crystal or solution, an alternating optical rotation can be introduced. This is analogous to the flip-flop just described. In the second design, a rotating polarizer is used, followed by the sample cell and the Faraday modulator. The emerging light passes through the analyzer and a photomultiplier pickup. The latter actuates a servosystem which drives the polarizer to balance. When the polarizer is exactly crossed with the analyzer, then, and only then will the alternating polarization introduced by the Faraday modulator have equal magnitude. This is the null point for the servosystem which thus establishes the balance automatically. The operator places the sample into the instrument (after it has been set to zero with the solvent) and then reads off the value of rotation from a magnified scale which allows estimation to 0.0025°. Several other designs have been developed for various measurements in optical rotatory dispersion. A number of spectropolarimeters, both automatic and recording, are available.

Kinetic Polarimetry

Polarimetry is particularly well suited for kinetic studies. The reason lies in the cyclic nature of the phenomenon, which allows the measurement of small changes in the angle of rotation with equal precision in the presence and absence of large background values. Moreover, subtle changes in structure, which are common in enzyme reactions, are often strongly reflected in rotatory power.

Spectropolarimetry

The determination of a rotatory dispersion curve is a prerequisite to the establishment of a sensitive polarimetric technique. This is analogous to colorimetry, where a complete spectrophotometric curve is required to establish the absorption peak best suited for routine work at a fixed wavelength. Similarly, in polarimetry, the gain in sensitivity may be enormous when working at an extremum (peak or trough). Thus, spectropolarimetry plays a role even though the analytical technique is simply polarimetry at a fixed wavelength. It is important to make a judicious choice in wavelength in an industrial assay.

POLARIZATION. 1. The process of bringing about a partial separation of electrical charges of opposite sign in a body by the superposition of an external field.

2. A vector quantity representing the dipole moment per unit volume of a dielectric medium. In rationalized units, the electric induction in a dielectric is given by $\mathbf{D} = \varepsilon\mathbf{E}$, which can be written

$$\mathbf{D} = \varepsilon_r\varepsilon_0\mathbf{E} = \varepsilon_0 E + (\varepsilon_r - 1)\varepsilon_0\mathbf{E}$$

where ε_r is the relative permittivity or dielectric constant (κ) of the medium. The term

$$(\varepsilon_r - 1)\varepsilon_0\mathbf{E}$$

is the additional induction attributable to the matter of the dielectric, and is called the polarization of the dielectric. The coefficient $(\varepsilon_r - 1)$ is the "electric susceptibility" of the dielectric, and is often written as χ_e. In unrationalized systems,

$$\chi_e = \frac{\varepsilon_r - 1}{4\pi}$$

3. The process of confining the vibrations of the magnetic (or electric) field vector of light or other radiation to one plane.

4. The formation of localized regions near the electrodes of an electric cell during electrolysis, of products which modify (usually adversely) the further flow of current through the cell.

5. In electrochemistry, the increase of solution resistance due to gas accumulation at the electrode or chemical depletion in part of the solution.

POLARIZED LIGHT. Whenever ordinary light is reflected from a glass plate, a varnished table-top, or other polished dielectric surface, we find upon suitable examination that a much larger part of the reflected beam is vibrating at right angles to the plane of incidence than in that plane; whereas in the incident beam there was no evidence of any preferential direction of vibration. A little experimenting shows that at a certain angle of incidence (the "polarizing angle," different for different dielectrics), the component vibrating in the plane of reflection is practically extinguished, all vibration being confined to the plane at right angles to this. The light is then said to be plane-polarized. The effect is more conveniently produced by a Nicol

prism or by one of the polarizing films that polarize by transmission with less loss of light.

When the light passes through two such polarizers in succession, as in a polariscope, the fraction of it finally emerging depends upon the angle between the transmission planes of the polarizers, and varies all the way from nearly 100% to zero. The same effect may be produced by two reflections at glass plates turned to reflect in different planes but at the same (polarizing) angle. It seems probable that when the polarizing films above mentioned have been further perfected and cheapened, this intensity-reducing effect will be turned to account in reducing automobile headlight glare.

Metallic reflectors do not produce plane-polarization, but when plane-polarized light falls on a polished metal, its vibration is in general changed from a rectilinear to an elliptic one, and the light is said to be elliptically polarized.

When plane-polarized light traverses a crystal exhibiting double refraction, such as calcite, at right angles to its axis, it is transformed into elliptically polarized, or even circularly polarized, light.

If plane-polarized light is passed through quartz along its axis, or in any direction through one of the many optically active liquids such as turpentine or sugar solution, it undergoes optical rotation. That is, its vibration plane is twisted around through an angle that steadily increases with the distance traversed in the substance. Different substances have very different rotatory power, and some rotate one way and some the other. The sacharimeter is especially adapted to the study of this effect in liquids, especially sugar solutions.

POLAROGRAPHIC ANALYZERS. Polarography is an electrometric method of chemical analysis that is based on the current-voltage relationship at a special type of electrode. In most electrometric processes, it is desirable to use electrodes of relatively large surface area and, in some cases, to stir the solution, and thus avoid an effect termed "concentration polarization." The cause of this effect is the formation of a region in the solution that differs in composition from the main body of the solution. There is a depletion layer in cases where the ions of the solution are discharging on the electrode, and an excess layer in cases where the electrode is ionizing. Under such conditions, the value of the current at the electrode will not be determined solely by the usual factors: impressed electromotive force, electrode potential, and concentration of the ions in question in the body of the solution. It will also be affected by the rate of diffusion of these ions, from the body of the solution into the depletion layer. Since this rate of diffusion depends in turn upon the concentration of the ions in question in the body of the solution, it can be used as a measure of that concentration by constructing a cell in such a way as to maximize the effect of "concentration polarization." This is done by using a *microelectrode* (an electrode having a very small area of contact with the solution) as the electrode at which the ionic reaction to be measured is to occur, and a large or normal size electrode as the other one in the cell. As a further step, there is added to the solution an excess of an electrolyte that is inert to the electrochemical reaction, so that the diffusion effect on the ion under analysis will not be masked by its migration effect, that is, by its role in carrying current through the cell.

The conditions described for the polarized electrode are met by the dropping mercury electrode, shown in Fig. 1. The size of the polarized

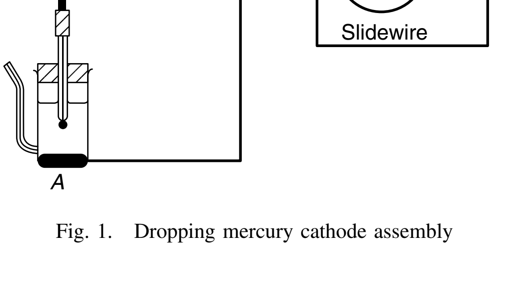

Fig. 1. Dropping mercury cathode assembly

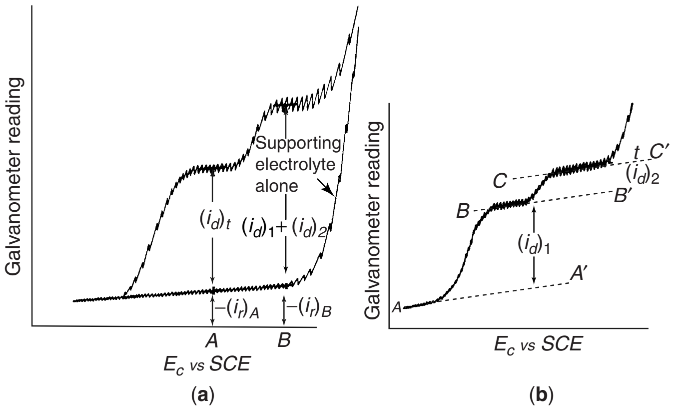

Fig. 2. Measuring a diffusion current: (**a**) exact method; (**b**) extrapolation method

electrode, which is merely a forming drop of mercury, is certainly small. It has the further advantage that it is constantly being replaced so that no solid deposit can form on its surface and so contribute an unwanted polarization effect to the one being measured. (Since the polarographic process involves the reduction of the ions, there is a deposition of metal on the mercury drop in all cases in which they are reduced to the metal, the effect of which is overcome by the constant replacement of the drop with fresh mercury.) This advantage is not processed by the other electrode, the pool of mercury in the bottom of the cell. For that reason, among others, the mercury pool electrode is not used as the other electrode in many instruments, being replaced by a standard calomel electrode connected electrically to the solution by a salt bridge, as described earlier in this entry. Moreover, the simple galvanometer and slidewire arrangement for measuring current and potential difference, respectively, is replaced and supplemented by more sensitive and easier-operated measuring and control devices, often automatic in operation and provided with recorders for producing the graphs of the current-potential difference directly. In fact, this instrumentation is so sensitive that it records the small fluctuations in the graph that occur during the formation of the drop of mercury and the beginning of the next one, the characteristic polarographic waves shown in Fig. 2. As can be seen from this figure, the polarographic method makes it possible to measure more than one concentration at a time, as represented by the two waves shown.

In addition to its advantage of permitting the determination of more than one ionic concentration in the same run, polarography also is most useful in determining very small ionic concentrations, of the order of millimoles per liter or lower.

POLAR MOLECULE. 1. A molecule with a positive charge on one end and a negative charge on its other end. Its vector sum of its bond dipoles is not zero.

2. Molecule in which the electrons forming the valency bond are not symmetrically arranged.

POLE FIGURE. A diagram used in metallurgy to show the preferred orientation of crystals in a metal. A pole figure is prepared by plotting, on a statistical basis, the positions in space of the poles of a specific crystallographic plane using a stereographic projection as the basis of the representation. The data for a pole figure is normally obtained using x-ray diffraction techniques.

POLISH. 1. A solid powder or a liquid or semi-liquid mixture that imparts smoothness, surface protection, or a decorative finish. The most widely used solid polishing agent is fine-ground red iron oxide (rouge), applied to the surface of plate glass, backs of mirrors, and optical glass. A wide variety of liquid and pastelike polishes are based on vegetable waxes (carnauba and candelilla), combined with softeners, fillers, and pigments or emulsified in alcohol or other solvent. Furniture polishes often contain red oil, lemon oil, and petroleum solvent; most types of metal and wood polish contain organic solvents and, hence, are flammable liquids. Nail polishes are nitrocellulose lacquers, usually with amylacetate solvent.

2. The hard outer coating of cereal grains, especially rice, which is usually removed in processing. These coatings are rich in vitamin B_1. Their removal robs the cereal of much of its nutritive value.

POLLUCITE. The mineral pollucite is rather rare. It contains cesium, aluminum, silicon, and oxygen, its chemical composition being approximately $(Cs, Na)_2(Al_2Si_4)O_{12} \cdot H_2O$. It is isometric, usually in cubic crystals or crystalline masses; conchoidal fracture; brittle; hardness, 6.5–7; specific gravity, 2.9; luster, vitreous on fresh surfaces; colorless and transparent. Found on the Island of Elba and in the pegmatites of Maine, and as masses 3–4 feet (0.9–1.2 meters) thick in South Dakota; at Varutrask, Sweden; in Italy; and in Kazakhastan, Russian. Pollucite and petalite were found in the granites of Elba and at first named pollux and castorite for the two famous brothers of Roman mythology, Castor and Pollux. Pollucite is derived from the Latin genitive *Pollucis*.

POLLUTION (Air). Prior to the Industrial Revolution (circa 1840s), the composition of "pure" air making up Earth's surrounding atmospheres essentially remained constant for several thousand years. True, certain natural phenomena, such as volcanic eruptions, may have altered the atmospheric composition over relatively short time spans.

By many orders of magnitude, the greatest alteration of the atmosphere occurred during the middle Precambrian period, between 2.9 and 1.8 billion years ago. It is generally accepted that prior to that time, the terrestrial atmosphere was chemically of a reducing nature—as contrasted with an oxidative environment of the present general composition required to support humans and other mammals and life forms which abound on the earth today. See also **Air**. Brought about by greatly accelerated plant growth, that earlier natural change represented the most dramatic pollution effect ever suffered by the earth's environment. During that period, the oxygen liberated by plant activity proved to be a very toxic substance for anaerobic life forms and eradicated most of the biotic community existing at that time. New types of life had to develop which were capable of survival in an oxidative environment. Geochemical processes took on new characteristics, based upon the slow oxidative degradation of both organic and inorganic materials.

Alteration of the earth's atmosphere as the result of human (anthropogenic) activities is extremely recent on the life scale of the earth. This altering process was essentially commenced when humans first discovered and started to use fire as a means of heating, cooking, etc. It is the *combustion* of organic fuels today that is the principal contribution to anthropogenic air pollution. For centuries the pollutants added to the atmosphere by humans were essentially insignificant in terms of the mass and the dynamics of the earth's atmosphere. Except on a local and sometimes regional basis, air pollution was no problem prior to the invention of the steam engine and, of course, the later invention of the internal combustion engine. Traditionally, air pollution has a direct relationship with increasing population and the growing sophistication of the population, which demands ever increasing quantities of energy and the manufacture of goods by processes which yield byproducts that require removal to some kind of sink, the earth's atmosphere being one of these sinks.

With few exceptions, air pollutants ultimately fall by gravity to the surface of the earth. On land, pollution of the soil and freshwater lakes and rivers and ultimately the groundwater occurs. Fallout on the seas and oceans also occurs, but unless radioactive, the effects are less easy to discern except on the long term. It is indeed difficult to separate air and water pollution. The relationship is explored in the article on **Wastes and Pollution**. The winds contribute both to the spread and, in some instances, to the contribution of air pollutants. Frequently, as in the case of "acid rain," the precipitation of water (an excellent solvent) in the form of rain, snow, sleet, ice pellets, etc. causes entrainment of pollutants (gases, mists, particles, etc.). Thus the soils, rocks, lakes, and rivers are subject to the corrosive and biodestructive processes brought about by the presence of alien substances. Acid rain is described later in this article.

During the last few decades and including the early 1990s, the total amount of pollutants in the atmosphere has increased exponentially. Currently, many hundreds of different pollutants, largely from anthropogenic sources, rise into the atmosphere. Even though many of these substances are measured on a scale of parts per million (ppm) or even parts per billion (ppb), a majority of these substances cause ill effects on the health and well-being of air-breathing creatures as well as corroding and eroding structures.

The following *incomplete* list is given here to dramatize the complexity of the current air pollution problem, to demonstrate the probable impracticality of finding a few simple solutions, and to illuminate why air pollution measurement and control presently requires the skills of many hundreds of scientists and engineers. To accomplish these tasks, many excellent instrumental techniques are required, as exemplified by chromatography, laser radar, various forms of spectrometers, and particle analyzers, among other advanced analytical tools. The use of radioactive isotopes has been effective in many instances of pollution source tracing.

Partial List of Air Pollutants

Common Gases—carbon monoxide (CO), carbon dioxide (CO_2), nitrogen oxides (NO_x), ammonia (NH_3), hydrogen sulfide (H_2S), chlorine (Cl_2).
Volatile Inorganics—sulfuric acid (H_2SO_4), hydrochloric acid (HCl), nitric acid (HNO_3), hydrogen peroxide (H_2O_2).
Volatile Organics—hydrocarbons*, fluoroalkenes, alcohols, polychlorinated biphenyls (PCBs), ketones, aldehydes.
Free Radicals—hydroxyl, sulfate.
Solid Particles—carbonaceous and metal particles (lead, zinc, manganese, cadmium, chromium).
Formulated Commercial Products and Byproducts—insecticides, pesticides, fungicides, herbicides, solvents, coatings, chlorinated fluorocarbons, petroleum and petrochemical products, plastics, fibers.
Radioactive Substances—from weapon testing, radon in some enclosed spaces.

Pollution also affects the manufacture of certain materials and products. This is evidenced by the need for "clean rooms" in metrology standards laboratories and in the production of certain electronics materials and of component assembly operations. In addition to elaborate filtering systems, such rooms are held at a slightly positive pressure (above outside atmospheric pressure) to prevent the entry of raw air from the outside.

Air Pollution Settings

In developing preventive and remedial technologies for air pollution abatement, it is helpful to consider the fundamental settings in which pollution occurs.

(1) *Workplace pollution* usually represents the highest concentration and length of exposure to specific pollutants. It usually is the most obvious mode of air pollution and, consequently, the easiest to correct. In this setting, workers breathe specific pollutants on a day-to-day basis. Well-known and publicized examples would include: miners; chemical plant workers; farmers; textile workers; metal production workers; transportation-related personnel (who are exposed to high concentrations of carbon monoxide and other gaseous products of fossil fuel combustion as well as coal dust and other carbonaceous particles and volatile hydrocarbons); and insulation installers (who are exposed to airborne tiny particles and strands of glass, plastics, and natural minerals, such as asbestos and mica). In the industrial and manufacturing complex, which has continued to expand markedly during the last several decades, hundreds of specific examples of exposure to dangerous air pollutants could be recited.

(2) *Point-source pollution* extends beyond a specific entity within a plant, such as a particular machine or process, and comprises a source of pollution that may emanate from only one or a few particular facilities within a small area. Point-source pollutants become mixed in the atmosphere with pollutants from other sources. Hence, beyond the immediate vicinity of a given facility, sources are difficult to identify. Considerable success has been achieved by isotopic matching to specific coals and other fuels that may be burned at a given facility.

(3) *Confined-area pollution*, where there may be no natural circulation of air and no effective air purification effluent system. This situation is found in factories or mines and inside improperly ventilated garages, service stations, and vehicular tunnels.

(4) *Limited-area pollution* occurs on a small geographic scale, such as strips of land adjacent to major highways or close to a pollution point source.

(5) *Regional pollution* is pollution that occurs in the greater part of a city, valley, or basin and frequently is publicized in connection with cities like Los Angeles, London, and, in more recent years, other major cities of the world, including New York. Regional pollution is particularly affected by weather conditions, such as, for example, an inversion layer hanging

over a natural basin. When pollution occurs on this scale, the beginnings of ecological damage (to trees, plants, natural life, etc.) are seen.

(6) *International pollution* or wide-area pollution is the occurrence of massive air pollution, usually extending over many years, to the extent that the atmosphere becomes severely overloaded with pollutants—that is, the atmosphere's ability to contain pollutants is exceeded. After holding pollutants for long periods, during which time prevailing winds transport the pollutants over long distances (from one country to the next, for example), the point is reached where pollutants "drop out" and contaminate the topography below. This is the type of pollution that has been the subject of debate, for example, between Canada and the United States—where pollutants from coal-burning power plants in the Midwestern states of the United States are transported to northeastern Canadian provinces (and northeastern U.S. states as well). Such pollution damages forests and lakes. See also "Acid Rain" later in this entry.

Other examples of international pollution occur in other parts of the world, but are less well understood at this time.

(7) *Worldwide pollution* is simply an extension of wide-area pollution and encompasses emissions that essentially become mixed with the entire atmosphere of the Earth. Even though the mixing time may be quite long, it is reasonable to assume that, over time, the ultimate effects of almost *any* pollution ultimately will affect the atmosphere on a worldwide basis. For example, as the result of nuclear events, particularly those that occurred prior to the ban on nuclear weapons testing, radioactive particles could be discerned over extensive regions of Earth. Depletion of Earth's ozone layer also is exemplary of how destruction of ozone can be caused by chlorine molecules, essentially without regard to where the pollutants are released into the atmosphere. **The Energy vs. Environment Conflict**

Just as it is difficult to separate the topics of air and water pollution, so is it hard to separate the problems of pollution from energy generation and consumption. With exception of some of the nontraditional sources of energy, such as nuclear energy and the more direct utilization of solar energy (as contrasted with combustion), the needs of the earth's population for energy tend to follow a collision course with concerns over the environment. For example, until the nontraditional energy sources can be reduced to practical usage (of which economics is an important, if not scientific factor in the equation), coal, wood, biomass, and other organic fuels when burned are air polluters unless very costly measures are taken to treat the effluents. Even when the numerous chemical and electroprecipitation measures, among others, are taken, there remains the problem of increasing the carbon dioxide content of the atmosphere.

Energy has an impact on the environment by tending to worsen the environment. The environment has an impact on energy by requiring considerable energy to alleviate the degradation of environmental quality. Environmental concerns also tend to limit the energy options available. It is generally agreed that the standard of living of the technologically sophisticated and developed nations is at least partially the result of inexpensive energy. Generally, the societies in these countries have not readied themselves to very high energy costs, there being a realization that these increased costs will, by and large, come out of so-called discretionary income and, consequently, impact the standard of living in a negative way. The significance of the incremental addition of energy required to effect environmental protection is shown in Table 1.

TABLE 1. AIR POLLUTION COSTS FOR REPRESENTATIVE TECHNOLOGIES (10^6 BTU/TON OF PRODUCT)*

Process option	Primary energy source	Process energy (10^6 Btu)	Air pollution control energy (10^6 Btu)	Percent of total for air pollution control
Glassmaking				
side port regenerative furnace	natural gas	7.0	0.57	7.5
side port regenerative furnace with preheat of charge	natural gas	5.7	0.37	6.0
electric furnace	electric power	8.2	0.03	0.3
coal gasification	coal	8.6	0.9	9.5
direct coal firing	coal	7.0	0.65	8.5
Cement				
long kiln (conventional)	oil	5.6	0.07	1.2
suspension preheater with long kiln	oil	4.2	0.05	1.2
fluid bed	oil	5.0	0.1	2.0
Copper Production				
roast-reverb smelting (conventional)	gas, oil, or coal	22.0	5.3	19.4
flash smelting (90–95% sulfur recovery)	oil	10.0	7.8	43.8

* 10^6 Btu = 252 × 10^3Calories

Principal Air Pollutants

The major air pollutants as identified by a number of countries in recent years in connection with pollutant regulatory programs are: (1) Particulate matter; (2) nitrogen oxides (NO_x); (3) sulfur oxides (SO_x); (4) hydrocarbons; and (5) carbon monoxide (CO).

Particulates and Aerosols. These may be comprised of numerous mineral and organic materials and frequently result from such operations as milling, crushing, screening, grinding, and demolition operations—as well as quarries and cement plants. Soot and fly ash as well as heavy carbonaceous smoke, arising from fuel-burning operations and smudge pots, also may fall into this category of pollutants. Aerosols generally are considered to be very tiny spherical droplets of a liquid that may be as small as 0.01 micrometer in diameter. These small liquid particles and the larger liquid particles, including mists and sprays, along with dusts, permit numerous physical separating and isolating means that do not apply to gases and vapors. Recent investigations of particle size distribution of atmospheric aerosols have revealed a multimodal character, usually with a bimodal mass, volume, or surface area distribution and frequently trimodal surface area distribution near sources of fresh combustion aerosols. These modes are attributed to the following factors: (a) the course mode (2 micrometers and greater) is formed by relatively large particles generated mechanically or by evaporation of liquid from droplets containing dissolved substances; (b) the nuclei mode (0.03 micrometer and smaller) is formed by condensation of vapors from high-temperature processes or by gaseous reaction products; and (c) the intermediate or accumulation mode (0.1 to 1.0 micrometer) is formed by coagulation of nuclei. This evidence indicates that atmospheric particles tend to form a stable aerosol having a size distribution ranging from 0.1 to 1.0 micrometer in general. However, larger and smaller particles occur. The larger particles (greater than 1.0 micrometer) settle out, and the very fine particles (smaller than 0.1 micrometer) tend to agglomerate to form larger particles which remain suspended. The nuclei mode tends to be highly transient and is concentration-limited by coagulation with both other nuclei and also particles in the accumulation mode. Therefore, the particulate content of a source emission and the ambient air can be viewed as composed of two portions, i.e., the settleable and the suspended.

Control of emissions in both size ranges is required because both settleable and suspended atmospheric particulates have deleterious effects upon the environment. Significantly, it is the suspended particles from an upper level of about 2 to 5 micrometers and smaller that health experts consider most harmful to humans because particles of this size have been found to penetrate the body's natural defense mechanisms and reach most deeply into the lungs. Efforts to control particulate emissions to the atmosphere have historically been geared to maximizing the efficiency of control (by weight) of the overall particulate loading emanating from the generating process. This work has led to the empirical understanding that present systems can perform with high control efficiencies down to a particle size of about 2–3 micrometers. But, below this size, the control efficiency appears to decrease with decreasing particle size to a minimum between 1.0 and 0.1 micrometer; and then increases again. This relationship of control efficiency and particle size is highly significant to any strategy for controlling particulate air pollution, and serves to underscore the need to adequately measure and evaluate both ambient particulate air pollution and source emissions.

The particle diameters of some substances commonly found in the atmosphere or important in various manufacturing operations are given in

gas cleaning equipment are given in Fig. 3. Modern instrumental techniques are shown in Fig. 4.

Source Identification of Airborne Particles. In recent years, ingenious methods of identifying the point source of airborne particles have been developed. If not specific point sources of pollution, rather small regional areas can often be identified. Source of particles can be important for numerous reasons, including the enforcement of regulation and also in sorting out, for example, the various distant sources that contribute to acid rain pollution.

As reported by Olmez and Gordon (University of Maryland), the concentration pattern of rare earth elements on fine airborne particles (less than 2.5 micrometers in diameter) is distorted from the crustal abundance pattern in areas influenced by emissions from oil-fired plants and refineries. The ratio of lanthanum (La) to samarium (Sm) is often greater than 20 (crustal ratio is less than 6). The unusual pattern apparently results from the distribution of rare earths in zeolite catalysts used in refining oil. Oil industry emissions have been found to perturb the rare earth pattern even in very remote locations, such as the Mauna Loa Observatory in Hawaii.

Rare earth ratios are probably better for long-range tracing of oil emissions than vanadium (V) and nickel (Ni) concentrations because the ratios of rare earths on fine particles are probably not influenced by deposition and other fractionating processes. Emissions from oil-fired plants can be differentiated from those of refineries on an urban scale by the much smaller amounts of V in the latter. Pb in urban areas originates mainly from combustion of leaded gasoline. Arsenic (As), selenium (Se), and other chalcophile elements are usually associated with coal-fired plants or sulfide ore smelters (or both). In addition to the use of receptor models on an urban scale, they also have been used on a global scale to identify sources of Arctic haze, based upon manganese (Mn) and V ratios.

R.W. Shaw (U.S. Army Research Office, Research Triangle Park, North Carolina) commented that in analyzing particle samples, one must always consider that a particle sample could be produced by various sources. Chemical-element balance copes with this complication by positing (on the basis of the known ratios) several different elemental concentrations that could be generated by the suspected sources. It then finds the "mix" that best fits the actual concentrations on the collected samples. Such manipulations might reveal, for example, that 80% of the fine fraction of a sample is a byproduct of coal combustion and 15% comes from motor vehicles. Or it might show that 94% of the lead in a specimen is from motor vehicles, 4% from the burning of refuse, and 1% from the burning of coal.

Smoky Mountain Haze. A rather thorough study of what contributes to the increasing haze that exists in the Great Smoky Mountains National Park in Tennessee was reported by Shaw in 1987. The overall purpose of the study was to determine the contributions of natural emissions, as from vegetation, and motor vehicle and industrial emissions. The researchers also conducted surveys in the Georgia region (former Soviet block), the latter highly regarded for clear air and massive areas of evergreen forests. The Smoky Mountains haze is ascribed to sulfate particles in the air. It was tentatively concluded that the sulfate is a byproduct of coal burned at distant power plants. Surprisingly, the concentration of coal-derived particles in the Smoky Mountains was not much lower than concentrations found at several sites in an industrialized city, St. Louis, Missouri. Sulfate particles also were found in Georgia, but considered to be much older and the particles contained thirty times more sulfur than in sulfur dioxide gas. These studies, however, did not make a direct link with remote coal-burning plants. This was accomplished later in a 16-month study in the Ohio River valley, with sampling stations located in rural Kentucky, Indiana, and Ohio, far away from cities, roads, and power plant smoke plumes. About 50% of the fine-particle mass was found to be sulfate. The total concentration nearly equaled that found in the industrialized cities of the regions. The link was confirmed by a consistent association between sulfate concentration and the trace element selenium. No other probable sources of selenium exist in or near the Ohio River valley. The investigators (R.W. Shaw, et al.) concluded in their report that there is little doubt that fuel combustion is the main source of acid deposition and particulate fallout.

Shaw also describes two techniques that now make it possible to analyze particles without removing them from collection filters. To determine the mass of a sample, technicians insert the particle-laden filter between a source that emits beta particles and a detector that counts them. As the mass increases, the number of particles that can penetrate the sample decreases. To determine the atomic elements in a specimen, laboratory workers may also separately carry out x-ray fluorescence spectroscopy. X-rays passed through the sample cause each element to emit characteristic x-rays. The energy levels of the rays reveal the identity of the elements: the intensity of the x-rays (number emitted) reflects the concentrations.

Sulfur Oxides. (Sulfur dioxide, SO_2, and sulfur trioxide, SO_3). The primary sources of these oxides SO_x are sulfur-bearing fuels—as used for heat and power, both industrially and residentially. Chemical and metallurgical plants of various kinds also emit SO_x as the result of processing activities, such as the manufacture of sulfuric acid, the roasting of ores, etc. In order of decreasing pollution, the fossil fuels contributing to SO_x pollution are: (a) Untreated coal; (b) untreated petroleum fuels, particularly those originating from so-called sour crude oils; and (c) natural gas. Thus, the preference for natural gas by many large fuel users, such as power plants. With only small variations in the cost of raw fossil fuels, there was an advantage in burning a naturally low-sulfur fuel as contrasted with installing elaborate SO_x removal or reduction systems. But, with a rapidly lessening natural gas supply and accompanying higher costs, it has become economically attractive to pay more for desulfurized coal and petroleum fuels, as well as to install SO_x abatement equipment. The allowable sulfur content of oil and coal fuels varies from one community to the next, ranging from 0.50% by weight or less, up to 4% and slightly higher. Such regulations usually take into consideration new versus old fuel-burning equipment, the incidence of serious pollution in a given area, as well as economic impact and practicability. Logically, for some years to come, such regulations must represent a compromise of social, economic, and technological factors. The chemical nature of the oxides of sulfur is given in the entry on **Sulfur**. Treatment of SO_x effluents is described later in this article.

Nitrogen Oxides. These compounds result from all fossil-fuel combustion processes where air is used as the oxidant. Oxygen from the air and nitrogen combine at combustion flame temperatures to form nitric oxide, NO, according to $N_2 + O_2 \longleftrightarrow 2NO$. The rate at which NO is formed and decomposed depends largely upon temperature. For the majority of stationary combustion processes, there is too short a residence time for the full oxidation of NO to NO_2, an estimated average of only 5 to 10% of this reaction occurring. Thus, it is important to observe that although NO_x emissions generally are given as "equivalent NO_2," the predominant NO_x in combustion gases is NO. Several factors affect the generation of NO_x pollutants. Factors which tend to decrease NO_x emissions are: (a) decrease in excess air for combustion; (b) decrease in preheat temperature; (c) decrease in the heat-release rate; (d) increase in the heat-removal rate; (e) increase in back-mixing; and (f) decrease in fuel nitrogen content. With exception of very large installations, coal appears to generate more NO_x than oil; and oil generates more NO_x than natural gas. Thus, as with SO_x, natural gas is the preferred fuel when properly burned to minimize NO_x.

The major sources of NO_x are the large fuel-burning operations as previously mentioned, automotive vehicles, and certain chemical plants, notably nitric acid manufacturing facilities. Research to date indicates that effective steps toward reducing the overall emission of NO_x can be effected from stationary combustion sources by: (a) using low excess air firing; (b) providing for two-stage combustion; (c) utilizing flue-gas recirculation; and (d) using water injection. These objectives, when reduced to terms

of hardware, mean changes in the configuration, location, and spacing of burners, and the kinds of firing and combustion techniques used. Two-stage combustion is defined as firing all fuel below stoichiometric amounts of primary air in a first stage of combustion, followed by injecting air in a second stage, whereupon burnout of the fuel is completed. There is removal of heat between the two stages. The formation of NO in the first stage is limited because the available oxygen for combustion with nitrogen is limited. The removal of heat between stages kinetically limits the formation of NO when excess air is added to the second stage. Experience shows that a 90% reduction in NO_x emission can be achieved in this manner. By recirculating flue gas, both the peak flame temperature and oxygen content are lowered. Injecting low-temperature steam or water also provides a diluting effect. Although probably of limited value for electric utility boilers (because thermal efficiency is lowered), the water-injection technique may be one of the better ways to reduce NO_x emissions in connection with internal-combustion engines of the stationary type. The situation in the case of internal combustion engines for automotive vehicles is considerably more complicated—there is a wide range of loads on such engines, high performance is required at all loading conditions, and the combustion process from fuel to exhaust must be kept simple and hence low-cost. As of the early 1980s, there remained some differences in opinion as regards the use of catalytic converters to remove NO_x from automobile exhausts. See also **Catalytic Converter (Internal Combustion Engine)**; **Combustion (Fuels)**; and **Petroleum**. The chemical characteristics of NO_x are described under **Nitrogen**.

Hydrocarbons. Extensive pollution of air occurs from the introduction of hydrocarbons either from (a) the incomplete combustion of hydrocarbon fuels in both stationary and vehicular engines; or (b) from paint spraying, solvent cleaning, printing, chemical and metallurgical, and other plants that use various fluids that have a high hydrocarbon content. Engine design and tuning are major factors in abating exhaust hydrocarbons. The intent is to fully burn the hydrocarbon content of the fuel. In a major city, industrial and commercial sources of organic solvent fumes (principally hydrocarbons) may average from 300 to 600 tons/day. For years, without legal restrictions, some operators found it more economical to permit vapor-laden air to escape to the atmosphere rather than to invest in solvent recovery equipment. Regulations coupled with higher costs of solvents have gone a long way toward eliminating this source of industrial pollution. Also, the chemical industry has successfully developed newer solvents, which are less volatile, and easier to handle and recover.

Carbon Monoxide. This pollutant is also associated with combustion operations, again being a product of incomplete combustion. Over the years, there has been a much greater awareness of carbon monoxide as a pollutant than the aforementioned gases because of its potent toxicity, dramatized by numerous deaths in earlier years as the result of keeping an automobile engine running in an enclosed space. Faulty residential heaters continue to take their toll of life and in recent years an important killer is the outdoor grill or hibachi with glowing coals taken into a camper or cabin as a means to temper the evening chill. Vehicular tunnel and large parking garage designers, of course, have practiced careful control over carbon monoxide concentrations for many years. See also **Carbon Monoxide**. The effects of carbon monoxide on human beings are shown in Fig. 5.

Other Pollutants. Some of these are gases; others fall into the particulate category. Of considerable importance are beryllium dust—very toxic and arising from ore preparation and metalworking operations, but of relatively limited extent because this metal is not a common structural

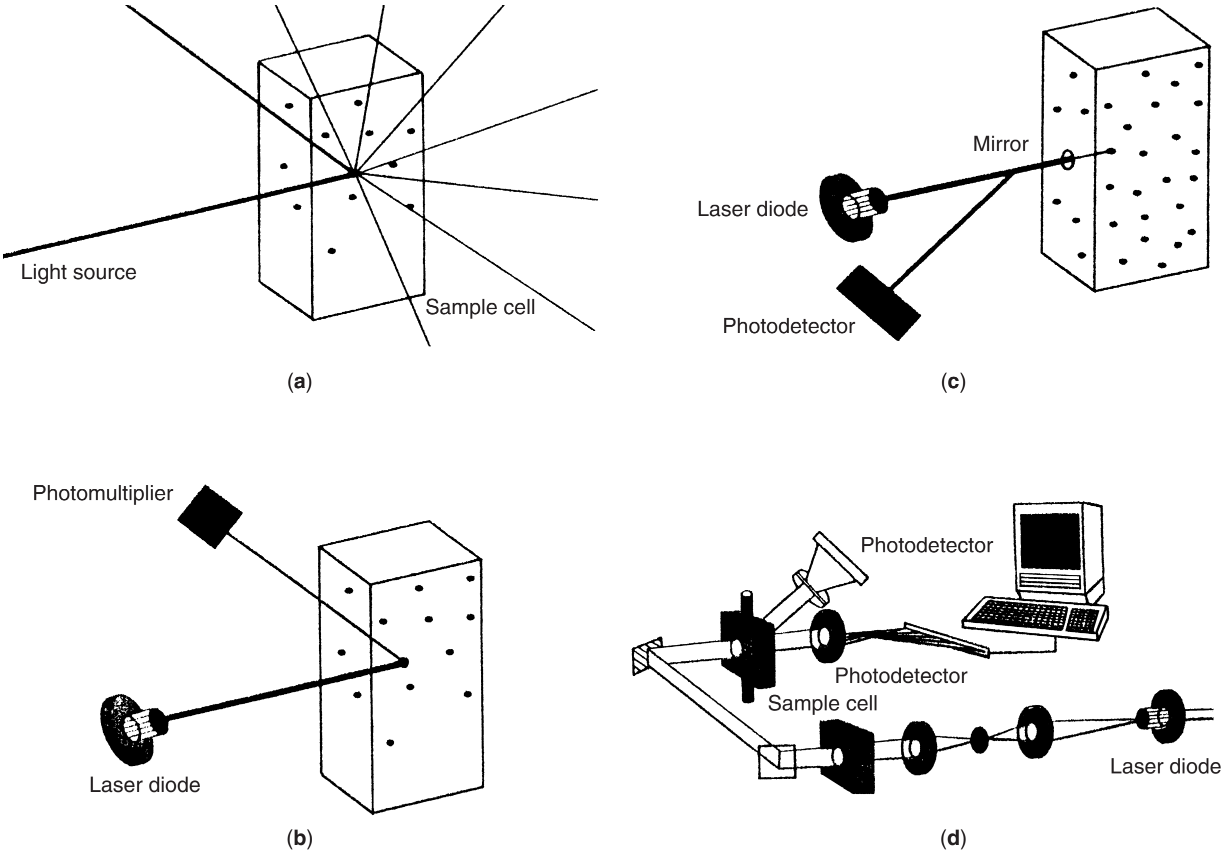

Fig. 4. Instrumentation for measuring air pollution particle dimensions. (**a**) Some fine-particle-size analyzers determine particle size by measuring the Doppler shift of light as it is scattered by moving particles. Smaller particles move faster, causing a greater Doppler shift in the light that they scatter. (**b**) In some conventional analyzers, light passes completely through an extremely dilute suspension and scatters in all directions. The detector measuring the Doppler shifts of the scattered light has no high-level signal to reference against the resulting low-level signal. The resulting low-level signals require amplification from photomultipliers, which can introduce noise errors. (**c**) In instrument shown (*Microtrac—Leeds & Northrup*), light travels to the sample via an optical wave guide. A mirror reflects some of the light, creating a high-level reference signal. Moving particles backscatter the light penetrating the mirror. The instrument combines the reflected and backscattered light to create a high-level signal sufficiently strong to be fed directly to a solid-state photodetector with a requirement for amplification. (**d**) Infrared light, emitted from a long-lived solid-state laser diode, scatters when it hits particles in the sample cell. Multi-train optics direct all scattered light onto solid-state photodetectors, which measure scattered-light angles and send signals to a computer control module. (*Leeds & Northrup*)

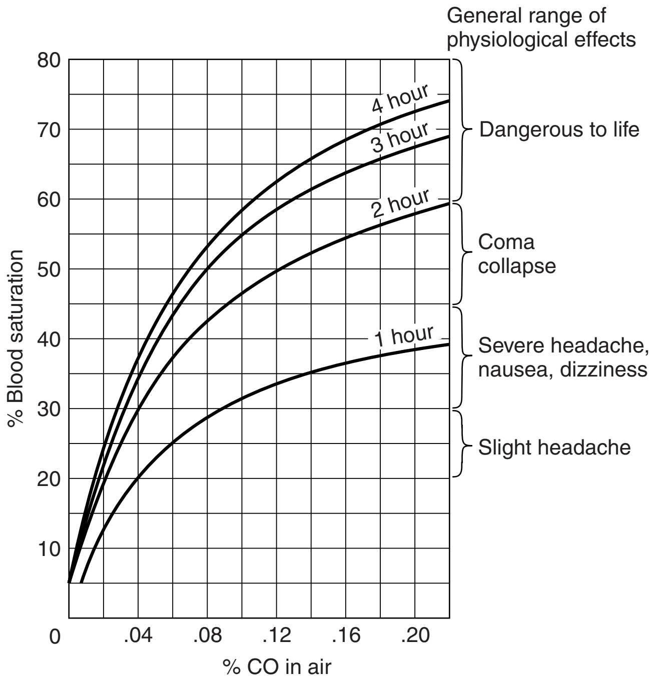

Fig. 5. Effects of carbon monoxide on human beings. This chart can be considered only as a general guide because the percent of CO blood saturation will vary with exertion, excitement, fear, depth of respiration, anemia, and general physical condition of the individual

material. Other contaminants include fluorides; metal fumes, such as arsenic, lead, and zinc; organic phosphates, notably from crop dusting and spraying; numerous kinds of organic vapors, including chlorinated hydrocarbons and hydrofluorocarbons (used in aerosol containers but suspect in connection with altering the ozone content of the upper atmosphere—see also **Aerosols**); radioactive fallout, such as ^{14}C, ^{137}Ce, and ^{90}Sr, arising from nuclear-device testing–no longer the major concern it was prior to the nuclear test ban accepted by most nations; and uranium dust. See also **Asbestos**; **Beryllium**; and **Pneumokonioses**.

Acid Rain

This term is used almost exclusively in connection with the effect of airborne pollutants on the natural health of forests and lakes. The term was coined by Angus Smith several years ago, when he referred to the effect of industrial emissions on precipitation over the British midlands. Unfortunately, the term does *not* fully or accurately describe what may be occurring in certain forests and lakes.

The topic of acid rain during the 1980s and early 1990s was one of controversy and of incomplete answers in terms of official policy and science—after an expenditure of many millions of dollars. In 1980, the National Acid Precipitation Assessment Program (NAPAP) was established and subsequently consumed thousands of scientific research hours and costly field investigations, including the use of numerous helicopter expeditions to northwestern mountain and lake areas of the United States and Canada. Thousands of hours of computer power were consumed.

Segments of the jigsaw puzzle were worked out in excruciating detail, but only a few of the larger pieces of the puzzle were put together. Bottom-line conclusions and recommendations needed for governmental and private forestry operators were not forthcoming. A 6,000-page report was generated by NAPAP. But, in terms of a summary, the findings can be condensed to the few following points:

1. Acid rain has adversely affected aquatic life in about 10 percent of eastern lakes and streams.
2. Acid rain has contributed to the decline of red spruce at high elevations by reducing that species' cold balance.
3. Acid rain has contributed to erosion and corrosion of buildings and materials.
4. Acid rain and related pollutants, especially fine sulfate particles, have reduced visibility throughout the Northeast and in parts of the West.

Ellis Cowling (Ecologist, North Carolina State University) observed in early 1991, "You can say no symptoms were found, and we looked hard"—but that is different from saying no problem exists. A. Johnson (University of Pennsylvania) has observed, "It is the marginal ecosystems, the tenuous ones on the edge, that are affected by acid rain at current levels. I think control measures are justified. They will probably go a small way toward restoring some of the ecosystems that have been altered. And they will largely prevent more harm from occurring." See also **Acid Rain**.

Air Treatment Methodologies

Numerous techniques have been used to reduce, if not fully eliminate, various forms of air pollution over the years. For example, in connection with particulates, see entry on **Electrostatic Precipitator**. Most methods, however, fall into what might be termed the category of wet-scrubbing processes. As of the early 1980s, there were nearly 100 such processes on the market. Progress in this field has been steady, but not characterized by major breakthroughs. The concentration of sulfur dioxide in stack gases emitted by steam generation plants is usually in the range of only 400 to 2,000 parts per million (ppm). However, the volume of gases produced by the utility industry results, for example, in the liberation of large tonnages of sulfur dioxide into the atmosphere.

Chemical scrubbing systems for SO_2 absorption fall into two broad categories: (a) Disposable systems; and (b) regenerative systems. Typical of systems in use for a number of years are those that use an aqueous slurry of an insoluble calcium compound, which can be discarded after use. Disposable SO_2-removal systems use aqueous slurries of finely ground materials, such as lime, limestone or dolomite, to produce a mixture of insoluble sulfites and sulfates. On passing through the scrubber, SO_2 from the waste gas dissolves to form sulfurous acid: $SO_2 + H_2O \longrightarrow H_2SO_3$. The dissolved SO_2 reacts with the lime, $Ca(OH)_2$ or limestone, $CaCO_3$, to form insoluble calcium sulfite, $CaSO_3$: $Ca(OH)_2 + H_2SO_3 \longrightarrow CaSO_3 + 2H_2O$; $CaCO_3 + H_2SO_3 \longrightarrow CaSO_3 + H_2O + CO_2$. Unfortunately, SO_2 is less soluble (and hence less easily removed by scrubbing) in slightly acid solutions, so that it is extremely difficult in practice to operate a calcium-based system in such a manner that SO_2 removal is maximized while the quantities of calcium chemicals are minimized in order to approach stoichiometric conditions. As calcium-based slurry systems are usually operated at pH 6–10, disposal of the very large masses of used slurry presents a major problem. A typical power station using a calcium-based SO_2-removal slurry system will produce several hundred tons of spent slurry per day. A further disadvantage of lime or limestone systems is their marked tendency to precipitate insoluble calcium salts inside the scrubber. Unless the scale is removed, the scrubber shortly becomes inoperable.

Although chemically analogous to calcium-based systems, magnesium-based scrubbing systems possess several advantages. A slurry of finely divided magnesium hydroxide, $Mg(OH)_2$, is pumped through the scrubber to remove SO_2 from stack gases. Insoluble magnesium sulfite, $MgSO_3$, is formed: $Mg(OH)_2 + SO_2 \longrightarrow MgSO_3 + H_2O$. Hydrated magnesium sulfite, $MgSO_3 \cdot 6H_2O$, can be disposed of as such, although it is usually heated to produce a rich stream of SO_2 and regenerate MgO. The SO_2 is compressed, liquefied, and stored in tanks for market; or catalytically oxidized to sulfur trioxide, SO_3, and treated with water to produce sulfuric acid, H_2SO_4. Alternatively, the SO_2 is mixed with hydrogen sulfide, H_2S, to produce elemental sulfur by the Claus process: $SO_2 + 2H_2S \longrightarrow 3S + 2H_2O$. Absorption efficiency of SO_2 attainable in a magnesium system is good, and removal efficiencies from 90 to 95% have been claimed without difficulty at reasonable liquor recirculation and MgO feed rates. As with calcium systems, serious scaling occurs due to build-up of insoluble $MgSO_3$.

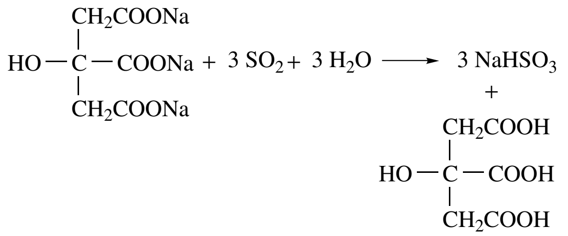
Scrubbing solutions containing sodium (or other alkali metals) compounds have been extensively studied for removal of SO_2. Justification for the use of sodium compounds includes: (a) complete solubility in water with no formation of scale; and (b) simple reactions with SO_2 : $Na_2CO_3 + SO_2 \longrightarrow Na_2SO_3 + CO_2$; $2NaHCO_3 + SO_2 \longrightarrow Na_2SO_3 + 2CO_2 + H_2O$; $2NaOH + SO_2 \longrightarrow Na_2SO_3 + H_2O$. In one commercial process, a scrubbing solution of sodium sulfite is used, which readily absorbs SO_2 to form the bisulfite: $Na_2SO_3 + H_2O + SO_2 \longrightarrow 2NaHSO_3$. In practice,

only a portion of the Na_2SO_3 is converted to $NaHSO_3$ because the SO_2 absorption efficiency diminishes as the bisulfite concentration increases. The resulting solution is heated to decompose the bisulfite and thermally regenerate the sulfite. The gaseous SO_2 is compressed, liquefied and handled as previously mentioned under the magnesium system.

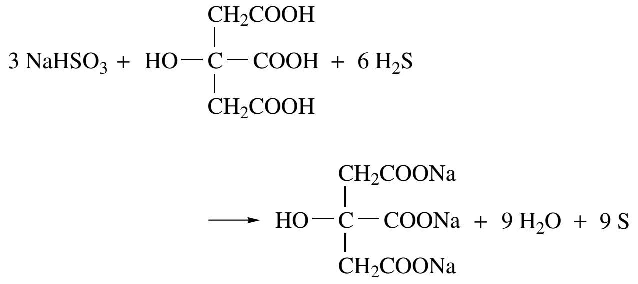
Ammonia-based chemicals appear to have some advantages over sodium systems. They are less costly, and regeneration by conventional means is possible, with the byproduct, ammonium sulfate, a marketable commodity for fertilizer.

Solutions containing ammonium sulfate, with or without the addition of ammonium hydroxide, have been widely used. The ammonium system can operate effectively only within a pH range of 4.0 to 7.0. As the pH value increases above 7.0, progressively more gaseous ammonia is liberated and this reacts in the gaseous phase with water vapor and SO_2 to produce a dense aerosol (white plume) which is difficult for scrubbers to remove. In an ammonia system, in order to regenerate the scrubbing solution, the ammonium bisulfite and sulfite mixture is heated to drive off gaseous $SO_2 : 2NH_4HSO_3 \longrightarrow (NH_4)_2SO_3 + H_2O + SO_2$. Alternatively, the ammonium bisulfite/sulfite mixture can be treated with calcium hydroxide. Gaseous ammonia is evolved and trapped in water, which is then recirculated to the scrubber.

Sodium citrate also is used in an SO_2 removal system. The solution is buffered at a pH 3.0–3.7 by the citrate ion, sulfur dioxide is absorbed, and an equilibrium mixture of sodium bisulfite and citric acid is produced.



The bisulfite leaving the scrubber is then reduced with gaseous hydrogen sulfide, which precipitates elemental sulfur by a modified Claus reaction:



A formate system uses two reactions involving potassium formate, HCOOK, which is regenerated after recovery of elemental sulfur. This method has the advantage over other wet scrubbing methods in that no precipitation of insoluble intermediates occurs at any stage of the process. Disadvantages include the need to heat K_2CO_3 solution, at high temperature and pressures, with carbon monoxide to regenerate the potassium formate. The energy requirements thus are high.

While it has been demonstrated that solutions of NaOH, $NaHCO_3$, and Na_2CO_3 are effective for SO_2 removal, these solutions are not effective for removal of mixtures of NO and NO_2, particularly when the gas stream velocities are reasonably high. Under conditions where from 95 to 99% SO_2 may be removed, the solutions may only be effective in removing from 5 to 15% NO_x. The fundamental difference between SO_2 and NO_x removal is that NO_x gases (mixtures of NO, N_2O_3, NO_2) are approximately 1,000 to 2,000 times less soluble in water than SO_2 at any given temperature. It has been found that conventionally designed wet scrubbers often do not provide sufficient liquid-to-gas contact surface areas or residence times to permit the NO_x to dissolve in the scrubbing solution. Consequently several stages may be required. Concentrations of NO_x in the range of 20,000 to 40,000 ppm require from 6 to 12 stages.

If no SO_2 is present, a sodium-based process may be used to remove NO_x efficiently. In the Neville-Krebs process (patent applied for), removal efficiencies of 60 to 90% have been achieved from gas streams containing up to 1,500 to 2,000 ppm of NO_x passing through a 3-stage scrubber (1 cubic foot; 0.028 cubic meter per stage) at 150 to 500 cubic feet (4.2 to 14.2 cubic meters) per minute.

The urea system is another relatively new system for removing NO_x from low-volume, slow-flowing waste gas streams. The system uses a slightly acid solution of urea, $CO(NH_2)_2$. Unfortunately, the cost of urea is quite high, particularly for a large installation.

Other systems using electron-donor compounds have been tried or are in development. Such compounds include tri-*n*-butyl phosphate, dimethylformamide, triethyleneglycol dimethyl ether, dimethylsulfoxide, hexamethylphosphoramide, diethyleneglycol dimethyl ether, tricresyl phosphate, and dioxane. Most of these compounds are expensive compared with inorganic compounds used in other scrubbing systems.

Thus, it is evident that as of the early 1980s, the panacea for stack gas treatment was yet to be realized. Difficulties in treating stack gases have provided incentives at the other end of the combustion cycle, namely, in the treatment of the fuels prior to combustion. Various means for treating coal are described in detail in the entry on **Coal**; and desulfurization of petroleum fuels is described under **Petroleum**.

Numerous other entries in this volume take the energy/pollution interface into consideration. These include: **Air**; **Catalytic Converter (Internal Combustion Engine)**; **Combustion (Fuels)**; **Energy**; **Fuel**; **Hydrogen (Fuel)**; **Natural Gas**; **Nuclear Power Technology**; **Oil Shale**; and **Tar Sands**.

POLONIUM. [CAS 7440-02-06]. Chemical element, symbol Po, at. no. 84, at. wt. 210 (mass number of the most stable isotope), mp 252°C, bp 960°C, sp gr 9.4. The element was first identified as an ingredient of pitchblende by Marie Curie in 1898. The element occurs in nature only as a decay product of thorium and uranium. Because of limited availability and high cost, relatively few practical uses for the element have been found. Meteorological instruments for measuring the electrical potential of air have used small quantities of the metal. It is interesting to note that when Mme. Curie first identified polonium, she found that an electroscope was a far better instrument for detecting the metal than spectroscopic means. Polonium-plated metal rods and strips have been used as static dissipators in textile coating equipment and in various electrical equipment. The alpha rays from the polonium ionize the air, causing it to conduct and draw off accumulations of static electrical charges. Polonium is a member of periodic group 16 (formerly 6a).

Three isotopes of polonium occur in the uranium ($4n + 2$) radioactive series: ^{218}Po (radium A), $t_{1/2}$ 3.05 min; ^{214}Po (radium C'), $t_{1/2} 1.6 \times 10^{-4}$ s; and ^{210}Po (radium F), $t_{1/2}$ 138.4 days, and the most stable isotope of polonium. It is used as a source of a-radiation. The thorium ($4n$) series has two isotopes, ^{216}Po (thorium A), $t_{1/2}$ 0.16 s, and ^{212}Po (thorium C'), $t_{1/2} 3 \times 10^{-7}$ s. The actinium ($4n + 3$) series also has two isotopes, ^{215}Po (actinium A), $t_{1/2} 1.83 \times 10^{-3}$ s, and ^{211}Po (actinium C′), $t_{1/2}$ 0.52 s, which occurs in a 0.3% branched chain disintegration of ^{211}Bi (actinium C). Several other isotopes of polonium have been prepared, one of which occurs in the neptunium ($4n + 1$) series as ^{213}Po, $t_{1/2} 4.2 \times 10^{-6}$ s.

Polonium exhibits the allotropy of the lower members of the chalcogen group, having a low-temperature, cubic form, α-polonium, and a high-temperature, rhombohedral form, β-polonium.

The tendency of the chalcogens to show increasing metallic character as one moves down the periodic table is quite marked for polonium; in fact, it resembles lead more than it does tellurium. Its compounds have a more ionic character in its lower oxidation states than do the tellurium compounds. The stability of the 6+ state is low, the existence of polonate(VI) ion being doubtful. The common oxidation states of the element are 2+ and 4+.

The halides, consisting of both dihalides and tetrahalides, are covalent and volatile, and they are not well characterized. The fluorides have not been established. The complex $PoCl_6^{2-}$ is known. Polonium compounds are usually colored, a fact that is useful in following their reactions. Thus, polonium(II) chloride, $PoCl_2$, formed by dissolving polonium(IV) oxide, PoO_2, in HCl is pink, and an oxidation by heating or treatment with chlorine yields yellow $PoCl_4$. Polonium(IV) bromide, $PoBr_4$, dark red, gives purple polonium(II) bromide, $PoBr_2$, on heating. $PoBr_4$ also gives ammonium polonium bromide, $(NH_4)_2[PoBr_6]$ with ammonia. Complex iodides $M_2[PoI_6]$ have been prepared.

Metallic polonium reacts with air readily on heating, to form PoO_2, which exists in a yellow face-centered form having fluorite structure at low temperatures, and a red tetragonal one on heating. Polonium(IV) hydroxide, $Po(OH)_4$, precipitated from polonium(IV) solutions by ammonia, exhibits only slight activity, and is thus not amphiprotic. On reaction of polonium with HNO_3, $Po(NO_3)_4$ is formed, and on treatment of polonium(IV) chloride, $PoCl_4$, with H_2SO_4, polonium(IV) sulfate, $Po(SO_4)_2$, is formed, both being ionic-type salts, as indeed are other oxyacid compounds. The sulfate, however, is quite reactive, being hydrated in solution, dehydrated on removal from solution, and forming a basic compound, $2PoO_2 \cdot SO_3$, on heating. H_2S precipitates black polonium(II) sulfide, PoS.

POLONOVSKI REACTION. Demethylation of tertiary (or Heterocyclic) amine *N*-oxides on treatment with acetyl chloride or acetic anhydride to give *N*-acylated secondary amines and formaldehyde, along with *O*-acylated aminophenols as a result of a side reaction.

POLYACETYLENE. A linear polymer of acetylene having alternate single and double bonds, developed in 1978. It is electrically conductive, but this property can be varied in either direction by appropriate doping either with electron acceptors (arsenic pentafluoride or a halogen) or with electron donors (lithium, sodium). Thus, it can be made to have a wide range of conductivity from insulators to *n*- or *p*-type semiconductors to strongly conductive forms. Polyacetylene can be made in both *cis* and *trans* modifications in the form of fibers and thin films, the conductivity

of the fibers increasing with their degree of orientation. Films can be applied on glass or metal substrates. Though still in an experimental stage, these polymers have significant possibilities for industrial application, e.g., in batteries.

POLYALLOMER RESINS. These are block copolymers prepared by polymerizing monomers in the presence of anionic coordination catalysts. The polymer chains in polyallomers are composed of homopolymerized segments of each of the monomers employed. The structure of a typical polyallomer can be represented as:

$$(PPPPPPPP\cdots\cdots)_x(EEEE\cdots\cdots)_y$$

where P represents a propylene molecule and E an ethylene molecule. The number and length of the individual segments can be varied within wide limits depending on the process conditions, monomer concentrations, and catalyst systems employed. The copolymers exhibit the crystallinity normally associated only with the stereoregular homopolymers of these monomers.

The word *polyallomer* is derived from the Greek words *allos, meros*, and *poly*. *Allos* means "other" and denotes a differentiation from the normal. The word *meros* means "parts" and the prefix *poly* is added to show that these materials are polymeric. Since allomerism is defined as a constancy of crystalline form with a variation in chemical composition, the polyallomers are examples of allomerism in polymer chemistry.

Polyallomers can be synthesized in slurries by contacting the parent monomers with anionic coordination catalysts of the Ziegler-Natta type at temperatures of 70–80°C. Polyallomers are also synthesized in solution at 140–200°C by contacting the parent monomers with hydrogen-reduced alpha-titanium trichloride and a lithium-containing cocatalyst. In both the slurry and solution processes the polyallomers are formed by alternate polymerization of the monomers employed. In the synthesis of polyallomers from monomers which differ widely in polymerization rates it is sometimes desirable to alternately polymerize a single monomer and then a mixture of monomers to obtain the most desirable properties.

Evidence for the crystalline nature of the polyallomers includes x-ray diffraction patterns, infrared spectra, and for olefin polyallomers, low solubility in hydrocarbon solvents.

The physical properties of polyallomers are generally intermediate between those of the homopolymers prepared from the same monomers, but frequently represent a better balance of properties than blends of the homopolymers. This is illustrated by comparing the properties of a propylene-ethylene polyallomer containing 2.5% ethylene with polypropylene, high-density polyethylene, and a blend of 5% high-density polyethylene and 95% polypropylene.

Compared to polypropylene, a propylene-ethylene polyallomer has a lower brittleness temperature, higher impact strength, and less notch sensitivity. Compared to high-density polyethylene, a propylene-ethylene polyallomer is harder, higher-melting, and of higher impact strength. Other advantages of this polyallomer over high-density polyethylene includes its excellent resistance to environmental stress cracking and its low and uniform mold shrinkage, which minimizes sinks and voids in molded parts. A propylene-ethylene polyallomer thus overcomes the most serious property deficiencies of polypropylene (poor impact and low-temperature properties) and of high-density polyethylene (poor stress-crack resistance and excessive mold shrinkage).

Propylene-ethylene polyallomer is used in vacuum forming, blow molding, injection molding, film and sheeting, wire covering and pipe. Propylene-ethylene polyallomer is the easiest of all polyolefins to vacuum form. The excellent melt strength and broad processing range permit a deep draw. Reproduction of mold detail and surface finish is very good. In film and sheeting, propylene-ethylene polyallomer has optical properties equal to polypropylene but much higher impact strength, particularly at low temperatures. In wire covering, blow molding, and pipe extrusion operations, the combination of good processability and excellent environmental stress crack resistance is important.

POLYAMIDE RESINS. These are synthetic polymers that contain an amide group, −CONH−, as a recurring part of the chain. Poly-alpha-aminoacids, i.e., proteins, whether natural or synthetic, are not normally included in this classification.

The polyamides trace their origin to the studies of W. H. Carothers, begun in 1928, on condensation polymerization, a process that involves the repetition many times of a reaction known to the organic chemist as a condensation reaction because it links two molecules together with the loss of a small molecule. Esterification and amidation are examples:

$$\underset{\text{acetic acid}}{CH_3COOH} + \underset{\text{ethyl alcohol}}{C_2H_5OH} \rightleftharpoons \underset{\text{ethyl acetate or ethyl ester of acetic acid}}{CH_3COOC_2H_5} + H_2O$$

$$\underset{\text{methyl acetate}}{CH_3COOCH_3} + \underset{\text{butyl amine}}{C_4H_9NH_2} \rightleftharpoons \underset{\text{N-butylacetamide}}{CH_3CONHC_4H_9} + CH_3OH$$

Polymerization requires at least two reactive groups per molecule as in the following example:

$$n\ \underset{\text{hexamethylenediamine}}{H_2N(CH_2)_6NH_2} + n\ \underset{\text{adipic acid}}{HOOC(CH_2)_4COOH} \rightleftharpoons$$

$$\underset{\text{poly(hexamethylene adipamide)}}{H[NH(CH_2)_6NHCO(CH_2)_4CO(CH_2)_4CO]nOH} + (2n-1)H_2O$$

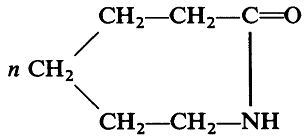
The first truly high-molecular-weight polyamide was made this way in 1935 and lead to the development of the first wholly man-made fiber which became popularly known as *nylon*, a name coined by Du Pont for fiber-forming polyamides. Numerals representing the number of carbon atoms in first the diamine and then the diacid are used to identify the nylon. Thus, poly(hexamethylene adipamide) is nylon-66 (six-six, not sixty-six), and poly(hexamethylene sebacamide) made from the 10-carbon sebacic acid is nylon-610 (six-ten).

Both reacting species may be present in the same molecule:

$$n\ \underset{\text{11-aminoundecanoic acid}}{H_2N(CH_2)_{10}COOH} \rightleftharpoons$$

$$\underset{\text{poly(11-aminoundecanoic acid)}}{H[NH(CH_2)_{10}CO]_nOH} + (n-1)H_2O$$

Here a single number is used to indicate the number of carbon atoms in the original nomomer, i.e., nylon-11 ("eleven" not "one-one"). In some instances the cyclic analogue or lactam is more accessible than the amino acid and is polymerized by a ring-opening rather than condensation mechanism:

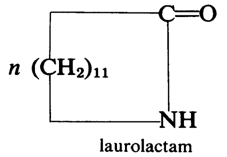


$+ H_2O \rightleftharpoons$

epsilon-caprolactam

$H[NH(CH_2)_5CO]_nOH$

polycaprolactam or polycaproamide
nylon-6



$+H_2O \rightleftharpoons H[NH(CH_2)_{11}CO]_nOH$

nylon-12

laurolactam

Some of the monomers commonly used to prepare the nylon resins are shown in the accompanying table. Both petrochemical and vegetable products provide the source materials that are transformed into the reactive intermediates. The table correctly suggests that there is a wider choice in diacids than in diamines. The most important commercial polyamide resins are nylons-66 and -6. Other commercial nylons include 610, 612, 11, and 12.

The above equations illustrate via the double arrows an important facet of polyamides—the equilibrium nature of the polymerization reactions. Achieving and maintaining useful molecular weights (about 10,000 or more) for plastics applications require low moisture contents in order

to avoid the reverse reaction of hydrolysis. Most commercial nylons are processed at melt temperatures in excess of 200°C, and molecular weight stability requires a water content below 0.3 weight percent. At a molecular weight of about 11,300, nylon-66 and nylon-6 have, on the average, 99 amide groups linking together 100 monomer units with one unreacted amine group and one unreacted acid group at the ends of the 700-atom long chain. This corresponds to 99% reaction. Because nylon plastics have average molecular weights in the 11,000 to 40,000 range, the need for pure materials and freedom from side reactions is seen to be essential for successful polymerization.

An average molecular weight (number average) is used because any one nylon comprises a broad range of molecular weights. Nylons typically have a "most probable distribution" in which the weight average is twice the number average.

As made, nylon-6 contains up to ten weight percent of lactam monomer that has to be extracted for most applications. Nylons made from larger lactam rings contain only about one percent monomer.

Not all polyamide resins are nylons, and not all nylons are polyamide resins. Some nylons such as nylon-4 or those with a high content of relatively inflexible rings are too unstable or have too high a melt viscosity to be melt processible and are not normally included in the "polyamide resin" category. However, spinning or casting from solution permits some such polymers to be converted into useful fibers or films. A class of polyamide resins distinct from the nylons is based upon polymerization or dimerized vegetable oil acids and polyalkylene polyamines (e.g., ethylenediamine or diethylenetriamine). These are relatively low in molecular weight (2000–10,000), vary from liquids to low melting solids, and are more soluble and flexible than the higher molecular weight, more crystalline nylons.

Nylons are semicrystalline polymers with fairly sharp melting points varying from 180°C for nylon-2 to 270° for nylon-66. The melting point increases in zigzag fashion with increasing concentration of amide groups, being higher where there is an even number of chain atoms between the amide groups. For example, nylon-66 averages five CH_2-groups per CONH but has either four or six chain atoms between amide groups; nylon-6 also has five CH_2/CONH but always has five chain atoms between amides and melts 40°C lower than nylon-66. The degree of crystallinity and the morphology of nylons are more readily controlled by choice of processing conditions than other crystalline polymers such as polyethylene or polyacetal.

The nylons are typically tough and strong. Nylon-66 was the first thermoplastic to provide a combination of stiffness and toughness suitable for mechanical applications. Nylons were therefore the first members of the family of engineering thermoplastics that now include newer materials such as the polyacetals, polysulfones, and polycarbonates. Nylons are outstanding in withstanding repeated impact, in resistance to organic solvents, and in water resistance. A low coefficient of friction, as ASTM self-extinguishing rating, reasonable electrical properties, adequate creep resistance, good fatigue properties, and good barrier properties, particularly to oxygen, are also characteristic of the nylons. Properties change with temperature but are often acceptable in the interval of about −60 to 110°C. Properties may change also with relative humidity because nylons characteristically absorb moisture and water acts as a plasticizer, that is, stiffness decreases and toughness increases. Water absorption decreases as the amide group concentration in the nylon decreases; for example, nylon-6 at saturation contains 9.5% water and nylon-11, 1.9%. Nylons are somewhat notch sensitive, and parts are typically designed to avoid sharp corners. Nylons are attacked by strong acids, oxidizing agents, and a few specific salt solutions such as aqueous potassium thiocyanate or methanolic lithium chloride.

Control of crystallinity and morphology provides one tool for changing properties as desired with any given nylon. But there are many other tools for modification of nylons, and this viability has been an important factor in meeting specific market demands in the face of increased competition from newer materials. Copolymerization and plasticization are alternatives that provide lower melting and tougher compositions with a somewhat different balance of properties. Lubricants as processing aids, nucleating agents to accelerate crystallization and give a little stiffer product, molybdenum disulfide or graphite to improve lubricity in gears or bearings, colorants, fire retardants, carbon black for weather resistance, and antioxidants for better resistance to thermal oxidation are examples of additives employed to achieve specific effects. Combination with other polymers is another technique. Reacting nylon-66 with formaldehyde in alcohol solution has yielded a low melting derivative, that can be cross-linked to provide a thermoset. Glass fiber reinforcement has proved to be particularly effective in nylons and has yielded products of exceptional strength, stiffness, and heat resistance.

The nylon resins are converted into useful shapes principally by injection molding or extrusion. These shapes are most often in finished form, but forming is sometimes employed to impart added strength via orientation. Machining of extruded stock shapes is often appropriate where the number of parts does not justify manufacture of a costly mold. Nylon-6 castings are made by the base catalyzed, anhydrous polymerization of monomer in molds that are relatively inexpensive because they do not have to sustain high pressures. Rotational molding, fluidized bed coating, and electrostatic spray coating are also used, especially with low melting nylons such as nylon-11.

Football face guards, hammer handle gears, sprockets, journal bearings, bristles, filaments, refrigerant tubing, film as a cooking pouch, coil forms, casters, package strapping, loom parts, automobile dome lights, power tool housings, and virtually thousands of other diverse articles attest to the performance of nylon resins in electrical appliances, automotive parts, business equipment, consumer products, and other industrial and home applications.

The non-nylon polyamide resins include relatively low-melting solids that are used with or without modifiers in hot melt cements, heat seal and barrier coatings, inks for flexographic printing of plastic film, and other specialty adhesives and coatings such as varnishes to provide a glossy, transparent, protective layer over print. The large hydrocarbon side chains that are present in the dimerized vegetable oil acids used to make these polyamide resins contribute to their low crystallinity, low water absorption, and flexibility. The fluid, "reactive" polymides are lowest in molecular weight and contain an excess of amine groups. Monomers with more than two amine groups per molecule such as diethylenetriamine ($H_2NCH_2CH_2NHCH_2CH_2\ NH_2$) are used, and care must be taken during polymerization to avoid premature gelation. The excess amine groups permit interaction with epoxy, aldehyde, hydroxmethyl, anhydride, acrylic, and other groups in other resins to produce a variety of thermosetting formulations. Combinations with epoxy or phenol-formaldehyde polymers

MONOMERS USED TO PREPARE NYLON RESINS

Monomer	Formula	Source(s)
hexamethylene diamine	$H_2N(CH_2)_6\ NH_3$	butadiene, furfural, or propylene
adipic acid	$HOOC(CH_2)_4COOH$	butadiene or cyclohexane
suberic acid	$HOOC(CH_2)_6COOH$	butadiene or acetylene
azelaic acid	$HOOC(CH_2)_7COOH$	oleic acid
sebacic acid	$HOOC(CH_2)_8COOH$	castor oil
dodecanedioic acid	$HOOC(CH_2)_{10}COOH$	butadiene
"dimer" acid	$HOOC\text{-}C_{34}H_{60}-COOH$	oleic and linoleic acids
caprolactam		toluene, benzene, or cyclohexane
7-aminoheptanoic acid	$H_2N(CH_2)_6COOH$	cyclohexane or ethylene
capryllactam		butadiene or acetylene
9-aminononanoic acid	$H_2N(CH_2)_8COOH$	soybean oil
11-aminoundecanoic acid	$H_2N(CH_2)_{10}COOH$	castor oil
laurolactam		butadiene

with or without added fillers are the most common. The epoxy compositions are cured at relatively low temperatures and are useful for bonding aluminum in aircraft, steel in automobiles, wood, leather, glass, ceramics, and other materials. The resin combination broadens the capacity of the adhesive to wet a variety of surfaces and enhances bond strengths. The phenolic-polyamide compositions require higher curing temperatures but withstand higher temperatures in use. They tend to form bonds less tough than the epoxy mixes but bond strongly to copper and other common components of printed circuits. The phenolic blends also produce acid and alkali resistant coatings useful as container linings or wire coatings.

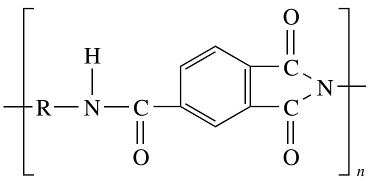
POLYAMIDE-IMIDE RESINS. An injection-moldable, high-performance engineering thermoplastic, polyamide-imide is the condensation polymer of trimellitic anhydride and various aromatic diamines with the general structure:



Polyamide-imides are available[1] in unfilled; 30% glass fiber-filled; 30% graphite fiber-filled; and modified 40% glass-filled grades. The unfilled grade has the highest impact resistance, while the graphite fiber-filled grade has the highest modulus or stiffness. The modified version offers the lowest cost while still maintaining an impressive slate of properties. The resins can be molded into complex precision parts and also can be extruded and machined to close tolerances. The resins are used extensively in the aerospace industry, offering significant weight reduction by replacing metal parts. Aircraft usage includes jet engine components, compressor and generator parts, and electronic/electrical devices. Polyamide-imide resins are also used in the hydraulic/pneumatic equipment industry for wear surfaces, bushings, seals, vanes, and flow control devices. The automative and heavy equipment industries use this material as parts in transmissions, universal joints, and power-assisted devices. Internal combustion engines use many polyamide-imide structural-mechanical parts, such as valve train components.

The material is opaque and characterized by good dimensional stability, creep resistance, impact resistance, and superior mechanical properties that persist up to temperatures of about 500°F (260°C). Unfilled polyamide-imide has a tensile strength of about 27,000 psi (186 mPa); flexural strength of about 35,000 psi (241 mPa); compressive strength of about 32,000 psi (221 mPa); and an elastic modulus of about 750,000 psi (5172 mPa). Mechanical properties at 450°F (232°C) exceed those of many polymers at room temperature. At cryogenic temperature, the unfilled polymer has a tensile strength of about 31,500 psi (241 mPa) with 6% elongation at −196°C (liquid nitrogen). Heat deflection is high (525°F; 273°C), while the coefficient of linear thermal expansion is low. When burned, polyamide-imide produces a char rather than drip and produces very little smoke. Electrical properties are attractive. Radiation resistance is good. The resin is virtually unaffected by aliphatic and aromatic hydrocarbons, halogenated solvents, and most acid and base solutions. It is attacked by high-temperature caustic, steam, and some acids. At 50% relative humidity, the material (70°F; 21°C) will absorb about 1% moisture in 1000 hours.

POLYARYLATES. These are clear, amorphous thermoplastics that combine clarity, high heat deflection temperatures, high impact strength, good surface hardness, and good electrical properties with inherent ultraviolet stability and flame retardance. No additives or stabilizers are required to provide these properties. Polyarylates are aromatic polyesters that are manufactured from various ratios of iso- and terephthalic acids with bisphenol A.[1] The resultant products are free-flowing pellets which can be processed by a variety of thermoplastic techniques in transparent and opaque colors. Because polyarylate's weatherability is obtained through polymer chemistry rather than additives (as with most UV-resistant polymers), the properties of polyarylate do not deteriorate significantly with time. (Over 5000 hours of accelerated weathering and actual Florida and Arizona aging resulted in virtually no change in performance with respect to luminous light transmittance, haze, gloss, yellowness, and impact.) The flammability characteristics are inherent. Properties include a high oxygen index, low smoke density, low flame spread, and low toxic gas formation. Because the flammability properties are achieved without additives, the resultant products of combustion are essentially limited to Commercially available as CO_2, CO, and water.

Polyarylates are offered in several glass-reinforced versions with loading available up to 40%. The glass fibers provide higher stiffness, improved tensile strength, and higher heat deflection temperatures. Polyarylates may also be mineral-filled and reinforced with other fibers, such as carbon. Alloys/blends with other polymers are also available.

These materials are useful in outdoor applications, such as high-intensity discharge lighting (traffic signals), automobile halogen headlamp lenses and bodies, and rear-end elevated automobile stop lights. High-temperature lighting and microwave cookware are suitable applications. Electronic/electrical connectors and housings are also important applications for the polymer.

Polyarylates have good optical properties. Luminous light transmission can range from 84% to 88% with only 1% to 2% haze. Refractive index is 1.61. An important feature of the polyarylate family is high heat resistance demonstrated by a 340°F (171°C) heat deflection temperature at 264 psi (1.8 mPa). The material exhibits good retention of properties at high temperature exposures: 270,000 psi (1380 mPa) at 300°F (149°C); and over 200,000 psi at 350°F (177°C).

Polyarylates are injection molded, using standard screw machines, as well as extruded, foam molded, and blow molded. Melt temperatures range from 600 to 680°F (316 to 360°C). Mold temperatures should be maintained between 200 and 300°F (93 and 149°C).

POLYBASITE. A mineral antimony sulfide of silver $(Ag,Cu)_{16}Sb_2S_{11}$, in which copper substitutes for silver to approximately 30 atomic percent. It crystallizes in the monoclinic system; hardness, 2–3; specific gravity, 6.3; color, black, dark ruby red in thin splinters with metallic luster; nearly opaque. From the Greek, meaning *many*, suggesting the many-metal basis.

Occurs in low-temperature silver deposits commonly associated with silver and lead minerals. Found in various Western States in the United States, and as superb crystals at Arizpe and Las Chiapas, Mexico; in Chile, Peru, Sardinia, Germany, and Australia.

POLYBENZIMIDAZOLES. These are heterocyclic polymers that have outstanding high thermal characteristics, the highest obtainable in commercial polymers. These materials also have superior ablative and hydrolytic stability as well as high compressive and dimensional stability. Polybenzimidazoles essentially are unaffected by solvents, acids, and bases. They are marketed in stock shapes and as finished parts. The materials are not available in resin form. Hoechst Celanese markets the products under the tradename *Celazole.*®

Parts are produced by a high-pressure sintering process wherein the melt polycondensation resin is densified and then coalesced. Metallurgical pressures at temperatures exceeding over 400°C (750°F) are required. Polybenzimidazoles have repeating benzimidazole groups in the polymer backbone. These materials were synthesized first in 1961. Currently, the products result from a melt polycondensation reaction of aromatic, bis-ortho-diamines (diphenylisophthalate). By way of compounding, fabrication and end-use performance characteristics can be customized to specific needs. Often the materials are preferred for tribological applications inasmuch as they have the desirable characteristics of low coefficient of friction, low abrasion, and good high-temperature dimensional stability.

Polybenzimidazoles have been used for seals, mechanical components, electrical connectors, valve seats, and as components of materials-handling equipment in the petrochemical, geothermal, chemical process, aerospace, defense, automotive, and electrical products industries. These materials frequently are procured as replacement parts for other materials in an effort to improve equipment performance.

[1] Commercially available as *Torlon*™. (*Amoco Chemicals Co.*)

[1] Data furnished by *Celanese Engineering Resins.*

POLYBUTYLENE RESINS. These materials (PBs) are semicrystalline polyolefin thermoplastics based on poly(1-butene) and include homopolymers and a series of poly(1-butene-ethylene) copolymers. The resins available commercially[1] are manufactured via stereospecific Ziegler-Natta polymerization of 1-butene monomer. The commercial products are based on isotactic (98% to 99.5%), high-molecular-weight (230,000 to 750,000) polymer. Five crystalline modifications of poly(1-butene) are known. Of these, the glass transition temperature ranges from about −4°F (−20°C) for the homopolymers to about −30°F (−34:18C) for the high-ethylene copolymers.

PB resins generally are resistant to acids, bases, solvents, paraffinic and naphthenic oils, detergents, and various chemicals. Resistance decreases, however, at elevated temperatures. They have good moisture barrier and electrical insulation properties. They exhibit a broad range of flexibility: tensile moduli vary from 41,500 psi (286 mPa) for homopolymers to 7500 psi (52 mPa) for the high-ethylene polymers. The resins are particularly resistant to creep, environmental stress cracking, chemicals, and abrasion. PB resins are offered in a special pipe grade, film grades, and five general-purpose grades.

PB pipe can be fabricated by conventional single-screw extrusion technology using vacuum or pressure sizing for dimensional control. The pipes can be joined by thermal fusion or mechanical fittings. Applications include cold and hot water plumbing. Other uses include well, heat pump, and fire-sprinkler piping as well as specialty hoses. Large-diameter PB pipe finds uses in the transport of abrasive or corrosive materials at high temperature, as found in the mining, chemical, and power generation industries.

PB film is usually made by the blown film process, but also can be cast on chill rolls. Film applications include food and meat packaging, compression wraps, and hot-fill containers. The material can be formulated to provide a wide range of seal strengths for peelable or easy-opening packaging.

The ability of PB to accept high filler loading (up to 80%) has resulted in its use as a color, mineral filler, and flame-retardant concentrate carrier. Polybutylene is compatible with polypropylene in all proportions and as a modifier it provides enhancement of processibility, impact, and weld line strength in injection molding and extrusion. It also provides improved impact strength and heat stability in films and improved hand and bondability in fibers of polypropylene. A comparatively recent use of PBs is for hot-melt adhesives and sealants where high strength, high-shear adhesion failure temperature, and a long open time are needed. They are particularly suited for use with aliphatic tackifying resins.

POLYBUTYLENE TEREPHTHALATE POLYSTERS. A semicrystalline thermoplastic polyester. Because of its rapid crystallization, injection molding is the preferred method of processing. The material has been used for many years in the connector industry because of its good chemical resistance, high-temperature capabilities, good electrical properties, and long flow lengths in thin sections. This material (PBT) typically is formed in a transesterification reaction between 1,4-butanediol and dimethylterephthalate. Unmodified PBT is translucent in thin sections and opaque white in thicker sections.

The glass transition temperature of PPBT is about 52°C (125°F). Melting point is about 230°C (440°F). Unreinforced PBT is obtainable in several molecular weights. Compounded resins are available with numerous types and levels of fillers and reinforcements. Glass fiber reinforcement has a wide spectrum of physical properties. These materials can be made flame-retardant through the use of additives.

Exceptional electrical properties and temperature resistance qualify the material for numerous electrical parts—connectors, coil bobbins, light sockets, terminal blocks, fuse holders, and motor parts. PBT provides weight reduction of final parts. PBT has replaced a number of thermoset materials and is particularly popular for appliance housings and fibers for paint brushes.

POLYCARBONATES. Polycarbonates are an unusual and extremely useful class of polymers. The vast majority of polycarbonates are based on bisphenol A (BPA) and sold under various trade names. BPA polycarbonates, having glass-transition temperatures, in the range of 145–155°C, are widely regarded for optical clarity and exceptional impact resistance and ductility at room temperature and below. Other properties, such as modulus, dielectric strength, or tensile strength are comparable to other amorphous thermoplastics at similar temperatures below their respective glass-transition temperatures. Whereas below their T_gs most amorphous polymers are stiff and brittle, polycarbonates retain their ductility.

Important products are based on polycarbonate in blends with other materials, copolymers, branched resins, flame-retardant compositions, and foams.

Properties and Characterization

Solubility and Solvent Resistance. The majority of polycarbonates are prepared in methylene chloride solution. Chloroform, *cis*-1,2-dichloroethylene, *sym*-tetrachloroethane, and methylene chloride are the preferred solvents for polycarbonates. Hydrocarbons and aliphatic alcohols, esters, or ketones do not dissolve polycarbonates. Acetone promotes rapid crystallization of the normally amorphous polymer, and causes catastrophic failure of stressed polycarbonate parts.

In general, polycarbonate resins have fair chemical resistance to aqueous solutions of acids or bases, as well as to fats and oils. Chemical attack by amines or ammonium hydroxide occurs, however, and aliphatic and aromatic hydrocarbons promote crazing of stressed molded samples. BPA polycarbonate has excellent resistance to hydrolysis.

Certain blends and copolymers of polycarbonate demonstrate dramatically improved solvent resistance. The blend of polycarbonate and poly(butylene terephthalate) combines the toughness of polycarbonate with the solvent resistance of the semicrystalline polyester.

Copolycarbonates of BPA and hydroquinone (HQ) can be prepared via the intermediacy of cyclic oligomeric cocyclics. Although hydroquinone linear oligomers having degrees of polymerization greater than two are insoluble in CH_2Cl_2, the cyclic analogues remain soluble when randomly cyclized with BPA.

Molecular Weight and Viscosity. BPA polycarbonates are commercially available in a wide range of molecular weights. As the molecular weight increases, melt and solution viscosities increase proportionally. Molecular weights may be determined or inferred by several means, including gel-permeation chromatography, light-scattering chromatography, measurement of intrinsic or inherent viscosity, and measurement of melt viscosity and flow. Correlation of intrinsic viscosity (IV), $[\eta]$, with weight-average mol wt (M_w) has been carried out on carefully characterized polycarbonate samples. The following relationship exists when $[\eta]$ is in mL/g. $[\eta] = 41.2 \times 10^{-3} \cdot M_w^{0.69}$.

The mechanical properties of polycarbonate, e.g., tensile strength, impact resistance, flexural strength, elongation, etc., improve dramatically with increasing polymer intrinsic viscosity up to a value of about 0.45 dL/g. After that point, slight increases in mechanical properties are seen with increasing molecular weight, but melt viscosity continues to climb. At IV values greater than 0.6 dL/g, the melt viscosity becomes so high that processing is very difficult.

Spectroscopy and Analysis. Polycarbonates have a strong C=O stretching-band at 1770 cm^{-1}, and strong C−O stretching bands at 1220 and 1235 cm^{-1}, distinguishing them from polyesters.

Differential scanning calorimetry reveals a T_g at around 154°C, shifting slightly with molecular weight or level of branching. End group and impurity analysis is best revealed by hydrolysis of the polycarbonate using KOH-methanol in tetrahydrofuran under nitrogen, followed by reversed-phase hplc analysis or by spectroscopic techniques. Trace levels of impurities, are determined by standard analytical techniques.

Structure and Crystallinity. The mechanical–optical properties of polycarbonates are those common to amorphous polymers. The polymer may be crystallized to some degree by prolonged heating at elevated temperature (8 d at 180°C), or by immersion in acetone. Powdered amorphous powder appears to dissolve partially in acetone, initially becoming sticky, then hardening and becoming much less soluble as it crystallizes. Enhanced crystallization of polycarbonate can also be caused by the presence of sodium phenoxide end groups.

Film or fibers derived from low molecular weight polymer tend to embrittle on immersion in acetone; those based on higher molecular weight polymer (>0.60 dL/g) become opaque, dilated, and elastomeric.

Glass-Transition Temperature and Melt-Behavior. The T_g of BPA polycarbonate is around 150°C, which is unusually high compared to other

[1] Commercially available as *Duraflex*™. (*Shell Chemical Co.*)

thermoplastics. The high glass-transition temperature can be attributed to the bulky structure of the polymer, which restricts conformational changes, and to the fact that the monomer has a higher molecular weight than the monomer of most polymers. The high T_g is important for the utility of polycarbonate in many applications, because, as the point which marks the onset of molecular mobility, it determines many of the polymer's properties such as dimensional stability, resistance to creep, and ultimate use temperature. Polycarbonates of different structures may have significantly higher or lower glass-transition temperatures.

BPA polycarbonate becomes plastic at temperatures around 220°C. The viscosity decreases as the temperature increases, exhibiting Newtonian behavior, with the melt viscosity essentially independent of the shear rate. At the normal injection molding temperature of 270–315°C, the melt viscosity drops from 1,100 to 360 Pa · s (11,000 to 3,600 poise). Because the viscosity of polycarbonate can only be reduced by increasing the temperature, the ultimate limit on molecular weight is controlled by the processing conditions and the thermal stability of the polymer.

Thermal, Flame-Retardant, and Hydrolytic Behavior. BPA polycarbonate exhibits excellent thermal stability, especially in the absence of oxygen and water. At temperatures above 400°C, rapid decomposition and cracking occur. BPA has an oxygen index of 26; this indicates that under test conditions, an atmosphere of 26% oxygen is required for combustion. Owing to thermal–oxidative stability, polycarbonate has some inherent flame resistant properties and can be classified as V-2 according to UL94 of the Underwriters Laboratory. Several polycarbonate grades have additives to increase the flame-retardant properties, and to decrease smoke.

Because of the low solubility of water in the resin, BPA polycarbonates are inherently resistant to aqueous acid and base, although strong nucleophilic bases can cause hydrolysis.

Optical Properties. Polycarbonate is a transparent colorless polymer, making it attractive for glass replacement. Visible light transmission is about 90%, and haze is minimal (1–2%). Absorption in the ultraviolet region is essentially complete. Polycarbonate's high (1.584) refractive index and light weight relative to glass make it attractive for eyewear.

Special polycarbonate grades have been developed for the optical information storage market e.g., compact disks.

Mechanical Properties. The room temperature modulus and tensile strength are similar to those of other amorphous thermoplastics, but the impact strength and ductility are unusually high. Whereas most amorphous polymers are glass-like and brittle below their glass-transition temperatures, polycarbonate remains ductile to about −10°C. The stress–strain curve for polycarbonate typical of ductile materials, places it in an ideal position for use as a metal replacement. Weight savings as a metal replacement are substantial, because polycarbonate is only 44% as dense as aluminum and one-sixth as dense as steel.

Impact strength can be measured by a variety of methods, including notched Izod, tensile impact, and falling dart impact. Polycarbonates are among the highest rated engineering polymers for impact resistance, and are the toughest transparent materials known.

Glass-reinforced polycarbonates are sold as high modulus materials having properties approaching those of metals, while retaining the basic plastic attributes of low cost processing, dielectric character, resistance to corrosion, and inherent color.

Preparation

Interfacial Polymerization. Most BPA polycarbonate is produced by an interfacial polymerization process utilizing phosgene. The interfacial process for polycarbonate preparation involves stirring a slurry or solution of BPA and 1–3% of a chain stopper, such as phenol, *p-t*-butylphenol, or *p*-cumylphenol, in a mixture of methylene chloride and water, while adding phosgene in the presence of a tertiary amine catalyst.

Transesterification. The transesterification process is an environmentally friendly process that utilizes no solvent during polymerization, producing neat polymer directly.

Processing. Polycarbonates may be fabricated by all conventional thermoplastic processing operations, of which injection molding is the most common.

Injection blow molding of polycarbonates produces an assortment of containers from 20-L water bottles and 0.25-L milk bottles to outdoor lighting protective globes.

Conventional thermoforming of sheet and film is applicable to the production of skylights, radomes, signs, curved windshields, prototype production of body parts for automobiles, skimobiles, boats, etc. Because BPA polycarbonate is malleable, it can be cold-formed like metal, and may be cold-rolled, stamped, or forged.

Health and Safety Factors

Polycarbonate is considered a slight or nonexistent fire hazard. Odor and volatiles are negligible. Processing fumes, which include water, carbon dioxide, diphenyl carbonate, methylene chloride, and phenol, are not formed in levels considered to be hazardous. Polycarbonate has very low acute oral and dermal toxicity, is not a primary skin irritant, and does not cause systemic or local sensitization. Polycarbonate does not degrade during storage, and no heating or cooling requirements are necessary.

Uses

Extreme toughness, transparency, low color, resistance to burning, and maintenance of engineering properties over a wide thermal range are the outstanding properties of polycarbonate that make it useful for a variety of applications. Glazing and sheet are the largest markets for polycarbonate resins. Other uses for polycarbonates include automotive components; packaging; electrical, electronic, and technical applications; and medical and health-care related applications.

Polycarbonate is popular because of its clarity, impact strength, and low level of extractable impurities.

Other Polycarbonates, Blends, and Copolymers

Blends of polycarbonate with ABS and with poly(butylene terephthalate) (PBT) have shown significant growth since the mid-1980s.

Copolymers. The copolymer of tetrabromoBPA and BPA was one of the first commercially successful copolymers. Low levels of brominated comonomer lead to increased flame resistance.

Polyester carbonates can be prepared by the copolymerization of BPA with diacyl chlorides, leading to high heat materials with $T_g \sim 190°C$.

Some of these block copolymers have improved low temperature impact strength and higher stress–crack resistance than neat BPA polycarbonate.

Blends. The concept of blending two or more commercially available materials to create a new material having properties different from either starting material has generated a great deal of interest. Polycarbonate blends are used to tailor performance and price to specific markets.

Fundamental studies of blends of polycarbonate with acrylonitrile–butadiene–styrene (ABS) indicate that the presence of ABS greatly decreases the melt viscosity in the blend, enhancing processibility. A synergistic improvement of the notched impact strength at low temperature is also seen for polycarbonate–ABS blends.

Polycarbonate–polyester blends are used on exterior parts for the automotive industry. Such blends combine the toughness and impact strength of polycarbonate with the crystallinity and inherent solvent resistance of PBT, PET, and other polyesters.

The most significant blends are with polyurethanes, polyetherimides, acrylate–styrene–acrylonitrile (ASA), acrylonitrile–ethylene–styrene (AES), and styrene–maleic anhydride (SMA).

POLYCYCLO-HEXYLENE-DIMETHYLENE TEREPHTHALATE.

PCT is 1,4-cyclohexylene-dimethylene terephthalate and is a high-temperature, semicrystalline thermoplastic polyester. PCT possesses excellent thermal properties. Injection molding is the predominant method of processing glass fiber-reinforced grades of PCT. It is widely used for

products where excellent thermal (heat-resistant) properties are needed, as exemplified by surface-mountable electronic components, automotive parts, and dual-ovenable cookware. The material also is used for flexible electronic circuitry. PCT-based polycarbonate is a polymeter that provides melt blends that exhibit excellent clarity, toughness, chemical resistance, flow, and gloss.

PCT is differentiated from other thermoplastic polyesters by its higher heat deflection temperature. Continuous use temperatures of up to 150°C (300°F) are possible.

Principal uses for this material are found in the electrical/electronics industries; automotive parts, such as alternator armatures and pressure sensors; optical uses, such as safety goggles; and garden vehicles, such as mower decks and shrouds, tractor hoods, grills, and fenders.

POLYDIMETHYLSILOXANE. A silicone polymer developed for use as a dielectric coolant and in solar energy installations. It also may have a number of other uses. It is stated to be highly resistant to oxidation and biodegradation by microorganisms. It is degradable when exposed to a soil environment by chemical reaction with clays and water, by which it is decomposed to silicic acid, carbon dioxide, and water.

POLYELECTROLYTES. These are macromolecules with incorporated ionic constituents. Polyelectrolytes may be cationic or anionic, depending on whether the fixed ionic constituents are positive or negative. Examples of cationic polyelectrolytes are polyvinyl-ammonium chloride and poly-4-vinyl-N-methyl-pyridinium bromide. Examples of anionic polyelectrolytes are potassium polyacrylate, polyvinylsulfonic acid, and sodium polyphosphate. If a polyelectrolyte contains both fixed positive and negative ionic groups, it is called a polyampholyte. Polyelectrolytes may be synthesized by polymerization of a monomer containing the ionic substituent, as for instance the polymerization of acrylic acid to polyacrylic acid, or by attaching the ionic constituent by chemical means to an already existing macromolecule, as for instance in the quaternization of poly-4-vinyl-pyridine with methyl bromide, or in the preparation of sodium carboxymethylcellulose from natural cellulose. Many macromolecules occurring in nature are polyelectrolytes. Examples are gum arabic, which carries carboxylate groups; carrageenin, which contains sulfate groups; proteins, which carry both negative carboxylate and positive ammonium groups; and nucleic acids, which contain negative phosphate groups and basic purine and pyrimidine groups, which acquire positive charges at low pH. Inorganic long-chain polyphosphates have also been isolated from biological materials.

A solution of a polyelectrolyte in water or other suitable solvent conducts an electric current, indicating that the polyelectrolyte is ionized. Transference and electrophoresis measurements show that both the macroion and the counterions (gegenions) contribute to the conductance. Because the counterions are osmotically active, polyelectrolytes show much higher osmotic pressures and diffusion rates than do nonionogenic macromolecules. The osmotic pressure of a polyelectrolyte solution is greatly reduced by the addition of a simple electrolyte which distributes itself among the two sides of the membrane according to the thermodynamic theory of Donnan equilibrium. Polyelectrolytes are called weak if they carry weakly ionized groups such as −COOH, and strong if they carry strongly ionized groups such as −COONa. On titrating polyacrylic acid with sodium hydroxide, the pH increases much more slowly than it does in a corresponding titration of a monocarboxylic acid, thus indicating a pronounced buffering capacity. Even in the case of strong polyelectrolytes, the full osmotic activity of the counterions is not realized; as counterions leave the macroion, the electrostatic potential on the latter builds up making it increasing difficult for additional counterions to escape. This binding effect becomes especially strong with multivalent counterions, whose effective concentration may be rendered several orders of magnitude smaller by a polyelectrolyte than their stoichiometric concentration.

The electric charge on the macroion has several important secondary effects. If the macroion is a flexible chain, intramolecular repulsion between charged segments will stretch out the macroion from a coiled to a more rod-like structure, resulting in much larger solution viscosities than are usually obtained with uncharged polymers under corresponding conditions. Intermolecular repulsion causes the macroions to arrange themselves so that they are as far from each other as is possible. With this ordering, the light scattering which is characteristic of solutions of ordinary macromolecules is greatly diminished, often to the vanishing point, as a result of destructive interference. These secondary effects of charge may be reduced by the addition of simple electrolytes which screen the charged elements from each other, and in some cases also lower the charge by specific counterion binding. At high enough concentrations of added salt, the light scattering of the polyelectrolyte may become sufficiently pronounced to allow its use for the determination of the molecular weight.

An interesting class of polyelectrolytes, denoted by polysoaps, is obtained by attaching soap-like molecules to the polymer chain. Such a polysoap is for instance produced by the quaternization of polyvinyl-pyridine with *n*-dodecyl bromide. The polysoap molecules differ from ordinary polyelectrolytes in that they may reach protein-like compactness in solution. They behave like prefabricated soap micelles and solubilize hydrocarbons and other compounds insoluble in water.

While the applications of polyelectrolytes for practical purposes depend on their general ionic properties, nevertheless large differences appear among individual members of the class in their applicability to a specific use. When polyelectrolytes are absorbed at interfaces, they affect the zeta-potential and a suspending action may result. Adsorption at growing crystal surfaces is also believed to be the reason for the high effectiveness of small amounts of certain polyelectrolytes in preventing or retarding the precipitation of calcium carbonate. The dispersion of clays by polyelectrolytes is applied in oil-well drilling. The ability of long-chain polyelectrolytes to bind together small particles has found uses in soil conditioning and in the flocculation of phosphate slimes. Because of their effect on the solution viscosity, certain polyelectrolytes are used as thickening agents. Because of their ability to bind di- and trivalent cations, some anionic polyelectrolytes are used in water softening and as enzyme inhibitors. When polyelectrolytes are adsorbed or otherwise incorporated into membranes, they make the latter permselective, hindering small ions of the same charge as the macroion from passing through the membrane while allowing free passage to small ions of opposite charge. The well-known ion-exchange resins are polyelectrolytes which have been cross-linked to prevent them from dissolving.

The most important and widespread use of polyelectrolytes is to aid in the removal of small suspended solids from waste water in the primary, secondary and dewatering stages of treatment.

ULRICH P. STRAUSS
Rutgers University
New Brunswick, New Jersey

POLYENE. Any unsaturated aliphatic or alicyclic compound containing more than four carbon atoms in the chain and having at least two double bonds. Examples are pentadiene, cyclooctatriene.

POLYESTER FIBERS. The principal characteristics of these fibers are described in the entry on **Fibers**. Polyester fibers are defined as synthetic fibers containing at least 80% of a long-chain polymer compound of an ester of a dihydric alcohol and terephthalic acid. The first polyester fiber to be commercialized was prepared from the ester in which the dihydric alcohol was ethylene glycol; this fiber is the material used in the largest quantity by the textile industry. For some other commercial uses, the ester 1,4-dimethyldicyclohexyl terephthalate is also used.

The original process, still in use for making the polymer, employs dimethyl terephthalate (DMT) and ethylene glycol as raw materials. A later process, using direct esterification of terephthalic acid (TPA) with ethylene glycol, also gained acceptance after the increased availability of highly purified TPA. With either process, the first step is the preparation of the intermediate diester, *bis*-hydroxyethyl terephthalate (bisHET), which then is further condensed to the polymer.

The basic process for making polyester fibers from the polymer is called *melt spinning*, i.e., heating the polymer above its melting point, forcing it through small holes in a metal plate, and then quenching the molten stream as it issues from the holes by means of a current of cool air. The spun yarn is weak and highly extensible because the polymer molecules are randomly oriented. To impart strength and dimensional stability the yarns must be drawn at temperatures above the glass-transition temperature of the material by pulling the yarn between two *godet wheels*, the second of which is rotating at a speed three to six times as fast as the first. The higher the draw ratio, i.e., the ratio of the two speeds, the more oriented the molecules become and the stronger the yarn.

The two main classes of polyester fibers are continuous-filament yarns and short-cut fibers, called staple. A wide range of deniers is available in continuous-filament yarns, varying from very fine deniers of about 20 up

to 2000 for heavy industrial yarns. (Denier is the weight in grams of 9000 meters of yarn). The number of filaments in these yarns ranges from about 7 for the 20-denier yarns up to 384 for the heavy material. Staple fiber is produced in sizes ranging from 0.5 to 1.5 denier per filament. The finer deniers are used in making blends with cotton and rayon for apparel, while the coarser-denier yarns generally are used for carpets. Staple lengths vary from $1\frac{1}{4}$ to 6 inches (3.1 to 15.2 centimeters).

Fiber with no added delustrant is designated as *clear. Bright* fiber has about 0.1% titanium dioxide (TiO_2); *semidull* fiber has about 0.25% TiO_2; and *dull* fiber has up to 2% TiO_2. Other variations in physical properties and dyeing characteristics include optically brightened, high-modulus, high-shrink, high-tenacity, low-pilling, deep-dyeable, and cationic-dyeable fibers.

POLYESTER FILM. Continuously extruded polyester sheet of various thickness, especially useful in electrical equipment because of its high resistivity. Its tensile strength of 25,000 psi is much greater than that of other plastic films. Sensitized polyester film is used in magnetic tapes, in the photocopying technique known as repography.

POLYESTER RESINS. Any of a group of synthetic resins, which have polycondensation products of dicarboxylic acids with dihydroxy alcohols. They are thus a special type of alkyd resin but, unlike other types, are not usually modified with fatty acids or drying oils. The outstanding characteristics of these resins are their ability, when catalyzed, to cure or harden at room temperature under little or no pressure. Most polyesters now produced contain ethylenic unsaturation, generally introduced by unsaturated acids. The unsaturated polyesters are usually cross-linked through their double bonds with a compatible monomer, also containing ethylenic unsaturation, and thus become thermosetting. Flame resistance is imparted by using either acid or glycol ingredients having a high content of halogens, e.g., HET acid.

The principal unsaturated acids used are maleic and fumaric. Saturated acids, usually phthalic and adipic, may also be included. The function of these acids is to reduce the amount of unsaturation in the final resin, making it tougher and more flexible. The acid anhydrides are often used if available and applicable. The dihydroxy alcohols most generally used are ethylene, propylene, diethylene, and dipropylene glycols. Styrene and diallyl phthalate are the most common cross-linking agents. Polyesters are resistant to corrosion, chemicals, solvents, etc.

Common uses for polyester resins are: reinforced plastics; automotive parts; boat hulls; foams; encapsulation of electrical equipment; protective coatings; ducts; flues; and other structural applications; low pressure laminates; magnetic tapes; piping; bottles; non-woven disposable filters and low-temperature mortars.

POLYETHER-ETHERKETONE. Abbreviated PEEK, polyether-ether ketone is a high-temperature resistant thermoplastic suitable for wire coating, injection molding, film, and advanced composite fabrication. The wholly aromatic structure of PEEK contributes to its high-temperature performance. Its crystalline character gives it important advantages, including resistance to organic solvents and dynamic fatigue, and retention of ductility on short-term heat aging. The material is available as dry, free-flowing granules and exhibits very low water absorption. Continuous service at temperatures up to 470°F (243°C) and intermittent use up to 600°F (316°C) are possible. PEEK has good resistance to aqueous reagents, with long-term performance in super-heated water at 500°F (260°C). It resists attacks over a wide pH range, from 60% sulfuric acid to 40% sodium hydroxide at elevated temperatures. Attack can occur with some concentrated acids. No organic solvent attack has been observed on molded parts, although a limited range of solvents will stress-craze highly stressed PEEK-coated wire. Radiation resistance is excellent. Typical applications include wire and cable, automotive engine parts, aerospace components, valve plates, valve linings, oil well data logging tools, bearings, woven monofilament, and film.

POLYETHERIMIDE. This is an amorphous, high-performance thermoplastic. The material is characterized by high strength, rigidity, heat resistance, dimensional stability, and electrical properties, combined with broad chemical resistance and processibility. Unmodified polyetherimide is amber-transparent in color and exhibits inherent flame resistance and low smoke evolution without the use of additives. The material is commercially available in several grades—unreinforced and in 10, 20, 30, and 40% glass fiber reinforced formulations for general-purpose molding and extrusion. Also available are easy-flow and release grades, wear-resistant grades, carbon fiber-reinforced grades for high-strength and static dissipation, along with a family of high-heat grades. A relatively new family of polyetherimide blends is available for use in vapor-phase soldering environments and for high-impact applications.

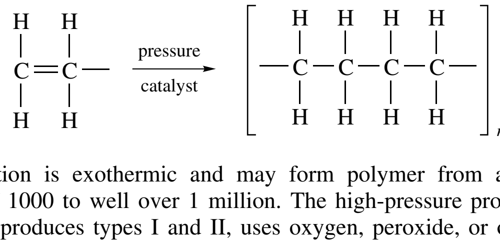
Polyetherimide has a chemical structure based on repeating aromatic imide and ether units. High performance strength characteristics at high temperatures are provided by rigid imide units, while the ether linkages confer the chain flexibility required for good melt processibility and flow. Polyetherimide is resistant to a wide range of chemicals, including most hydrocarbons, alcohols, and fully halogenated solvents. It is resistant to mineral acids and tolerates short-term exposure to mild bases. These resins are rated for 170–180°C (338–356°F) in continuous-use applications. Intermittent use at 200°C (392°F) is possible.

Resins are used in electronic/electrical applications (connectors, circuit boards that are vapor and wave solderable, microwave transparent radomes, integrated circuit chip carriers, miniature switches, explosion proof enclosures, lamp reflectors, and high-precision fiber optic components). Polyetherimide is used for medical components that require all forms of sterilization. Other uses are found in the transportation field, dual-ovenable cookware, as well as bearings, fasteners, and advanced composites.

POLYETHYLENE. A thermoplastic molding and extrusion material available in a wide range of flow rates (commonly referred to as melt index) and densities. Polyethylene offers useful properties, such as toughness at temperatures ranging from −76 to +93°C, stiffness, ranging from flexible to rigid, and excellent chemical resistance. The plastic can be fabricated by all thermoplastic processes.

Polyethylenes are classified primarily on the basis of two characteristics, namely, density and melt index. The former is the criterion used to distinguished the type; and the latter for the designation as to category (ASTM-D-1248). ASTM type I polyethylene (sp. gr. 0.910–0.925) is commonly referred to as low-density, conventional, or high-pressure polyethylene. ASTM type II polyethylene (sp. gr. 0.926–0.940) is commonly referred to as medium-density or intermediate-density polyethylene. ASTM type III polyethylene (sp. gr. 0.941–0.965) is commonly called high-density, linear, or low-pressure polyethylene. High-density type III polyethylene has been divided into two ranges of density: 0.941–0.959 (considered type III); and 0.960 and higher, commonly considered type IV. Within each density classification, products with different melt indexes are categorized numerically as follows: category 1 has a melt index (MI) greater than 25; category 2 has an MI greater than 10 to 25; category 3, MI $>$ 1.0 to 10; category 4, MI $>$ 0.4 to 1.0; category 5 has a 0.4 maximum.

Chemical Composition. Polyethylene is formed from the polymerization of ethylene under specific conditions of temperature and pressure and in the presence of a catalyst, according to:



The reaction is exothermic and may form polymer from a molecular weight of 1000 to well over 1 million. The high-pressure process, which normally produces types I and II, uses oxygen, peroxide, or other strong oxidizers as catalyst. Pressure of reaction ranges from 15,000 to 50,000 psi (∼1,020–3,400 atmospheres). The polymer formed in this process is highly branched, with side branches occurring every 15–40 carbon atoms on the chain backbone. Crystallinity of this polyethylene is approximately 40–60%. Amorphous content of the polymer increases as the density is reduced.

The low-pressure processes, such as slurry, solution, or gas phase, can produce types I, II, III, and IV polyethylenes. Catalysts used in

these process vary widely, but the most frequently used are metal alkyls in combination with metal halides or activated metal oxides. Reaction pressures normally fall within 50 to 500 psi (~3.4–34 atmospheres). Polymer produced by this process is more linear in nature, with branching occurring about every 1000 carbon atoms. Linear polyethylene of types I and II is approximately 50% crystalline and types III and IV are as high as 85% crystalline.

Ethylene has been polymerized with other monomers, e.g., propylene, butene-1, hexene, ethyl acrylate, vinyl acetate, and acrylic acid, to develop such specific properties as environmental stress crack resistance, low-temperature toughness, and improved flexibility and toughness. High-molecular-weight (HDPE) and chlorinated polyethylenes have been developed to extend the property range of polyethylenes from extremely rigid to elastomeric.

Applications

Polyethylene products include extruded films for food packaging (baked goods, frozen foods, produce); nonfood packaging (heavy-duty sacks, industrial liners, shrink and stretch pallet wrap); nonpackaging (agricultural, diaper liners, industrial sheeting, trash bags); extrusion coating of films, foils, paper, and paperboard; blow molding of bottles, drums, tanks, toys, and pails; injection molding of industrial containers, closures, housewares, toys; extrusion of electrical cable jacketing, pipe, sheet, and tubing; and rotational molding of tanks, drums, toys, and sporting goods.

Properties

Tensile strength, hardness, chemical resistance, surface appearance, and flexural modulus increase with an increase in density (from type I through type IV).

Polyethylene is translucent to opaque white in thick sections, opacity increasing with density. Relatively clear film can be extruded from polyethylene, especially if it is quenched rapidly. The plastic accepts pigmentation readily. Most coloring is performed using dry-blend techniques. Color dispersion devices are required to ensure thorough mixing of resin and pigment.

Mechanical properties of polyethylenes vary with density and melt index. Low-density polyethylenes are flexible and tough; high-density products are quite rigid and have creep resistance under load. Toughness is the primary mechanical property affected by melt index, with lower-melt-index polyethylenes having greater toughness. Under loads, polyethylene is subject to creep, stress relaxation, or a combination of both.

Excellent dielectric characteristics at all frequencies and high electrical resistivity have made polyethylene one of the most important insulating materials for wire and cable.

At no-load conditions, polyethylene has good heat resistance. However, small loads can cause distortion at relatively low temperatures. Dimensional stability of polyethylene is fair to good. Dimensional changes caused by crystallization during cooling usually occur in a non-uniform pattern, resulting in warpage. Narrower molecular weight distribution resins within given families result in less warpage. Types I and II polyethylenes produced by the low-pressure process offer significant improvement in heat distortion temperatures. This property is directly related to melting point and is much higher for low-pressure, low-density resins than for conventional LDPE resins. This allows molded parts to be exposed to significantly higher service temperatures, e.g., dishwasher parts, without undergoing distortion or warpage. Most shrinkage occurs within 48 hours after fabrication and for type I and type II materials is 0.01–0.03 inch/inch (centimeter/centimeter).

Rupture of molecular bonds by external and internal stress in the presence of certain compounds is referred to as environmental stress cracking. Small molecular fractures in the amorphous regions propagate until visible cracks appear. In time, the part may fail. Chemical agents which accelerate stress cracking in polyethylene include detergents; aliphatic and aromatic hydrocarbons; soaps; animal, vegetable, and mineral oils; ester-type plasticizers; organic acids; and aldehydes, ketones, and alcohols. There is no adequate test for stress cracking.

Deterioration occurs in uncolored polyethylene exposed to weather. Ultraviolet light causes photoactivated oxidation. Satisfactory weathering formulations contain 2–2.5% well-dispersed carbon black and stabilizers. The carbon black prevents ultraviolet light penetration.

Unmodified polyethylenes are flammable and are classified in the slow-burning category by the National Board of Fire Underwriters. Burning rate is approximately 1–1.5 inches (2.5–3.8 centimeters) per minute. The flammability of polyethylene may be retarded significantly by the addition of flame retardant compounds, such as antimony trioxide along with halogenated compounds.

At room temperature, polyethylene is insoluble in practically all organic solvents, although softening, swelling, and environmental stress cracking can occur. At high temperatures, some concentrated acids and oxidizing agents chemically attack polyethylene. Above 60°C, the material becomes increasingly soluble in aliphatic and chlorinated hydrocarbons. Chemical resistance increases slightly as density is increased.

Polyethylene is water-resistant and is a good water vapor barrier. Less than 0.1% water is absorbed in a 2-inch (5-centimeter), 1/8-inch (3-millimeter) thick disk of polyethylene in 24 hours. Transmission of other gases is high when compared with that of most other plastics. Polyethylene is not satisfactory for retention of vacuum.

Fabrication

Polyethylene is readily fabricated by all methods of thermoplastic processing. The principal methods used are film and sheet extrusion, extrusion coating, injection molding, blow molding, pipe extrusion, wire and cable extrusion coating, rotomolding, and hot melt and powder coatings.

Decorating

Polyethylene parts are decorated by silk screening, hot stamping, or dry offset printing. For satisfactory printing, the surface must be oxidized by hot air, flame, chlorination, sulfuric acid-dichromate solution, or electronic bombardment. Hot air or flame methods are used with molded parts; flame or electronic methods with films. Inks specially made for polyethylene give best results. Roll-leaf hot stamping does not require pretreatment of the surface.

Design

Because of high mold shrinkage, parts must be carefully designed to minimize warpage. Wall cross-sectional thicknesses should be uniform throughout the part. Large flat areas should be avoided. Corners should be curved rather than square. Stiffening ribs should be less than 80% of the thickness of the wall to which they are attached. Thermoformed parts require liberal radii and draft angles. Slight undercuts can be incorporated when a female mold is used. Dimensional variations in a part made of polyethylene are difficult to predict. In general, greater tolerances should be allowed than with more rigid plastics.

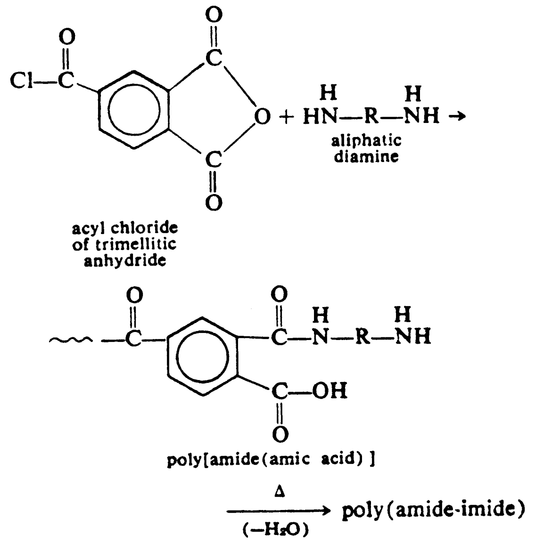
POLYHALITE. Polyhalite, K_2Ca, $Mg(SO_4)_4 \cdot 2H_2O$ is a late evaporate mineral associated with halite, sylvite and carnallite from the famous oceanic salt deposits at Stassfurt, Germany, and near Carlsbad, New Mexico. It is of triclinic crystallization, with color grading from gray to brick-red; hardness, 3–3.5; specific gravity 2.78; translucent with vitreous luster; very bitter taste. It is a source of potassium.

POLYIMIDES. These are heat-resistant polymers which have an imide group (−CONHCO−) in the polymer chain. Polyimides, poly(amide-imides), and poly(esterimides) are commercially available.

Poly(amide-imides) are prepared by the thermal degradation of a soluble poly[amide-(amic acid)]. The latter may be produced by the condensation of an aliphatic diamine with less than a molar equivalent of pyromellitic dianhydride or with a molar equivalent of a derivative of trimellitic

anhydride, such as the acyl chloride in dimethylacetamide as shown in the following equation:



The poly(amide-imides) are soluble in dimethylacetamide but are insoluble in less polar solvents such as toluene and perchloroethylene. They are used for wire enamels, high-temperature adhesives, laminates and molded articles.

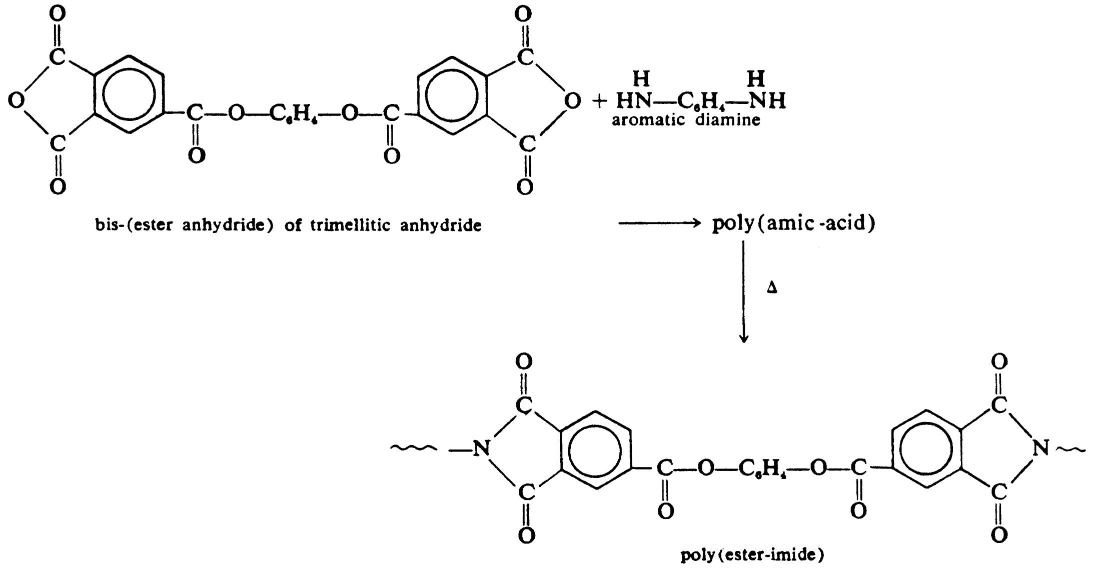
The poly(ester-imides) are produced by the thermal decomposition of the soluble poly(amic acids) which are obtained by the condensation of an aromatic diamine and the bis-(ester anhydride) of trimellitic anhydride as shown in the following equation:

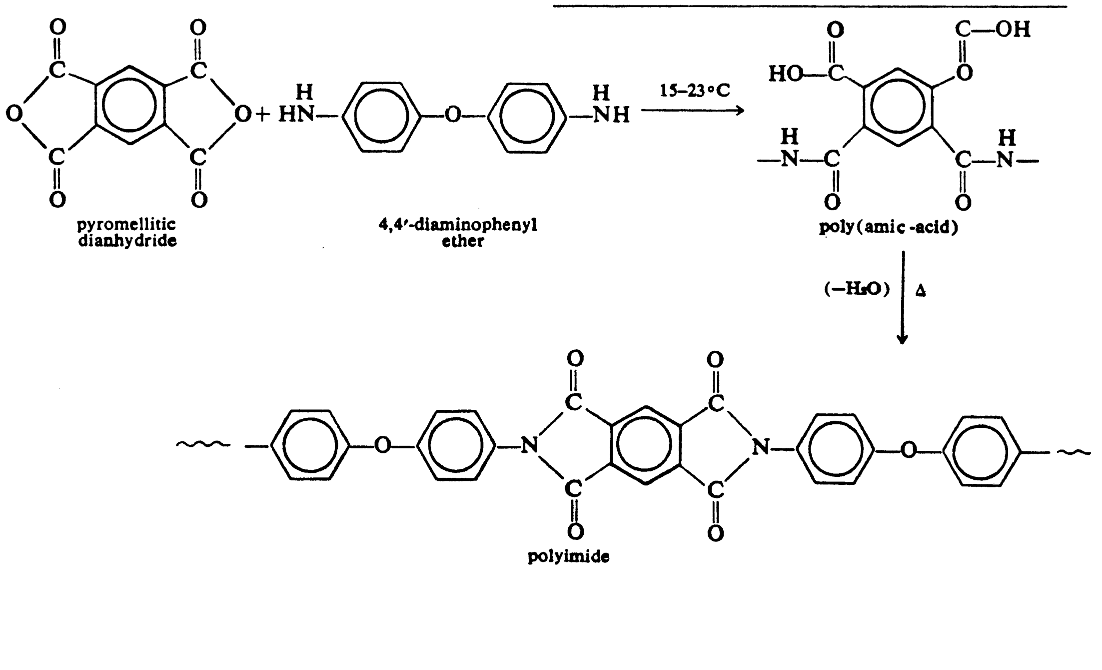
These poly(ester-imides) have good electrical properties. Their tensile-modulus is about 400,000 psi (2759 MPa) at 25°C and approximately 50 percent of this modulus is retained at 200°C. Poly(ester-imide) films fail when heated at 240°C for 1000 hrs.

Polyimides are produced by the thermal dehydration of the soluble poly(amic -acid) which is obtained by the condensation of a diamine, such as 4, 4′-diaminophenyl ether and a dianhydride, such as pyromellitic dianhydride called PMDA as shown in the following equation:

It is customary to apply these polymers as the poly(amic -acids) and to dehydrate the film, coating, fiber or molded forms by heating to produce the polyimides. Polyimides are insoluble in most solvents but are attacked by alkalies, ammonia and amines. These heat resistant polymers are used without fillers and with a graphite filler.

Polyimide films have excellent electrical properties and a tensile modulus of over 400,000 psi at 25°C. Over 60 percent of this modulis is retained at 200°C. Polyimide wire enamels are stable for up to 100 thousand hours at 200°C. Polyimide fibers have a tenacity of 7 g/denier at 25°C and over 1000 hrs at 283°C is required to reduce the value to 1 g/denier.





The coefficient of linear expansion of polyimides is 4.0–5.0 × 10^{-5} in./in./°C. The heat deflection is 680°F (360°C). Polyimides have been used as binders for abrasive wheels, high-temperature laminates, wire coatings, insulating varnishes and in aerospace applications.

POLYMERIZATION. Chemical reaction, particularly in organic chemistry, which provides very large molecules by a process of repetitive addition. These are of great practical importance in the field of rubbers, plastics, coatings, adhesives and synthetic fibers. The initial materials which give rise to such reactions are called *monomers*; they have molecular weights between 50 and 250 and have certain reactive or functional groups which enable them to undergo *polymerization*. The large molecules, which are formed by a polymerization reaction are called *high polymers, macromolecules*, or simply *polymers*; they usually consist of several hundred and in many cases even of several thousand monomeric units and, consequently, have molecular weights of many hundred thousands and even of several millions. The number of monomers contained in a polymer molecule determines its *degree of polymerization* (D.P.).

Polymerization processes never lead to macromolecules of uniform character but always to a more or less broad mixture of species with different molecular weights, which can be described by a *molecular weight distribution function*. The individual macromolecules of such a system belong to a *polymer-homologous series*; the molecular weight and the degree of polymerization of a given material have, therefore, always the character of *average* values.

There exist many ways to assemble small molecules to give large ones and, hence, there exist several types of polymerization reactions. The most important are the following:

(1) *Vinyl-type addition polymerization*. Many olefins and diolefins polymerize under the influence of heat and light or in the presence of catalysts, such as free radicals, carbonium ions or carbanions. Free radicals are particularly efficient in starting polymerization of such important monomers as styrene, vinylchloride, vinylacetate, methylacrylate or acrylonitrile. The first step of this process—the so-called *initiation* step—consists in the thermal or photochemical *dissociation* of the catalyst, and results in the formation of two *free radicals*:

$$\underset{\text{Catalyst molecule}}{R{-}R} \xrightarrow[\text{or light}]{\text{heat}} \underset{\text{two free radical type]fragments}}{2R} \quad \cdot \qquad (1)$$

The most commonly used catalysts are peroxides, hydroperoxides and aliphatic azocompounds, which need activation energies between 25 and 30 kcal for decomposition.

The free radicals R· attack the monomer and react with its double bond by adding to it on one side and reproducing a new free electron on the other side:

$$R\cdot + CH_2{=}CHX \longrightarrow R{-}CH_2{-}CHX\cdot \qquad (2)$$

This step is called *propagation* reaction; it adds more and more monomer units to the growing chain and builds up the macromolecules while the free radical character of the chain end is maintained. Each single addition represents the reaction of a free radical with a monomer molecule—a process which requires an activation energy of 8–10 kcal.

Whenever two free radical chain ends collide with each other they can react in such a manner that the resulting products have lost their free radical character and are converted into normal stable molecules. One way is a process of *recombination*:

$$\begin{aligned} &R{-}({-}CH_2{-}CHX{-}){-}_xCH_2{-}CHX\cdot \\ &\quad + R{-}({-}CH_2{-}CHX{-}){-}_yCH_2{-}CHX\cdot \\ &\longrightarrow R{-}({-}CH_2{-}CHX){-}CH_2{-}CHX \\ &{-}CHX{-}CH_2{-}(CH_2{-}CHX{-}){-}_yR \end{aligned}$$

where *one* macromolecule of the degree of polymerization $(X + y + 2)$ is formed. The other is a process of *disproportionation*:

$$\begin{aligned} &R{-}({-}CH_2{-}CHX)_x{-}CH_2{-}CHX\cdot \\ &\quad + R{-}({-}CH_2CHX{-}){-}_yCH_2{-}CHX\cdot \\ &\longrightarrow R{-}({-}CH_2{-}CHX{-}){-}_x{-}CH_2{-}CHX\cdot \\ &\quad + R{-}({-}CH_2{-}CHX{-}){-}_yCH_2{=}CH_2X \end{aligned} \qquad (4)$$

where a hydrogen atom moves from one molecule to the other so that one of the two resulting molecules—the $(x + 1)$ mer—has a double bond at its end, whereas the other one—the $(y + 1)$ mer—has a saturated chain end. Reactions in the course of which free radicals are destroyed are called *termination* or *cessation* steps; they convert the transient reactive intermediates into stable polymer molecules.

Vinyl-type addition polymerization can also be carried out with *acidic catalysts* such as boron trifluoride or tin tetrachloride and with *basic catalysts* such as alkali metals or alkali alkyls. An example of the first case is the low-temperature polymerization of isobutene, which gives "Vistanex" and butyl rubber; an example of the second type is the polymerization of butadiene with sodium, which leads to buna rubber.

(2) Another important kind of addition polymerization is the formation of polyethers by the opening of epoxy ring compounds. Polyoxyethylene ("Carbowax") is produced by a sequence of additions of ethylene oxide to an alcohol or amine, as initiator:

$$\begin{aligned} &CH_3{—}CH_2OH + \underset{\diagdown\;O\;\diagup}{CH_2{—}CH_3} \rightarrow \\ &CH_3{—}CH_2{—}O{—}CH_2{—}CH_3{—}OH + \\ &\underset{\diagdown\;O\;\diagup}{CH_2{—}CH_2} \rightarrow \\ &CH_3{—}CH_2{—}O{—}CH_2{—}CH_3{—}O\text{-} \\ &{—}CH_2{—}CH_2OH,\ \text{and so on} \end{aligned}$$

No termination reaction occurs in this case; the reaction proceeds until all the monomer is used. This process is catalytically accelerated by the presence of alkali. A similar addition polymerization involving the opening of a ring compound is the conversion of caprolactam into polycaprolactam ("Perlon" or 6-nylon) under the influence of acidic or basic catalysts. All addition polymerizations are typical *chain reactions* with at least two or three different elementary steps cooperating in building up the resulting macromolecules.

(3) There exist other, different classes of reactions which form large molecules, namely processes in the course of which a *small fragment*, usually H_2O, is *split out* of two reacting monomers and where the monomers are chosen in such a manner that the removal of the fragment can be repeated many times. Multi step reactions of this type are called *polycondensations*; they involve the use of at least a pair of bifunctional monomers and proceed by a sequence of identical condensation steps. One important process of this type is the formation of polyesters from glycols and dicarboxylic acids. Thus the progressive removal of water from ethylene glycol and adipic acid leads to a soft, rubbery polyester ("Paracon")

$$\begin{aligned} &HOCH_2{-}CH_2OH \\ &\quad + HOOC{-}({-}CH_2{-}){-}_4COOH \\ &\longrightarrow HOCH_2CH_2{-}O{-}CO{-}({-}CH_2{-}){-}_4COOH \\ &\quad + HOCH_2{-}CH_2OH \longrightarrow HOCH_2{-}CH_2OCO \\ &= {-}({-}CH_2{-})_4{-}COOCH_2{-}CH_2OH, \quad \text{and so on.} \end{aligned}$$

As long as in processes of this type only *bifunctional* monomers are used, the resulting macromolecules are *linear* and, as a consequence, are of the soluble and fusible type. They can be used as fiber formers, rubbers or thermoplastic resins. If, however, some of the monomers are tri- or tetramethylolurea, the reaction leads to three-dimensional polymeric networks which are hard and brittle thermosetting resins, such as "Bakelite" or "Glyptal."

The preceeding classification of polymerization reactions concentrates essentially on the organic chemical character of the involved monomers

and on the mechanism of their interaction. There exists, however, another classification which is concerned about the manner in which polymerization reactions are carried out in practice and which is of interest and importance whenever industrial application is contemplated. We shall, therefore, briefly enumerate here the most important *polymerization techniques*.

(1) Polymerization in the *gas phase* is usually carried out under pressure (several thousand psi) and at elevated temperatures (around 200°C); the most important example is the polymerization of ethylene to form polythene.

(2) Polymerization in *solution*, essentially under normal pressure and at temperatures from −70°C to 70°C; important examples are the production of butyl rubber with boron trifluoride and the synthesis of the various "Vinylites" with benzoyl peroxide.

(3) Polymerization in *bulk* (or in block) under normal pressure in the temperature range from room temperature to about 150°C. The batch polymerization of methylmethacrylate to give "Lucite" or "Plexiglass" and the continuous polymerization of styrene to give the various types of polystyrene can be quoted as examples.

(4) Polymerization in *suspension* (bead or pearl polymerization) under normal pressure in the range from 60 to 80°C operates with a suspension of globules of an oil-soluble monomer in water and uses a monomer soluble catalyst. Substantial quantities of polystyrene and polyvinyl acetate are made by this method.

(5) Polymerization in *emulsion* under normal pressure and in the temperature range from −20°C to 60°C uses a fine emulsion of oil-soluble monomers in water and initiates the reaction with a system of water-soluble catalysts. This method is probably the most important of all, because it is used in very large scale in the copolymerization of butadiene and styrene and in the polymerization of many other monomers, such as chloroprene and vinyl chloride, to produce latices of the various synthetic rubbers.

POLYMERIZATION (Emulsion). Since an aqueous system provides a medium for dissipation of the heat from exothermic addition polymerization processes, many commercial elastomers and vinyl polymers are produced by the emulsion process. This two-phase (water-hydrophobic monomer) system employs soap or other emulsifiers to reduce the interfacial tension and disperse the monomers in the water phase. Aliphatic alcohols may be used as surface tension regulators.

Formulas for emulsion polymerization also include buffers, free radical initiators, such as potassium persulfate ($K_2S_2O_8$), chain transfer agents, such as dodecyl mercaptan ($C_{12}H_{25}SH$). The system is agitated continuously at temperatures below 100°C until polymerization is essentially complete or is terminated by the addition of compounds such as dimethyl dithiocarbamate to prevent the formation of undesirable products such as cross-linked polymers. Stabilizers such as phenyl Beta-naphthylamine are added to latices of elastomers.

The final product in latex form may be used for water-type paints or coatings or the water may be removed from the finely divided high-molecular weight polymer. Separation may be brought about by the addition of electrolytes, freezing or spray drying.

It is believed that polymerization of hydrophobic monomers is initiated by free radicals in the aqueous phase and that the surface-active oligomers produced migrate to the interior of the emulsifier micelles where propagation continues. Monomer molecules dispersed in the water phase also solubilize by diffusing —to the expanding lamellar micelles. These micelles disappear as the polymerization continues and the rate may be measured by noting the increase in surface tension of the system.

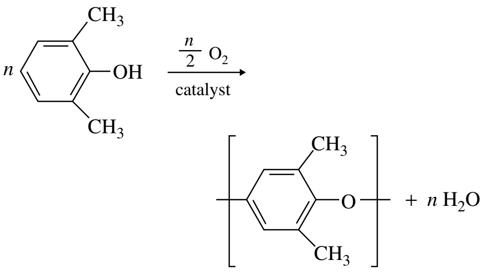
POLYMERIZATION (Oxidative-Coupling). A technique for preparation of high-molecular-weight linear polymers. Schematically the reaction is represented below and involves the oxidative coupling of certain organic compounds containing two active hydrogen atoms to give a linear polymer. The hydrogens ultimately, with oxygen, form water. High-molecular-weight polymers have been prepared in this manner from phenols, diacetylenes, and dithiols.

$$n\text{HRH} \xrightarrow[\text{catalyst}]{\frac{n}{2}\,O_2} -\!\!(\text{R})\!\!-_n + n\text{H}_2\text{O}$$

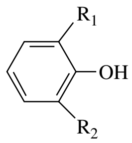
When 2,6-dimethylphenol is oxidized with oxygen in the presence of an amine complex of a copper salt as catalyst a high-molecular weight polyether (PPO) is formed.



The reaction is exothermic and proceeds rapidly at room temperature. The polymerization is generally performed by passing oxygen or air through a stirred solution of the catalyst and monomer in an appropriate solvent. When the desired molecular weight is attained, the polymer is isolated by dilution of the reaction mixture with a nonsolvent for the polymer. The precipitated polymer is then removed by filtration, washed thoroughly and dried. The polymer is soluble in most aromatic hydrocarbons and chlorinated hydrocarbons and insoluble in alcohols, ketones and aliphatic hydrocarbons.

A large number of other 2,6-disubstituted phenols have been oxidatively coupled. A representative list of the results is presented below.

Polymer formation readily occurs if the substituent groups are relatively small and not too electro-negative. When the substituents are bulky, the predominant product is the diphenoquinone formed by a tail-to-tail coupling. No appreciable reaction occurs when 2,6-dinitrophenol is oxidized even at 100°C.



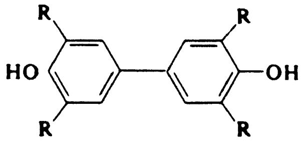
R_1	R_2	Principal Product
methyl	methyl	polymer
methyl	ethyl	polymer
methyl	*i*-propyl	polymer
methyl	*t*-butyl	diphenoquinone
methyl	phenyl	polymer
methyl	chloro	polymer
methyl	methoxy	polymer
ethyl	ethyl	polymer
i-propyl	*i*-propyl	diphenoquinone
t-butyl	*t*-butyl	diphenoquinone
methoxy	methoxy	diphenoquinone
nitro	nitro	no reaction

A family of engineering thermoplastics based on the above technology includes PPO polyphenylene oxide, Noryl® thermoplastic resins (modified

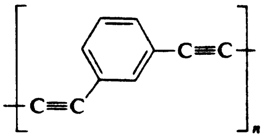
phenylene oxide) and glass reinforced varieties of each. The phenylene oxide resins are characterized by: (1) outstanding hydrolytic stability; (2) excellent dielectric properties over a wide range of temperatures and frequencies; and (3) outstanding dimensional stability at elevated temperatures. Because of these properties modified phenylene oxides are finding major application in the areas of business machine housings, appliances, automotive, TV and communications, electrical/electronic, and water distribution.

Oxidative polymerization of 2,6-diphenylphenol yields a crystallizable polymer that is characterized by a very high melting point (~480°C) and excellent electrical properties. It can be spun into a fiber with excellent thermal, oxidative and hydrolytic stability. It is marketed under the trademark Tenax®.

By performing the oxidation at elevated temperatures the phenols which would ordinarily yield polymers are converted instead to diphenoquinones. These quinones are readily reduced to the corresponding hydroquinones, compounds which promise to be useful as antioxidants and polymer intermediates.



Oxidative coupling of diacetylenes yields another unusual class of polymers. From *m*-diethynylbenzene, for example, is obtained a high-molecular weight polymer that can be cast into a tough, flexible film.



The polymer contains 96.75% carbon and on heating to about 350°F (177°C) or above it spontaneously rearranges to an insoluble and infusible material. When ignited the hydrogen in the polymer burns leaving a carbon residue.

In the same manner dithiols can be converted to polydisulfides.

POLYMERIZATION (Radical). In addition polymerization, polymer is the sole product of the reaction so that the monomer and polymer have essentially the same chemical composition—for example, monomeric styrene and polystyrene. In a polymerization of this type, polymer is formed by a stepwise reaction in which molecules of monomer are added one at a time to a reactive center; the center grows in size while retaining its reactivity.

In a radical polymerization, the reactive centers are free radicals and the process is a typical chain reaction. The monomers in radical polymerizations normally contain carbon-carbon double bonds in their molecules; styrene is typical. Usually radical polymerization is performed in the liquid phase. The chain reaction can be divided into the following steps:

1. *Initiation.* Formation of a reactive free radical and its capture by monomer to form a center
2. *Propagation.* Reaction of a center with a molecule of monomer to form a larger center
3. *Termination.* Deactivation of a center so that it becomes incapable of further growth
4. *Transfer.* Reaction of a center with another molecule so that further growth of that particular center is prevented but a new center, capable of growth, is formed.

Commonly in radical polymerizations, initiation occurs continuously at a steady rate and is balanced by termination so that a steady concentration of growing centers (usually in the region of 10^{-8} mole/l) is established. The number of propagation reactions greatly exceeds the number of reactions of other types so that *macromolecules* are built up. The life-time of an active center is very much less than the duration of the whole process of polymerization and so the macromolecules are produced even in the earliest stages; there is not a continuous rise in the molecular weight of the polymeric product as found in polymerizations of certain other types. It is instructive to consider in some detail the component reactions in the overall process of radical polymerization.

Initiation

In principle, the simplest method for initiation is to add to the purified monomer a small amount of a substance which dissociates to fairly reactive free radicals. This initiator (or sensitizer) is chosen so that its decomposition occurs at a suitable rate at the working temperature; thus azo*iso*-butyronitrile is commonly used at about 60°C dissociating according to the equation:

$$(CH_3)_2C(CH) \cdot N{:}N \cdot C(CN)(CH_3)_2 \longrightarrow 2(CH_3)_2C(CN) \cdot + N_2$$

The radical adds to monomer thus

$$(CH_3)_2C(CN) \cdot + CH_2 : CHX \longrightarrow (CH_3)_2C(CN) \cdot CH_2 \cdot CHX \cdot$$

forming the starting point of a polymer chain, i.e., an *end-group*; this reaction is the real initiation of polymerization. Initiators of other types are also used, notably peroxides, both organic and inorganic. In some cases, the initiator is chosen to give free radicals under the influence of light; this process can be useful for initiating polymerizations at comparatively low temperatures. Two-component initiating systems are widely used in this connection, an example being

$$H_2O_2 + Fe^{2+} \longrightarrow Fe^{3+} + OH^- + \cdot OH$$

which clearly would be selected for aqueous systems. At elevated temperatures or under the influence of external sources of energy (light, high-energy radiations, ultrasonics, mechanical work), many monomers polymerize apparently spontaneously without deliberate addition of sensitizer; the mechanisms of initiation under such circumstances are not completely understood.

Propagation

The propagation reaction in a radical polymerization can be represented by the general equation

$$P \cdot CH_2 \cdot CHX \cdot + CH_2 : CHX \longrightarrow P \cdot CH_2 \cdot CHX \cdot CH_2 \cdot CHX \cdot$$

which corresponds to the conversion of a carbon-carbon double bond to two carbon-carbon single bonds. The group $-CH_2 \cdot CHX-$ in the polymer chain is referred to as the *monomer* unit. If the growing center includes more than a few monomer units, the characteristics of the growth reaction are reasonably supposed to be independent of the size of the center.

The growth reaction is exothermic (in the region of 20 kcal/mole, i.e., about 80 kj/mole); under some circumstances, polymerizations may become self-heating and difficult to control. The growth reaction involves a decrease in entropy since a free molecule of monomer becomes organized in a polymer chain. The opposing effects of changes in enthalpy and entropy indicate that, for every polymerizing system, there is a *ceiling temperature* below which the growth reaction is favored thermodynamically but above which the reverse process is favored; the value of the ceiling temperature depends on the nature of the monomer and on its concentration in the system. Certain monomers, e.g., α-methyl styrene, were once thought not to polymerize by a radical mechanism but it is now clear that they will do so provided that the experiment is performed below the ceiling temperature.

The growth reaction shown above represents *heat-to-tail* addition; the CHX groups occur at alternate sites along the main polymer chain and the unpaired electron is sited on a substituted carbon atom. Head-to-head addition, to give a polymer radical $P \cdot CH_2 \cdot CHX \cdot CHX \cdot CH_2\cdot$, may occur occasionally but is likely to be followed by tail-to-tail addition to give $P \cdot CH_2 \cdot CHX \cdot CHX \cdot CH_2 \cdot CH_2 \cdot CHX\cdot$ which can be regarded as the normal growing radical. Head-to-head groupings may well be sites of instability in the polymer.

The substituted carbon atoms in the polymer chain are asymmetric. *Stereoregular polymers* are produced if all these carbon atoms have the same configuration (all d or all l) or if the d and l configurations occur alternately; pronounced stereo-regularity is seldom achieved in radical polymerizations except perhaps at very low temperatures. When dienes are polymerized by a radical mechanism, the resulting polymers contain several distinct types of monomer unit, thus butadiene can give rise to $-CH_2 \cdot C(CH{:}CH_2)-$, $-CH_2 \cdot CH{:}CH \cdot CH_2-$ *cis*, and $-CH_2 \cdot CH{:}CH \cdot CH_2-$ *trans*.

Termination

In many radical polymerizations, termination occurs by interaction of pairs of growing radicals, either by combination to give $P \cdot CH_2 \cdot CHX \cdot CHX \cdot CH_2 \cdot P$ or by disproportionation to give $(P \cdot CH{:}CHX + P \cdot CH_2 \cdot CH_2X)$. The relative importances of these alternative processes depend upon the chemical nature of the monomer and, to a lesser extent, upon the temperature in the sense that the chance of disproportionation rises as the temperature is increased. Combination gives rise to a head-to-head grouping in the chain, and disproportionation to some unsaturated end-groups for molecules; both structural features may give rise to instability.

Termination can occur for polymer radicals of any size and so there is inevitably a wide *distribution of sizes* among the final molecules. The distribution can be predicted by application of kinetic principles and can be determined experimentally by fractionation of the whole polymer, e.g., by gel permeation chromatography. It is possible to quote only *average molecular weights* for polymers; they can be determined by several experimental methods, e.g., osmometry and viscometry.

The average *chain length* or *degree of polymerization* (DP) of the molecules in a sample of polymer is the average number of monomer units contained in them. The average *kinetic chain length* (v) in a polymerization is the number of growth reactions which, on average, occur between an initiation step and the corresponding termination process. The relationship between degree of polymerization and kinetic chain length depends on the relative frequencies of combination and disproportionation (for 100% combination $DP = 2v$; for 100% disproportionation $DP = v$) but may also be affected by the occurrence of transfer reactions (see later).

Termination is commonly *diffusion-controlled*, i.e., it is governed by the rate at which the reactive sites in growing radicals can come together rather than by chemical factors. In viscous media, termination may be so seriously impeded that both the overall rate of polymerization and the degree of polymerization increase markedly. In systems where the polymer is insoluble in the reaction medium, polymer radicals may be trapped in the precipitated material and be able to grow but unable to participate in termination processes.

Transfer

The average molecular weight of a polymer produced in a particular system may be substantially reduced by occurrence of some types of transfer reactions. If the system contains certain substances, e.g., mercaptans, a growing polymer radical may abstract hydrogen thus

$$P\cdot + R \cdot SH \longrightarrow P \cdot H + RS\cdot$$

giving a dead polymer molecular and a new radical which can react with monomer to reinitiate polymerization. If reinitiation is 100% efficient, the effect of transfer of this type is to reduce the average degree of polymerization without affecting the rate of polymerization or the kinetic chain length. In practice, transfer is commonly accompanied by retardation since some of the new radicals are consumed in side-reactions instead of reacting with monomer; this type of transfer is said to be degradative.

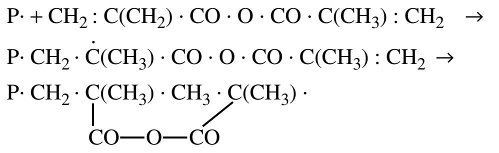
Other components of the polymerization mixture, including monomer and initiator, may engage in transfer reactions. They are particularly significant for allyl monomers for which *degradative transfer* to monomer is of such importance that rates and degrees of polymerization are very low. The radical produced in the reaction

$$P \cdot CH_2 : CH \cdot CH_2 \cdot O \cdot CO \cdot CH_3 \longrightarrow P \cdot H + CH_2 : CH \cdot CH(O \cdot CH \cdot CH_3)\cdot$$

is so stabilized by resonance that it is not reactive enough to initiate efficiently.

Transfer to polymer, causing reactivation of a polymer molecule at some point along its length, leads to the growth of *branches*. The process can occur intermolecularly and also intramolecularly; the latter process is particularly important in the free radical polymerization of ethylene at high pressure where it leads to the production of numerous short branches which considerably affect the properties of the polymer.

Transfer to polymer, the subsequent growth of branches and termination of their growth by combination lead to *cross-linking* whereby the separate polymer molecules are united to form an insoluble three-dimensional network. Cross-linking is however much more likely to occur during the polymerization of those monomers which contain more than one carbon-carbon double bond per molecule. The monomer unit in the polymer first formed still possesses an unsaturated grouping which can participate in another polymerization chain. Certain monomers of this type however engage in a special type of reaction so that reaction of one double bond in a monomer is immediately followed by reaction of the second double bond; this type of growth is shown by, for example, methacrylic anhydride.



Inhibitors and Retarders

Various substances can reduce the rate at which a monomer is converted to polymer. Inhibitors completely suppress polymerizations whereas retarders only reduce the rate. The former deactivate very readily the primary radicals so that growth of polymer chains cannot begin; the latter deactivate growing polymer radicals so causing premature termination. Inhibitors are commonly used to stabilize monomers during storage. Many nitro compounds and quinones act as inhibitors and retarders.

Copolymerization

A process known as copolymerization can occur if reactive radicals are generated in a mixture of monomers; the resulting polymer molecules contain monomer units of more than one type. Copolymerization is of great significance academically, where it leads to information about the reactivities of monomers and radicals, and also industrially where it is used for the production of materials with special properties. Usually the composition of a copolymer is different from that of the mixture of monomers from which it is derived. For this reason, the average compositions of feed and copolymer drift during the course of a copolymerization. There are useful analogies between copolymerization and fractional distillation; special mixtures of monomers producing copolymers without change of composition are said to give azeotropic copolymerizations.

Extensive tables of so-called *monomer reactivity ratios* are available and make it possible to predict the compositions of copolymers formed from particular mixtures of monomers.

In many binary copolymerizations, there is a pronounced tendency for the two types of monomer unit to alternate along the copolymer chain. In extreme cases, there is almost perfect alteration, notably for pairs of monomers, e.g., maleic anhydride and stilbene, which do not polymerize on their own. Ternary copolymerizations are of practical importance; the kinetic treatments developed for binary copolymerizations can be extended to these systems.

POLYMERS. Polymers are very large molecules made by covalently binding many smaller molecules. The word polymer is derived from the Greek *poly* (many) and *meros* (part). The size of polymer molecules imparts many interesting and useful properties not shared by low molecular weight materials. Polymers are the fundamental materials of plastics, rubbers and most fibers, and surface coatings and adhesives, and as such are essential to modern society. Also, many important constituents of living organisms, e.g., proteins and cellulose, are biopolymers.

Classification and Nomenclature

Polymers were initially classified according to their response to temperature. Those that are softened (plasticized) reversibly by heat are known as thermoplastics. Others, though they might initially be liquid or soften once upon heating, undergo a curing (setting) reaction that solidifies them, and further heating leads only to degradation. These are known as thermosets. The ability of polymers to soften and flow at least once is one of their most valuable assets, as it allows them to be formed into complex shapes easily and inexpensively.

In general, polymers are formed by two types of reactions: condensation and addition. The formation of a polyester by polycondensation may be illustrated as follows.

$$\underset{\text{diol}}{x\,\text{HOROH}} + \underset{\text{diacid}}{x\,\text{HOOCR}'\text{COOH}} \longrightarrow \underset{\text{polyester}}{\text{H}\!\left(\!\text{ORO}{-}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{R}'\overset{\text{O}}{\overset{\|}{\text{C}}}\!\right)_{x}\!\text{OH}} + (2x-1)\,\text{H}_2\text{O}$$

In the polyester formula shown, parentheses enclose the repeating unit. The quantity x is the degree of polymerization, sometimes also called the chain length, the number of repeating units strung together like identical beads on a string. Neglecting the ends of the molecule, which is usually justified for large x, the molecular weight M of the polymer molecule is given by $M = mx$, where m is the molecular weight of the repeating unit. Since x can easily be in the thousands, the term macromolecules is also used to describe these materials.

Addition or chain-growth polymerization involves the opening of a double bond to form new bonds with adjacent monomers, as typified by the polymerization of ethylene to polyethylene:

$$x\text{H}_2\text{C}{=}\text{CH}_2 \longrightarrow \!\left(\text{CH}_2{-}\text{CH}_2\right)_x$$

Because no molecule is split out, the molecular weight of the repeating unit is identical to that of the monomer.

In terms of molecular structure, there are three principal categories of polymers, illustrated schematically in Figure 1. If each monomer is difunctional, that is, can react with other monomers at two points, a linear polymer is formed. Polymers that contain two different repeating units, say A and B, are known as copolymers. A linear polymer with a random (AABBABAAABABB) arrangement of the repeating units is a random or statistical copolymer, or just copolymer. It is termed poly(A-*co*-B), with the primary constituent listed first. A molecule in which the two repeating units are arranged in long, contiguous blocks $([\text{A}]_x[\text{B}]_y)$ is a block (b) copolymer, poly (A–b–B).

A few points of tri- or higher functionality introduced along the polymer chains, either intentionally or through side reactions, give a branched polymer. Branches may grow from a linear backbone. A branched structure with the backbone consisting of one repeating unit (A) and the branches of another (B), is a graft (g) copolymer, poly(A–g–B).

As the length and frequency of branches increase, they may ultimately reach from chain to chain. If all the chains are connected together, a cross-linked or network polymer is formed. Cross-links may be built in during the polymerization reaction or may be created chemically or by radiation between previously formed linear or branched molecules (curing or vulcanization).

Structure and Properties

Various levels of structure ultimately determine the properties of a polymer.

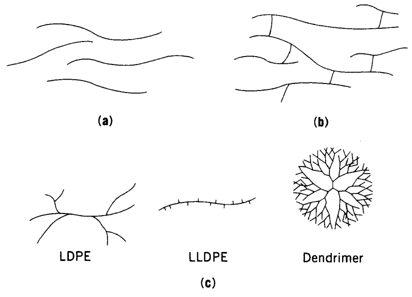

Fig. 1. Schematic diagram of polymer structures: (**a**) linear; (**b**) cross-linked; and (**c**) branched, where LDPE = low density polyethylene and LLDPE = linear low density polyethylene.

Molecular Weights. With the exception of some naturally occurring polymers, all linear and branched polymers consist of molecules with a distribution of molecular weights. Two average molecular weights are commonly defined; the number-average, $\overline{M}_n$, and the weight-average, $\overline{M}_v$.

It may be shown that $\overline{M}_w \geq \overline{M}_n$. The two are equal only for a monodisperse material, in which all molecules are the same size. The ratio $\overline{M}_w/\overline{M}_n$ is known as the polydispersity index and is a measure of the breadth of the molecular weight distribution.

Most molecular weight characterization now is done by size-exclusion chromatography (sec), also known as gel-permeation chromatography (gpc).

Size-exclusion chromatography easily and rapidly gives the complete molecular weight distribution and any desired average.

Secondary Bonding. The atoms in a polymer molecule are held together by primary covalent bonds. Linear and branched chains are held together by secondary bonds: hydrogen bonds, dipole interactions, and dispersion or van der Waal's forces. By copolymerization with minor amounts of acrylic ($CH_2{=}CHCOOH$) or methacrylic acid followed by neutralization, ionic bonding can also be introduced between chains. Such polymers are known as ionomers.

$$\sim \text{COOH} + \text{M(OH)}_2 + \text{HOOC} \sim \longrightarrow \sim \text{COO}^{-+}[\text{M}]^{+-}\text{OOC} \sim +2\ \text{H}_2\text{O}$$

Secondary bonds are considerably weaker than the primary covalent bonds. When a linear or branched polymer is heated, the dissociation energies of the secondary bonds are exceeded before the primary covalent bonds are broken, freeing up the individual chains to flow under stress. When the material is cooled, the secondary bonds reform. Thus, linear and branched polymers are generally thermoplastic. On the other hand, cross-links contain primary covalent bonds like those that bond the atoms in the main chains. When a cross-linked polymer is heated sufficiently, these primary covalent bonds fail randomly, and the material degrades. Therefore, cross-linked polymers are thermosets.

Stereoisomerism. Vinyl monomers, $CH_2{=}CHR$, generally polymerize in a head-to-tail fashion, placing the R group on every other carbon atom in the chain backbone. If a chain is conceptually stretched out, the carbon atoms in the backbone will lie in a plane. The arrangement in which the R groups are all on one side of that plane is the isotactic stereoisomer. Regular alternation of the R groups from side to side is the syndiotactic form. Random placement of the R groups is the atactic (without order) polymer. Stereoisomers are formed during polymerization, and cannot be altered subsequently by rotation about the bonds.

Crystallinity. Crystals are an ordered, regular arrangement of units in a repeating, three-dimensional lattice structure. Small molecules, which in the liquid state have three-dimensional mobility, crystallize readily when cooled. It is not so easy for polymers, because a repeating unit cannot move independently of its neighbors in the chain. Nevertheless, some polymers can and do crystallize, though never completely.

Liquid-crystal polymers exhibit considerable order in the liquid state, either in solution (lyotropic) or melt (thermotropic). When crystallized from solution or melt, they have a high degree of extended-chain crystallinity, and thus have superior mechanical properties.

The Amorphous Phase and T_g. Not all polymers crystallize, and even those that do are not completely crystalline. Noncrystalline polymer is termed amorphous. Four types of molecular motion have been identified in amorphous polymers. Listed in order of decreasing activation energy, they

are *(1)* translational motion of entire molecules, *(2)* coiling and uncoiling of 40–50 C-atom segments of chains, *(3)* motion of a few (five to six) atoms along the main chain or on side groups, and *(4)* vibrations of individual atoms. Type 1 motions are responsible for flow. Type 2 motions give rise to rubber elasticity. The temperature below which type 1 and 2 motions are frozen out is known as the glass-transition temperature, T_g. Below its T_g, an amorphous polymer is a glass; hard, rigid, and often brittle. Above T_g, it becomes rubbery, and at still higher temperatures, if it is not cross-linked, it flows easily.

Effects of Crystallinity on Properties. In polymers that can crystallize, the ratio of crystalline to amorphous material has a profound effect on properties. Because the chains are packed more tightly and efficiently in the crystalline areas than in the amorphous, the crystalline phase has a higher density and greater mechanical strength. In fact, density is a common measure of degree of crystallinity.

The stiffest polymers are both crystalline and have a glassy amorphous phase. They are often useful as engineering (structural) plastics.

Solubility. Cross-linking eliminates polymer solubility. Crystallinity sometimes acts like cross-linking because it ties individual chains together. Thus, there are no solvents for linear polyethylene at room temperature, but as it is heated toward its crystalline melting point, T_m (135°C), it dissolves in a variety of aliphatic, aromatic, and chlorinated hydrocarbons. A rough guide to solubility is that like dissolves like, i.e., polar solvents tend to dissolve polar polymers and nonpolar solvent dissolve nonpolar polymers.

Polymer Synthesis

Step-Growth Polymerization. Step-growth polymerization is characterized by the fact that chains always maintain their terminal reactivity and continue to react together to form longer chains as the reaction proceeds, i.e., $x - \text{mer} + y - \text{mer} \rightarrow (x + y)$-mer. Because there are reactions that follow this mechanism but do not produce a molecule of condensation, the terms step-growth and polycondensation are not exactly synonymous.

Chain-Growth Polymerization. Chain-growth polymerizations are characterized by chains that propagate by adding one monomer molecule at a time, i.e., $x - \text{mer} + \text{monomer} \rightarrow (x + 1)$-mer. There are, however, several mechanisms by which this occurs.

Free-Radical Addition. In free-radical addition polymerization, the propagating species is a free radical. The free radicals are most commonly generated by the thermal decomposition of a peroxide or azo initiator. See also **Initiators (Free-Radical)**.

Unlike step-growth polymerization, free-radical chains do not continue to grow as the reaction proceeds. The average lifetime of a growing chain, from initiation to termination, is typically less than a second. Thus, high molecular weight polymer is produced right from the beginning.

Polymerization Processes. Free-radical polymerization is carried out in a variety of ways.

Bulk polymerization involves only monomer and initiator. It gives the greatest polymer yield per unit of reactor volume and a very pure polymer.

In solution polymerization an inert solvent is added to the reaction mass. The solvent adds its heat capacity and reduces the viscosity, facilitating convective heat transfer.

In suspension polymerization, the organic reaction mass is dispersed in the form of droplets 0.01–1 mm in diameter in a continuous aqueous phase. Each droplet is a tiny bulk reactor. Heat is readily transferred from the droplets to the water, which has a large heat capacity and a low viscosity, facilitating heat removal through a cooling jacket.

In emulsion polymerization the organic monomer is emulsified with soap in an aqueous continuous phase.

Ionic Polymerization. Addition polymerization may also be initiated and propagated by anions. Ionic polymerizations are almost exclusively solution processes.

There are some important differences between anionic and free-radical addition. First, unlike free-radical initiators, which decompose and start chains randomly throughout the course of the reaction, anionic initiators ionize readily in fairly polar organic solvents or at low concentrations in hydrocarbons, and chains are started immediately, one for each molecule of initiator. Second, in the absence of impurities, there is no termination.

When the initial monomer supply is exhausted, the anionic chain ends retain their activity. Thus, these anionic chains have been termed living polymers. If more monomer is added, they resume propagation. If it is a second monomer, the result is a block copolymer.

Cationic polymerization has been used commercially to polymerize isobutylene and alkyl vinyl ethers, which do not respond to free-radical or anionic addition. See also **Elastomers**; and **Rubber (Synthetic)**.

Stereospecific Polymerization. In the early 1950s, Ziegler observed that certain heterogeneous catalysts based on transition metals polymerized ethylene to a linear, high density material at modest pressures and temperatures. Natta showed that these catalysts also could produce highly stereospecific poly-α-olefins, notably isotactic polypropylene, and polydienes. They shared the 1963 Nobel Prize in chemistry for their work. More recently, metallocene catalysts that provide even greater control of molecular structure have been introduced.

POLYMERS (Electroconductive). Most polymers are electrical insulators and have conductivities of 10^{-15} ohm^{-1} cm^{-1} or less. However, there are several ways to arrive at compositions of polymeric nature that have higher conductivity. A simple way to obtain such a system is to use electrically conductive fillers such as metal powders or special types of carbon black. In these physical mixtures the polymer itself does not become conductive but acts only as an inert matrix to keep the conducting filler particles together. Conduction then occurs through chains of touching, conducting particles. Control of conductivity is limited in that it tends to be high as long as continuous chains of conducting particles are present. When fewer particles are present and an insufficient number of contacts between them can be established, the conductivity drops sharply. With metal fillers, conductivities of 10^2 ohm^{-1} cm^{-1} can be realized. The particle size and the effectiveness of dispersion are important. In polymer-filler systems the conducting particles may rearrange under the influence of thermal or mechanical cycles, and the bulk conductivity tends to change as a result of such cycles.

Ionic conductivity can be found in polyelectrolytes such as the salts of polyacrylic acid, sulfonated polystyrene or quaternized polyamines (ion-exchange resins). When dry, these materials have low conductivities. However, in the presence of small amounts of polar solvents or water—some of these polyelectrolytes are somewhat hygroscopic—electrical conductivity can be observed. The currents are carried by ions (protons, for instance). Such systems can only be used in cases where very small currents are expected. Large currents would result in observable electrochemical changes of the materials. In applications as antistatic electricity coatings, conductivities of 10^{-8} ohm^{-1} cm^{-1} are sufficient.

Thermal decomposition of a large number of organic solids yield carbonaceous materials which are electrically conductive. It is believed that the conductive pyrolysis products are of polymeric nature, and that at high temperatures a carbon skeleton similar to graphite is formed. Since these products are insoluble, infusible mixtures, very little is known about their structure. Variation of the pyrolysis conditions leads to products with different conductivities. A well-studied example is polyacrylonitrile. Upon pyrolysis, an originally colorless piece of polyacrylonitrile (Orlon) fabric turns black with remarkable retention of its structure and becomes electrically conductive. Depending on the pyrolysis conditions, conductivities up to 10^{-1} ohm^{-1} cm^{-1} have been obtained. It is believed that an aromatic system of condensed six-membered rings analogous to graphite is formed.

A number of polymers of more defined chemical structure exhibit *electronic* electrical conduction. According to one of the early concepts, long conjugated unsaturated chains would make good electronic conductors, assuming that resonance would render a fraction of the electrons in the molecules mobile, and thus give rise to electrical conductivity. Synthesis of long conjugated chains has been attempted by polymerization of acetylene derivatives (phenylacetylene), by dehydration or dehydrohalogenation of polyalcohols (polyvinylalcohol) or polyhalides (polyvinylchloride) and by polycondensations of suitable monomeric reaction partners, for instance, diamines with dialdehydes. In addition to the conjugated systems with only carbon in the chain and those with carbon and nitrogen, polymeric chelates have also been reported. Here the d-orbitals of the transition elements are supposed to form a part of the conjugated system.

Problems associated with the study and fabrication of these polymeric materials arise from the fact that many of them cannot be purified because crosslinking renders them infusible or insoluble, or both. Consequently the molecular weights and other structural details cannot be determined. Some noncrosslinked polymers of these types have been described with low molecular weight and low conductivities.

In another approach, the fact that crystalline monomeric charge transfer complexes exhibit electrical conductivity led to preparation of polymeric charge transfer complexes. These can be obtained from a polymeric electron donor and a monomeric electron acceptor or from a polymeric acceptor and a monomeric donor, the former type being the more common. These polymers are not crosslinked and some are soluble, but their conductivities are generally low.

Another example of an extension of the properties of monomeric compounds into the realm of polymers is the case of the 7,7,8,8-tetracyanoquinodemethan (TCNQ) compounds. Some monomeric, salt-like derivatives of TCNQ have conductivities of the order of 1 ohm^{-1} cm^{-1}. Apparently stacks of TCNQ$^-$ ions and neutral TCNQ are responsible for these high conductivities. The polymeric TCNQ compounds consist of polycations, TCNQ$^-$ ions and neutral TCNQ, and have conductivities ranging from 10^{-10} to 10^{-3} ohm^{-1} cm^{-1}. These polymeric materials are soluble in organic solvents, can have high molecular weights (several million) and can be cast as films from solutions. Although the compounds are polyelectrolytes, they exhibit electronic conduction when dry. Among the many types of electrically conducting polymeric compositions the TCNQ derivatives seem to have an advantage because of an attractive combination of properties, namely controllable molecular weight, solubility, known chemical structure, fair chemical and thermal stability and electronic conduction controllable over several orders of magnitude.

The possibility of synthesizing polymeric superconductors has been proposed, but at the present time these ideas have not been confirmed by successful experiments.

POLYMERS (Inorganic). Most inorganic materials can be considered polymeric since they are built up of a relatively simple atomic grouping repeated a very large number of times. Metals and simple ionic materials are easily excluded, but there still remains a large group of covalently bonded, regularly repeating materials. For example, many mineral silicates are based on the monomer $[SiO_4]^{4-}$ which is covalently bonded to form the large, two-dimensional sheets from which these materials are built. Still, we do not normally think of most of these inorganic, covalently bonded polymeric materials as polymers, because their behavior is so different from what we have come to expect of organic polymers. Such properties as high viscosity in the melt and in solution, rubbery elasticity, moldability, ability to form fibers, films, and so on, are not possessed by most of these materials. In a few cases, enough of them are present to suggest the underlying similarity in structure, for example, in the silicate minerals, crysotile asbestos forms fibers of excellent textile quality. Such samples show the possibility of obtaining useful inorganic polymers.

In the light of this discussion inorganic polymers will be considered to be those materials in which the main polymiric chain contains no organic carbon and in which behavior similar to that of organic polymers can be developed.

The question "Why is there such a difference in behavior between the usual inorganic and organic polymeric materials?" is helpful in guiding such a development. The contrast must be due to differences in molecular structure. For example, in the case of quartz the $[SiO_4]^{4-}$ tetrahedra are covalently bonded together. The high regularity of the structure and the large number of cross-links per $[SiO_4]^{4-}$ unit lead to a material which is strong and dimensionally stable, but brittle. The same situation of over-crosslinking can be found with organic polymers. If the number of cross-links in quartz is reduced by substituting organic groups, such as methyl, for some of the oxygen-silicon linkages, the silicone polymers are produced. These polymers, the only commercial inorganic ones, show that inorganic materials which behave as organic polymers can be made. However, a number of obstacles are found which are not as troublesome with organic polymers. For example, six to eight membered rings are more stable than long-chains. In the case of organic materials, if chains can be formed initially, they have considerable stability. With inorganic materials, the bonds are much more labile (constantly forming and breaking) and the long chain may break down to a collection of smaller rings.

Other factors which influence the properties of polymers can be illustrated by examining the bond energies or bond strengths and the ionic character of bonds based on Si as contrasted to similar ones based on C.

From the bond energies we would expect the homo-atomic silane polymers with Si−Si bonds to be considerably less stable than the more familiar C−C chain polymers. This expectation fits the observed facts. On the other hand, one could expect little gain in stability in the carbon series by going to an ether linked chain (−C−O−C−), while in the silicon series a silicon-oxygen linkage is stronger than any of the others. This is reflected in the very good stability of the silicone polymers. From bond energies one might also expect that a chain of alternating Si and N atoms would have good stability.

Bond Energies			
Si—Si	53 kcal	C—C	83 kcal
Si—O	106	C—O	86
Si—N	82	C—N	73
Si—C	78		
Ionic Character			
Si—Si	0	C—C	0
Si—O	51%	C—O	22%
Si—N	30	C—N	7
Si—C	12		

In addition to pure thermal stability, if the polymer is to be heated in air, one must also consider oxidative stability. In the carbon series oxidation always leads to more stable species and tends to occur, but in the silicon series there is a much higher tendency towards reaction with oxygen. This is the principal reason for the low utility of the silane polymer. Finally, a third factor in polymer stability is the ease of attack by solvents, acids, bases, etc. This is largely determined by the ionic nature of the bonds involved. The silica based polymers should be more susceptible to such attack than carbon, since they have a higher percent of ionic nature.

We do find that acidic or basic water solutions attack silicones when they are heated together under pressure. Their resistance is still high, however, because of other details of the way the polymer molecules are bound together.

The polymers which have been used to illustrate problems of inorganic polymer formation have been heteroatomic, that is, their chains are built from different atoms alternating with each other. The other structure mentioned has been homoatomic—all the atoms in the chain are the same. There are only a few homoatomic polymers of any promise. Most elements will form only cyclic materials of low molecular weight if they polymerize at all. In addition to the silane polymers, black phosphorus, a high-pressure modification of the element, forms in polymeric sheets.

Boron has similar tendencies in its compounds. The outstanding member of this class is sulfur. A transition from S_8 rings to long sulfur chains takes place over a narrow temperature range around 159°C. An increase in the viscosity of the liquid by 2000 times or more, within a range of 25°, is the tangible evidence of polymerization. The material also forms rubbery, plastic and fibrous forms when chilled to room temperature. However, it has a strong tendency to revert to the cyclic form unless stable groups are placed at the end of the chain or copolymerization hinders the process. Attempts to improve the stability of polymeric sulfur have met with some success. This is the only homoatomic inorganic polymer which appears technically interesting at present.

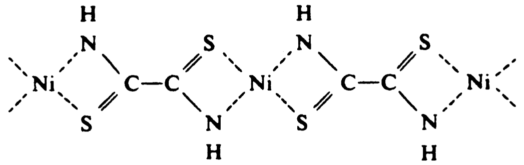
The class of heteroatomic polymers, besides containing the silicones, offers more promise for useful materials. Most nonmetals and many of the less positive metals form heteroatomic compositions. In many cases they are high polymers. The silicones themselves behave quite the same as organic polymers and are used as oils, rubbers and resins. The rubber is vulcanized either by the reaction of organic peroxides with the methyl groups on the chain or by incorporating groups such as Si—OH or Si—OR which crosslink on exposure to moisture in the atmosphere. The properties in which they excel over organic polymers are high thermal stability, resistance to oxidation and inertness to organic reagents. These are usually the special properties one hopes to get from inorganic polymers. The polymers may be modified by substitution of other groups for the methyl groups on the side chain and by copolymerization with other heteroatoms in which B—O—Si, Al—O—Si, Sn—O—Si, Ti—O—Al and other combinations are produced.

A similar class is the titanates. Three-dimensional Ti—O chains form pigments and pigment binders for paints and water-proofing compounds for use on cloth. Their properties can be modified by substituting monofunctional groups for some of the oxygen, for example, by forming esters to interrupt the chains.

The polyphosphates have also been widely studied. Here the phosphate ion is found as a high polymer. The molecular weight of the polymer ranges from 250,000 to 2,000,000. The polyphosphates are water soluble and form fibers. No uses have been found for this class of materials. They hydrolyze slowly in atmospheric moisture and also embrittle on standing.

Other attempts to base a polymer on B—N heteroatomic chains are being vigorously pursued although the B—O bond with an energy of 130 kilocalories is thermally more stable than the B—N bond at 100 kilocalories. The borates formed with B—O chain links, however, are too hydrolytically unstable and too thoroughly cyclized to be useful. B—N compounds are also plagued with the same weakness. However, the very high thermal stability of low molecular weight materials has encouraged the search for high polymers with the same basic structure. The combination of boron and nitrogen approximates that of carbon with carbon due to its location in the Periodic Table. See **Boron**.

One other area of materials deserves mention here. Coordination polymers are found when metal atoms are joined together by coordinating bonding involving some bridging group, e.g.



In view of the high thermal stability of monomeric chelation compounds, coordination polymers were expected to be promising for use at high temperatures. This has not proved to be the case. Thermal stabilities are usually lower than for low molecular weight materials. In addition, if the polymerization goes beyond a few monomer units, the materials tend to become insoluble and infusible so they cannot be fabricated into useful items. See **Chelation Compounds**.

POLYMERS (Organic). Organic high polymers have a great number of different chemical structures, ranging from completely nonpolar to very polar and even ionic materials. They all clearly resemble each other, however. The basis for this resemblance is that many of their properties are governed by their high molecular weights, which range from 5,000 to tens of millions. For example, as the molecular weight increases in a given polymer family, the tensile strength of the polymer increases markedly. In some cases it approaches that of steel on a weight-for-weight basis, especially when oriented fibers are fabricated.

In a similar way, the viscosity of the molten material changes from a free flowing liquid at low molecular weights to the highly viscous polymeric liquid where flow may be observed only over a long period of time or under a considerable applied pressure. A property which shows up only in the case of high polymers is rubbery elasticity. Here again the development of a sufficiently long and flexible molecule is necessary before rubbery behavior develops.

Because of this striking dependence on molecular size, the measurement of molecular weight and dimensions is very important. Some of the

most significant early work of Staudinger was the demonstration of the existence of large molecules joined by covalent bonds. (Others felt that such large molecules were not possible). In order to determine these molecular properties the molecules must be dissolved. Thus each molecule can be separated from its neighbors and its effect measured independently. Solution properties such as osmotic pressure, light scattering and viscosity are used to measure the molecular weight of polymers. In the case of many natural polymers the ultracentrifuge has proved uniquely useful.

The osmotic pressure determination of molecular weights is based on the thermodynamic interaction of solvent and solute to lower the activity of the solvent. Experimentally, the solution is separated from the solvent by a semipermeable membrane. The solvent tends to pass through the membrane to dilute the solution and bring the activity of the solvent in both phases to equilibrium. The quantitative measurement of this tendency is obtained by allowing the liquid solution to rise in a vertical capillary connected to the solution compartment. The equilibrium height it achieves or the rate at which it rises can be measured.

The measurements are converted to effective pressure (π) at zero polymer concentrations (c) and the average molecular weight ($\overline{M}_n$) gotten from the following relation:

$$\lim_{c \to 0} \frac{\pi}{c} = \frac{RT}{\overline{M}_n}$$

(R = gas constant; T = absolute temperature).

The light-scattering method is based on similar thermodynamic interactions. In any solution there are random variations in concentration and refractive index. These scatter some light out of a beam passing through the liquid. In a polymer solution the nature of the fluctuations and thus the amount of scattered light (τ) depend on the attractive forces between polymer and solvent molecules. This, in turn, depends on the polymer molecular weight ($\overline{M}_w$). The following equation describes the behavior:

$$\lim_{c \to 0} \frac{Hc}{\tau} = \frac{l}{\overline{M}_w}$$

(H = a constant)

This method was developed by Peter J. W. Debye in 1944. Its evolution has been one of the most stimulating chapters of polymer physics.

In contrast to these thermodynamic methods, the viscosity molecular weight determination depends on the interference in the flow of the solvent caused by the dissolved molecules. In contrast to osmometry and light scattering, it has not been possible to develop the viscosity effect into an absolute measure of molecular weight. Rather, it must be calibrated, preferably by light scattering measurements.

The relationship between the measured limiting specific viscosity $[\eta]$ and the molecular weight ($\overline{M}_v$) is as follows:

$$\lim_{c \to 0} \frac{\eta_{sp}}{c} = [\eta] = K\overline{M}_v^a$$

K and a are determined by calibration for a given polymersolvent system.

$$\eta_{sp} = \frac{\eta_{\text{solution}}}{\eta_{\text{solvent}}} - 1$$

In each of the equations above a different symbol has been used for the molecular weight. Most polymers are heterodisperse, i.e., have many molecular weight species of the same chemical nature, thus the experiments yield an average molecular weight. Osmotic pressure gives a lower average ($\overline{M}_n$) or number average) because it emphasizes the effect of small molecules, while light scattering emphasizes the larger molecules and gives a higher average, ($\overline{M}_w$) or weight average). The viscosity average ($\overline{M}_v$) is between the two and closer to the weight.

Many natural polymers are monodisperse (all molecules have the same molecular weight). In this case the ultracentrifuge which separates materials according to their effective density in solutions is a most powerful tool for molecular weight determination. With poly-disperse materials, the interpretation of ultracentrifuge results becomes more complex and widespread application of this method to synthetic polymer molecular weight determination has not yet been achieved.

In addition to the primary effect of the great length of the molecule, the details of the distribution of functional groups along the polymer chain modify the behavior of these materials. This leads to differences in their applications. For example, natural rubber exists in the rubbery state at room temperature. If cooled below zero degrees Celsius it becomes a hard, inflexible material, brittle and easily broken. On the other hand, if heated too far above room temperature, it begins to flow quite rapidly and behaves more like a fluid than a rubber. The same pattern is observed with other materials. For example, polystyrene, hard and brittle at room temperature, becomes rubbery when heated up sufficiently. The study of the mechanical behavior of polymers at various temperature is called rheology. The temperature at which the rubbery material becomes glassy is called the glass transition temperature (T_g). This transition temperature depends on the nature of the backbone and the substituent groups on the polymer chain. Rubbery materials, e.g., polyisoprene, polychloroprene, polybutadiene, the copolymer of butadiene and styrene, etc., have molecular chains with considerable flexibility. Usually small side groupings and irregularities in the chain prevent them from coming together in a regular structure. Instead the molecules stay in an amorphous random packing much like a pile of cooked spaghetti. As with cooked spaghetti, there is a tendency for the whole mass to flow, by the movement of chains past one another. With natural rubber this flow at room temperature and above had to be inhibited by tying the chains together with chemical bonds before a useful product was obtained. This cross-linking is called vulcanization in the case of rubber. The process was discovered by Charles Goodyear in 1839. A similar cross-linking to inhibit the motion of the chains is necessary to make useful products from the newer synthetic rubbers also.

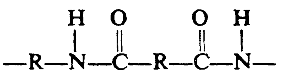
Other polymers are not rubbery at room temperature, instead they exist in the glassy state. They are amorphous, but because of more bulky substituents on the polymer chain the molecule is less flexible. There is less ease of molecular motion under applied stress at room temperature. Examples of such polymers are polystyrene and polymethylmethacrylate, which are transparent due to their amorphous, homogeneous nature. When heated they first become rubbery and then, at higher temperatures, show viscous flows so that they may easily be molded. When they are cooled to room temperature the rate of flow is vanishingly small due to the stiff chains; thus items made in this way can be used at ordinary temperatures if they are not required to bear too large a load. These common organic glasses are brittle and easily broken on impact. One of the interesting problems for polymer development is to obtain impact resistance without losing transparency and without increasing the cost by an excessive amount.

A related class of polymers is the crystalline, thermoplastic materials. These also are fabricated by heating to a high temperature so that they flow; but when they are cooled ordered regions develop within them, which makes them translucent. They have much tendency to flow because of these mechanical "crosslinks" and have good dimensional stability. Polyethylene and polypropylene belong to this class. Here the chain is simple and regular so that different polymer molecules, or different parts of the same molecule, can pack next to each other. The same situation exists with "Teflon" (polytetrafluoroethylene).

As might be expected, there are polymers intermediate between the crystalline and glassy ones. For example, polyvinylchloride shows enough order to prevent its classification as glassy, but not enough to be considered crystalline.

Many crystalline polymers form part of another class of materials, the fiber-forming polymers. The formation of fibers of significant strength depends on the growth of ordered structures when the fiber is stretched. Thus crystalline materials, such as polypropylene, whose crystallites can grow on elongation, form strong fibers. In some cases fiber formation is aided by polar groups on the polymer chain. These interact with each other to give strong attractive forces which aid the molecular alignment that is needed. For example, polyacrylonitrile, the base polymer of "Orlon" and "Acrilan," has a −CN dipole in each monomer unit. The cooperative attraction of hundreds of these units along a chain gives a very strong cumulative effect. The fibers are strong even though they are not crystalline. The intermediate degree of order they develop is referred to as paracrystallinity.

In the case of other common fibers the polar groups are found in the polymer chain itself. In nylons the amide group,



offers the possibility of both dipolar attraction and hydrogen bonding. The ester group in "Dacron" and similar polyesters contributes the −C=O dipole. See **Fibers**.

The introduction of oxygen and nitrogen into the chain changes its flexibility, stability toward chemical reaction, resistance to solvents, strength and other properties. In this way quite extensive changes in behavior are obtained. Most of these heterochain polymers are prepared by condensation or ring opening reactions. The first important work in this field was the classic investigation of W. H. Carothers in the late 1920's on polyesters and polyamides. See **Polyimides**.

The toughness, high melting points and high tensile strength of many of these polymers have since led to their widespread use of fibers, films and molded objects. In general these polymers are rather high cost materials, which are used, because of their unusual properties, in places where ordinary polymers are inadequate. For example, polysulfide rubbers show outstanding solvent resistance, while the silicones are a unique class of materials inert to many environmental conditions and unwettable by most liquids. Polycarbonates and acetals are so dimensionally stable that they can be used in place of metals in molded items. Many of the interesting developments in polymers over the last few years have involved new syntheses and new variations in structure of such heterochain materials.

The materials described above are thermoplastic resins, i.e., they all melt on being heated to sufficiently high temperatures and can be molded while molten. This characteristic is associated with molecular chains which are long and stringlike with few branches on them. If, however, the polymer chains have many covalent bonds linking them together into a network, a thermosetting resin develops which may flow at an early stage of its history, but is insoluble and infusible after the full crosslinking reaction has taken place. Any of the previous chain compositions can be used in making thermosetting resins if provision for crosslinking is made by using multifunctional monomers. Some are used more commonly, e.g., the epoxy resins, phenolformaldehyde, urea formaldehyde, melamine, etc. Separate articles describing the properties of many of these plastics are found in other parts of this encyclopedia. In general they are useful because of their inertness to solvents, resistance to dimensional change on heating, rigid dimensions, physical strength, chemical resistance and abrasion resistance.

Many of the varieties of polymers which have been discussed have analogs in polymers isolated from natural systems, for example, natural rubber is a polyisoprene with a purely carbon chain. Other natural polymers are based on the C−O−C bond. The cellulose and starch polymers, which are found in plants are composed of chains of six-membered carbon-oxygen rings joined through an oxygen linkage. Cellulose and starches differ from each other in the spatial orientation of the links joining the six membered rings.

Products from different sources in each class differ in degree of branching of the molecule and in amount of crosslinking.

In unmodified cellulose the hydroxyl groups give a large amount of hydrogen bonding which leads to insolubility in most solvents. On the other hand if these are changed by chemical reactions to ether or ester groups a much more tractable material results. Cellulose acetate, butyrate and nitrate; methyl and ethyl ether and carboxy methyl ether are widely used modified celluloses. Starches also are modified, but much less commercial success has been had with them.

The polymers described above have been chemically pure, although physically heterodisperse. It is often possible to combine two or more of these monomers in the same molecule to form a copolymer. This process produces still further modification of molecular properties and, in turn, modification of the physical properties of the product. Many commercial polymers are copolymers because of the blending of properties achieved in this way. For example, one of the important new polymers of the past ten years has been the family of copolymers of acrylonitrile, butadiene and styrene, commonly called ABS resins. The production of these materials has grown rapidly in a short period of time because of their combination of dimensional stability and high impact resistance. These properties are related to the impact resistance of acrylonitrile-butadiene rubber and the dimensional stability of polystyrene, which are joined in the same molecule.

Since they are organic materials most polymers are not water soluble, however, water solubility can be obtained by substituting the proper side groups on the polymer chain. Such polymers include the nonionic materials polyvinyl alcohol, polyethylene glycol, etc., where the strong dipolar and hydrogen bonding interactions cause the solubility; and the polyelectrolytes where ionizable groups such as the carboxylate, sulfonate, quaternary ammonium, etc., cause the solubility. Many of these water soluble polymers are used to increase the viscosity of water based systems. As little as 0.1 or 0.2% of the polymer is needed to produce a very viscous solution. They also are of wide biological interest.

POLYMERS, WATER-SOLUBLE. Any substance of high molecular weight which swells or dissolves in water at normal temperature. These fall into several groups, including natural, semisynthetic, and synthetic products. Their common property of water solubility makes them valuable for a wide variety of applications as thickeners, adhesives, coatings, fooe additives, textile sizing, etc.

Natural

This type is principally composed of gums, which are complex carbohydrates of the sugar group. They occur as exudations of hardened sap on the bark of various tropical species of trees. All are strongly hydrophilic. Examples are arabic, tragacanth, karaya.

Semisynthetic

This group (sometimes called water-soluble resins) includes such chemically treated natural polymers as carboxymethylcelluose, methylcellulose, and other cellulose esters, as well as various kinds of modified starches (esters and acetates).

Synthetic

The principal members of this class are polyvinyl alcohol, ethylene oxide polymers, polyvinyl pyrrolidone, polyethyleneimine.

POLYMETHINE DYES. Polymethine dyes (PMD) represent a large class of organic colored compounds that contain a chain of methine groups (−CH=) as the basic constitutive elements. According to S. Daehne's triad theory, polymethines, together with polyenes and aromatics, are the three main types of conjugated systems. The term polymethine dyes was introduced by W. Koenig in 1922. The formula of PMDs having the stable closed electron shell, in its general form, can be written as two resonance structures, where n is the number of vinylene groups in the polymethine chain,

$$[G_1^{\pm}\text{—}(CH{=}CH)_n\text{—}CH{=}G_2]X^{\mp} \leftrightarrow [G_1{=}CH\text{—}(CH{=}CH)_n\text{—}G_2^{\pm}]X^{\mp}$$

(1)

and G_1 and G_2 are terminal or end groups of various chemical structure, i.e., acyclic, carbo-, or heterocyclic residues. Polymethine chains of symmetrical dyes ($G_1 = G_2$) consist of an odd number of carbon atoms, and these systems carry charges, i.e., they exist as either cations or anions. In formula (**1**), end groups differ by a number of π-electrons, and thus one is written in electron donor, and the other in electron acceptor, form.

The simplest PMDs include the polymethines (**2**), streptocyanines (**3**), oxonols (**4**), and merocyanines (**5**).

$$H_2C{=}CH{-}(CH{=}CH)_n{-}CH_2^{\pm} \qquad R_2N^+{=}CH{-}(CH{=}CH)_n{-}NR_2$$

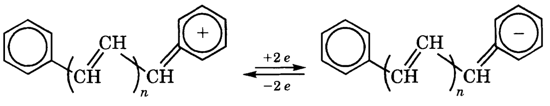
(**2**) (**3**)

$$O{=}CH{-}(CH{=}CH)_n{-}O^- \qquad R_2N{-}(CH{=}CH)_n{-}CH{=}O$$

(**4**) (**5**)

A great number of different heterocyclic residues have been used as the terminal groups of PMDs. PMDs containing residues with quaternary nitrogen atoms are traditionally called cyanine dyes.

Polymethines with branched polymethine chains also exist. Among these, PMDs with symmetrically branched chains are the best known; they are referred to as trinuclear polymethine dyes (TPMD) (**6**).

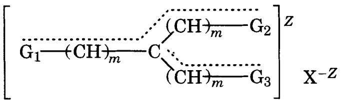


(**9a**) (**9b**)

PMDs demonstrate pronounced absorption and contain fluorescence bands that are relatively narrow and highly intense, which arise from electron transitions occurring within the polymethine chromophore $-[(CH{-}CH)_n{-}CH]-$. These spectral properties give rise to a wide range of applications of PMDs such as silver halide sensitizers, laser media components, polymerization initiators, etc.

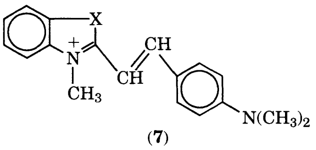
According to one classification, symmetrical dinuclear PMDs can be divided into two classes, A and B, with respect to the symmetry of the frontier molecular orbital (MO). Thus, the lowest unoccupied MO (LUMO) of class-A dyes is antisymmetrical and the highest occupied MO (HOMO) is symmetrical, and the π-system contains an odd number of π-electron pairs. On the other hand, the frontier MO symmetry of class-B dyes is the opposite, and the molecule has an even number of π-electron pairs.

For convenience, unsymmetrical PMDs should be considered as the derivatives of the corresponding symmetrical polymethines, commonly called parent dyes. In contrast to symmetrical compounds, unsymmetrical PMDs can contain an even number of methine groups in the polymethine chains, for example, styryls (**7**), where X = S, O, NCH_3, $C(CH_3)_2$, or CH=CH; and (**8**), where Y = O, S, Se or NCH_3.

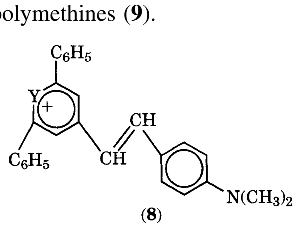


(**6**)

Unsubstituted PMDs (**2**) or dyes containing odd alternate hydrocarbon residues as end groups can exist in two relatively stable forms distinguished by a π-electron pair, e.g., α, ω-diphenylpolymethines (**9**).



(**7**)



(**8**)

Electron Structure

A considerable number of experiments have shown that symmetrical PMDs in the ground state have an all-trans configuration and are nearly planar with practically equalized carbon-carbon bonds and slightly alternating valence angles within the polymethine chain.

Electron Transitions

PMD color or the nature of the electron transitions produces the widest application for PMDs. Depending on the polymethine chain length, the end-group topology, and the electron shell occupation, polymethines can absorb light in uv, visible, and near-ir spectral regions.

Chemical Reactivity

As conjugated systems with alternating π-charges, the polymethine dyes are comparatively highly reactive compounds. Substitution rather than addition occurs to the equalized π-bond. If the nucleophilic and electrophilic reactions are charge-controlled, reactants can attack regiospecifically.

Protonation. As expected from π-electron distribution, the proton attacks the negatively charged odd positions in the polymethine chain e.g.,

$$G^+{-}CH{=}CH{-}CH{=}CH{-}CH{=}G \xrightarrow{H^+} G^+{-}CH_2{-}CH{=}CH{-}CH{=}CH{-}G^+$$

The destruction of the total π-system causes the color to vanish the protonated molecule absorbs light in the uv region. Protonation has been proved to be reversible.

Other Electrophilic Reactants. Reversibility of the electrophilic reactions enables substituted dye derivatives to be obtained. Halogen atoms are mobile in the polymethine chain, and the derivatives themselves can function as halogenation reagents.

The dye can be formulated by means of a phosgene, Chloromethylation leads to the alkylated polymethines; nitration of cyanines results in mononitro-substituted compounds.

Nucleophilic Reagents. In contrast to electrophilic reactions, nucleophiles attack positively charged, even carbons in the chain. The reactions lead to the exchanging of substituents or terminal residues. Thus, SR and OR groups, or halogen atoms can be exchanged by other suitable nucleophiles.

If the dye contains no mobile substituents in the chain, nucleophiles attack primarily the end carbon atoms (changing of terminal residues). Nucleophilic reactions with the methylene bases of the corresponding heterocycles result in polymethines containing new end groups.

The asymmetrical polymethines appear to be ambivalent systems, and the number of possible reaction paths increases considerably as a result.

Reactions with Parting of Radicals. The one-electron oxidation of cationic dyes yields a corresponding radical dication. The stability of the radicals depends on the molecular structure and concentration of the radical particles. They are susceptible to radical-radical dimerization at unsubstituted, even-membered methine carbon atoms.

Photochemistry. The most important photochemical processes that proceed from the excited state are geometrical isomerization and photochromic reactions. Photoisomerization of polymethines is a reversible trans-cis transfer. The cis-isomer absorbs at longer wavelength with a smaller intensity than the trans-isomer.

Applications of Polymethines. The most important reason for the large number of technical applications of polymethine dyes is their relatively low electron-transition energies and their highly intense and narrow spectral bands. Indeed, polymethines display strong light absorption and emission, between 300 and 1600 nm. These dyes have been used as photographic sensitizers and desensitizers, as laser dyes, as probes of membrane potentials, and in other applications where the theoretical aspects of polymethines are useful.

Spectral Sensitization. Photographic silver halide emulsions are active with light only up to about 500 nm. However, their sensitivity can be extended within the whole visible and near-ir spectral region up to about 1200–1300 nm. This is reached by the addition of deeply colored dyes that transfer excited electrons.

According to the electron-transfer mechanism of spectral sensitization, the transfer of an electron from the excited sensitizer molecule to the silver halide and the injection of photoelectrons into the conduction band are the primary processes. Thus, the lowest vacant level of the sensitizer dye is situated higher than the bottom of the conduction band. The regeneration of the sensitizer is possible by reactions of the positive hole to form radical dications. If the highest filled level of the dye is situated below the top of the valence band, desensitization occurs because of hole production.

Based on correlations between energy level positions and electrochemical redox potentials, it has been established that polymethine dyes with reduction potentials less than -1.0 V (vs SCE) can provide good spectral

sensitization. On the other hand, dyes with oxidation potentials lower than +0.2 V are strong desensitizers.

Improvement of spectral sensitization can be accomplished by dye combinations. The effect has been found to often be greater than the predicted additive sensitivity increase. This phenomenon is called supersensitization, which is applied most effectively to polymethine aggregates. The opposite phenomenon, a decrease of sensitivity, is known as desensitization. The main reasons for desensitization are the results of relative electron level positions as well as the secondary processes of the photoelectrons.

Quantum Electronics and Laser Dyes. In quantum electronics, PMDs are usually applied as mode-locking compounds in passive mode-locked lasers as well as active laser media. The required characteristics of dyes used as passive mode-locking agents and as active laser media differ in essential ways. For passive mode-locking dyes, short excited-state relaxation times are needed; dyes of this kind are characterized by low fluorescence quantum efficiencies caused by the highly probable nonradiant processes. On the other hand, the polymethines to be applied as active laser media are supposed to have much higher quantum efficiencies, approximating a value of one.

Photopolymerization. In many cases polymerization is initiated by irradiation of a sensitizer with ultraviolet or visible light. The excited state of the sensitizer may dissociate directly to form active free radicals, or it may first undergo a bimolecular electron-transfer reaction, the products of which initiate polymerization.

Synthesis

By varying the molecular structure, it is possible to synthesize dye initiators with the required characteristics. Polymethine dyes with different chain length, end groups, and substituents, or with other variations of the chromophore, have been synthesized.

Polymethine dyes consist of three main structural elements: two identical or different end groups and a conjugated chain containing an odd number of methine groups. There are many possibilities for changing the chromophore constitution: using new heterocyclic systems for the end groups, introducing specific substituents in either the chain or in the residues, branching of the polymethine chromophore, replacement of the methine groups by heteroatoms, and cyclization of the chain by conjugated or unconjugated bridges.

General Aspects. As a rule, the end-group synthones have the following reactive centers: an activated methyl or methylene group with high CH acidity, a functional group (OR, SR, X(halide), NR_2) leaving as an anion in the reaction, and a carbonyl or heteroanalogous group as a leaving group. Complementary reactive centers are needed in the chain synthones in the α- and ω-positions. In particular, derivatives of formic acid are used to prepare monomethine dyes; for dyes with longer chromophores, the application of vinylogous aminals or ω-methylpolyenals are preferred.

Molecular Design

Extension of the applications of polymethine dyes has required special spectral and other characteristics. As a rule, the search for and synthesis of promising new compounds having desired properties imply the preliminary estimation of their most important parameters on the basis of elaborated theoretical conceptions. Thus, an effective way of governing electron properties consists of the variation of molecular topology of polymethines.

The first encouraging results for engineered dyes having desired ground- and excited-state properties were reported in 1992. To design effective spectral sensitizers, it is necessary to engineer dyes having special positions of their frontier levels, desired wavelengths of the absorption band, and special thermodynamic stability after light excitation.

Also, using dyes as laser media or passive mode-locked compounds requires numerous special parameters, the most important of which are the band position and bandwidth of absorption and fluorescence, the luminescence quantum efficiency, the Stokes shift, the possibility of photoisomerization, chemical stability, and photostability. Applications of PMDs in other technical or scientific areas have additional special requirements.

POLYMETHYLBENZENES. Polymethylbenzenes (PMBs) are aromatic compounds that contain a benzene ring and three to six methyl group substituents (for the lower homologues see **Benzene**; **Toluene**; **Xylenes and Ethylbenzene**). Included are the trimethylbenzenes, C_9H_{12} (mesitylene (**1**), pseudocumene (**2**), and hemimellitene (**3**)), the tetramethylbenzenes, $C_{10}H_{14}$ (durene (**4**), isodurene (**5**), and prehnitene (**6**)), pentamethylbenzene, $C_{11}H_{16}$ (**7**), and hexamethylbenzene, $C_{12}H_{18}$ (**8**). The PMBs are primarily basic building blocks for more complex chemical intermediates.

Physical Properties

The structures of the eight PMBs are shown here and their physical and thermodynamic properties are given in Table 1.

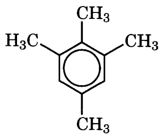
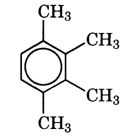
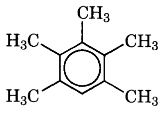
(**4**)



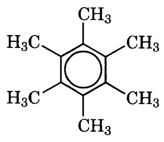
(**5**)



(**6**)



(**7**)



(**8**)

Manufacture

High purity mesitylene, hemimellitene, and durene are often produced synthetically, whereas pseudocumene is obtained from extracted C_9 reformate by superfractionation.

Koch Chemical Company is the only U.S. supplier of all PMBs (except hexamethylbenzene).

Health and Safety Factors

The PMBs, as higher homologues of toluene and xylenes, are handled in a similar manner, even though their flash points are higher (see Table 1). Containers are tightly closed and use areas should be ventilated. Breathing vapors and contact with the skin should be avoided.

Uses

Pseudocumene is used as a component in liquid scintillation cocktails for clinical analyses. Pseudocumene and durene are oxidized to trimellitic anhydride and pyromellitic dianhydride, respectively. Mesitylene is a key building block for important antioxidants and agricultural chemicals. Prehnitene, isodurene, pentamethylbenzene, and hexamethylbenzene

POLYMORPHISM. 1. A phenomenon in which a substance exhibits different forms. Dimorphic substances appear in two solid forms, whereas trimorphic exist in three, as sulfur, carbon, tin, silver iodide, and calcium carbonate. Polymorphism is usually restricted to the solid state. Polymorphs yield identical solutions and vapors (if vaporizable). The relation between them has been termed "physical isomerism." See **Allotropes** under **Chemical Elements**. See also **Mineralogy**.

2. The occurrence of individuals of distinctly different structure or appearance within a species. In many cases two such forms occur and the species is said to be dimorphic rather than polymorphic.

Polymorphism depends upon many different conditions in various groups of animals. The various forms may be adapted for different places in a life cycle, for special parts in a colonial or social organization, or for special stages in a metamorphosis. They may also result from the incidence of different environmental conditions due to seasons or to unusual climatic conditions.

POLYOL. A polyhydric alcohol, i.e., one containing three or more hydroxyl groups. Those having three hydroxyl groups (trihydric) are glycerols; those with more than three are called sugar alcohols, with general formula $CH_2OH(CHOH)_nCH_2OH$, where n may be from 2 to 5. These react with aldehydes and ketones to form acetals and ketals.

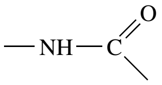
See also **Alcohols**; and **Glycerol**.

POLYOLEFIN. A class or group name for thermoplastic polymers derived from simple olefins; among the more important are polyethylene, polyproplene, polybutenes, polyisoprene, and their copolymers. Many are produced in the form of fibers. This group comprises the largest tonnage of all thermoplastics produced.

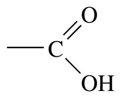
See also **Elastomers**; **Polyethylene**; **Polypropylene**; and **Thermoplastic**.

POLYORGANOSILICATE GRAFT POLYMER. An organoclay to which a monomer or an active polymer has been chemically bonded, often by the use of ionizing radiation. An example is the bonding of styrene to a polysilicate containing vinyl radicals, resulting in the growth of polystyrene chains from the surface of the silicate. Such complexes are stable to organic solvents. They have considerable use potential in the ion-exchange field, as ablative agents, reinforcing agents, and hydraulic fluids.

POLYPEPTIDE. A compound composed of two or more amino acids, similar in many properties to the natural peptones. The amino acids are joined by peptide groups



formed by the reaction between an $-NH_2$ group and a



group, whereby there is elimination of a molecule of water, and formation of a valence bond. They may be termed di-, tri-, tetra-, etc., peptide according to the number of amino acids present in the molecule.

The sequence of amino acids in the chain of a protein is of critical importance in the biological functioning of the protein, and its determination is very difficult. The chains may be relatively straight, or they may be coiled or helical. In the case of certain types of polypeptides, such as the keratins, they are crosslinked by the disulfide bonds of cystine. Linear polypeptides can be regarded as proteins. See also **Amino Acids**; and **Proteins**.

R.C.V.

POLYPROPYLENE. [CAS: 9003-07-0]. A synthetic crystalline thermoplastic polymer, $(C_3H_5)_n$, with molecular weight of 40,000 or more. Low-molecular-weight polymers are also known which are amorphous in structure and used as gasoline additives, detergent intermediates, greases, sealant, and lubricating oil additives. They are also available as high-melting-point waxes.

Polypropylenes are derived by the polymerization of propylene with stereospecific catalyst, such as aluminum alkyl. These polymers are translucent, white solids, insoluble in cold organic solvents, softened by hot solvents. They maintain their strength after repeated flexing. They are degraded by heat and light unless protected by antioxidants. Polypropylenes are readily colored, exhibit good electrical resistance, low water absorption and moisture permeability. They have rather poor impact strength below 15°F (−9.5°C). They are not attacked by fungi or bacteria, resist strong acids and alkalies up to about 140°F (60°C), but are attacked by chlorine, fuming nitric acid, and other strong oxidizing agents. They are combustible, but slow burning.

Polypropylenes are available as molding powder, extruded sheet, cast film, textile staple, and continuous-filament yarn. They find use in packaging film; molded parts for automobiles, appliances, and housewares; wire and cable coating; food container closures; bottles; printing plates; carpet and upholstery fibers; storage battery cases; crates for soft-drink bottles; laboratory ware; trays; fish nets; surgical casts; and a variety of other applications.

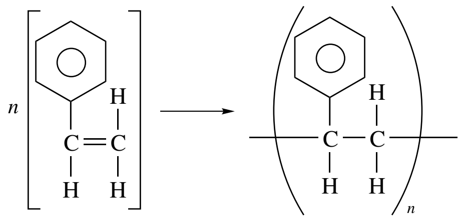
See also **Fibers**; and **Polymers**.

POLYSTYRENE. [CAS: 9003-53-6]. General purpose (or crystal) polystyrene is a clear, water-white, glassy polymer commonly derived from coal tar and petroleum gas. Physical properties of this material can be altered by addition of modifying agents, such as rubber (for increased toughness), methyl or α-methyl styrene (for heat resistance, methyl methacrylate (for improved light stability), and acrylonitrile (for chemical resistance). In general, varying the level of modifying agent (e.g., comonomer) will alter the level of desired property improvement.

Special grades of polystyrene include impact polystyrene modified with ignition-resistant chemical additives. These were developed because of increased emphasis on product safety and used in many electrical and electronic appliances. The addition of flame-retardant chemicals does not make the polymer noncombustible, but increases its resistance to ignition and decreases the rate of burning when exposed to a minor fire source.

Chemistry

The polymerization of styrene is an exothermic chain reaction which proceeds by all known polymerization techniques. This reaction can be shown schematically as:



The exact nature of the beginning and end of such a polymer chain is not certain. In general, the polymer can be characterized by its average degree of polymerization, i.e., the value of n, or more precisely by the distribution of n values. The heat of polymerization is 17.4 ± 0.2 kcal/mole at 26.9°C. The reaction may be initiated by heat or by means of catalysts. Organic peroxides are typical initiators. Styrene also will polymerize in the presence of various inert materials, such as solvents, fillers, dyes, pigments, plasticizers, rubbers, and resins. Moreover, it forms a variety of copolymers with other mono- and polyvinyl monomers.

It is a matter of general observation that with styrene, the polymerization-rate curves will exhibit three distinct phases, the nature of which can be determined by the polymerization conditions and the purity of the monomer: (1) an initial slow period at the beginning of the reaction, known as the *induction period*, which appears to be associated with the presence of an inhibitor or other impurity in the monomer; (2) a period of relatively rapid polymerization, which persists almost to the end of the reaction, and for which the rate is exponentially dependent upon temperature; and (3) a final slowing down in rate as the reaction approaches completion and the monomer becomes exhausted. This effect is particularly apparent at low temperatures with relatively impure monomers.

General Properties

The *specific gravity* of general purpose and impact polystyrene is 1.05. It can vary for copolymers. It is higher for some specialty grades. Density varies slightly with pressure, but for practical purposes, the polymer is noncompressible.

In terms of *heat-resistance*, deflection temperatures range from about 66 to 99°C (170 to 215°F), depending upon the formulation. Continuous resistance to heat for polystyrene is usually 60 to 80°C (140 to 175°F). Time and load have a significant influence on the useful service temperature of a part.

Polystyrene is nontoxic when free from additives and residuals. It has no nutritive value and does not support fungus or bacterial growth.

Dimensional stability of polystyrene resins is excellent. Mold shrinkage is small. The low moisture absorption (about 0.02%) allows fabricated parts to maintain dimensions and strength in humid environments.

General-purpose polystyrene is water white, and transmission of visible light is about 90%. Modifiers reduce this property, and translucence results. The refractive index is about 1.59; critical angle about 39. Polystyrene molecules do not have the same optical properties in all directions. When molecules become oriented in a given direction during fabrication, a double refraction occurs and a birefringence effect can be observed if the part is examined through a polarized lens under a polarized light source. Injection moldings often exhibit birefringence in a random pattern. This can be beneficial if the birefringence is in the direction of load.

In terms of *weatherability*, polystyrene does not exhibit ultraviolet stability and is not considered weather-resistant as a clear material. Continuous, long-term exposure results in discoloration and reduction of strength. Improvement in weatherability can be obtained by the addition of ultraviolet absorbers, or by incorporating pigments. The best pigmenting results are obtained with finely dispersed carbon black.

In terms of *chemical resistance*, polystyrene has a high resistance to water, acids, bases, alcohols, and detergents. Chlorinated solvents will mar the surface and, in the presence of an external load or high internal stresses, will cause failure. Aliphatic and aromatic hydrocarbons, in general, will dissolve polystyrene. Such foodstuffs as butter and coconut oil should be avoided. The chemical resistance depends upon chemical concentration, time, and stress.

Typical mechanical properties of polystyrene are given in the accompanying table. The long-term load-bearing strength of most polystyrene materials is about one-third of the typical tensile strength given in Table 1.

Uses

Packaging applications are the most extensive. Meat, poultry, and egg containers are thermoformed from extruded foamed polystyrene sheet. The fast-food market also accounts for a substantial amount of polystyrene for takeout containers where the insulation value of a foamed container is an advantage. Containers, tubs, and trays formed from extruded impact polystyrene sheets are used for packaging a large variety of food. Biaxially oriented polystyrene film is thermoformed into blister packs, meat trays, container lids, and cookie, candy, pastry, and other food packages where clarity is required.

TABLE 1. COMPRESSION MOLDED PROPERTIES OF POLYSTYRENE

Property	General purpose psi (MPa)	Impact psi (MPa)
Tensile strength	5500–8000 (38–55)	2500–5000 (17–35)
Compressive strength	21,000–16,000 (145–110)	4500–9000 (31–62)
Flexural strength	9000–15,000 (62–104)	5000–10,000 (35–69)
Tensile (Young's) modulus	400,000–500,000 (2760–3450)	200,000–400,000 (1880–2760)
Impact strength, Izod, foot-pounds/inch	0.3–0.5	1–4
Hardness, Rockwell M	65–80	60
Elongation, %	0.8–2.0	5–50

Housewares is another large segment of the use of polystyrenes. Refrigerator door liners and furniture panels are typical thermoformed impact polystyrene applications. Extruded profiles of solid or foamed impact polystyrene are used for mirror or picture frames, and moldings for construction applications.

General-purpose polystyrene is extruded either clear or embossed for room dividers, shower doors, glazings, and lighting applications. Injection molding of impact polystyrene is used for household items, such as flower pots, personal care products, and toys. General-purpose polystyrene is used for cutlery, bottles, combs, disposable tumblers, dishes, and trays.

Injection blow molding can be used to convert polystyrene into bottles, jars, and other types of open containers.

Impact polystyrene with ignition-resistant additives is used for appliance housings, such as those for television and small appliances. Structural foam impact polystyrene modified with flame-retardant additives is used for business machine housings and in furniture because of its decorability and ease of processing. Consumer electronics, such as cassettes, reels, and housings, is a fast growing area for use of polystyrenes. Medical applications include sample collectors, petri dishes, and test tubes.

In an effort to make homes and other buildings more energy efficient, the use of polystyrenes in extruded foam board with flame-retardant additives for walls and under slabs has experienced exceptional growth in recent years. Used as a sheeting material, extruded foam board complies with the requirements of the major building codes as well as federal and military specifications.

In general, polystyrene is used in applications where ease of fabrication and decorability are required. Polystyrene has excellent electrical properties, good thermal and dimensional stability, resistance to staining, and low cost. General purpose polystyrene is preferred where clarity is also of prime concern. Impact polystyrene is preferred where toughness is needed.)

POLYSULFONE. This is a transparent, heat-resistant, ultrastable high-performance engineering thermoplastic. It is amorphous in nature and has low flammability and smoke emission. It possesses good electrical properties that remain relatively unchanged up to temperatures near its glass transition temperature of 374°F (190°C). The molecular structure of polysulfone features the diaryl sulfone group. This group tends to attract electrons from the phenyl rings. Oxygen atoms para to the sulfone group enhance resonance and produce oxidation resistance. High resonance also strengthens the bonds spatially, fixing the grouping into a planar configuration. The polymer consequently has good thermal stability and rigidity at high temperatures. Ether linkages provide chain flexibility, thereby imparting good impact strength. The polymer resists hydrolysis and aqueous acid and alkaline environments, because the linkages connecting the benzene rings are hydrolytically stable.

Polysulfone is available in transparent and opaque colors in both molding and extrusion grades (unfilled). A special medical grade meets U.S.P. criteria. Two mineral-filled grades are available; one is designed specifically for plating using conventional techniques; the other is a combination of polysulfone compounds with glass fiber or beads as well as other fillers, such as *Teflon*.

Polysulfone is widely used in medical instrumentation and trays to hold instruments during sterilization. It is also used in food processing equipment, including piping, scraper blades, milking machines, steam Tables, microwave oven cookware, coffee makers, coffee decanters, and beverage dispensing tanks. Electrical/electronic uses include connectors, fuse and switch housings, coil bobbins and cores, TV components, capacitor film, and structural circuit boards. In chemical processing equipment, uses are found in corrosion-resistant piping, both transparent and glass fiber-bonded, tower packing, pumps, filter modules, and membranes.

Polysulfone has high resistance to acids, alkalies, and salt solutions, and good resistance to detergents, oils, and alcohols, even at elevated temperatures under moderate stress. It is attacked by polar organic solvents, such as ketones, chlorinated hydrocarbons, and aromatic hydrocarbons. Polysulfone can be used continuously in steam at temperatures up to 300°F (149°C). Maximum stress in water at 180°F (82°C) is about 2000 psi (14 mPa) for steady loads and up to 2500 psi (17 mPa) for intermittent loads. Polysulfone offers a good combination of electrical properties—dielectric strength and volume resistivity are high, while dielectric constant and dissipation factor are low. The latter two properties (which determine lossiness) remain relatively constant over a wide range of temperatures and frequencies (including microwave). Polysulfone can be plated by an electroless nickel or copper process.

POLYTROPIC PROCESSES. The expansion or compression of a constant weight of gas may assume a variety of forms, depending on the extent to which heat is added to or rejected from the gas during the process, and also on the work done. There are, theoretically, an infinite number of ways possible in which a gas may expand from an initial pressure p_1, and volume v_1 to a final volume v_2. All these expansions may be grouped generically as polytropic expansions, and all could be represented graphically on the PV plane by the family of curves $pv^n = C$. They are all, in theory, perfectly reversible. $n$may have any positive value, 0 to ∞, and having been selected numerically it defines the type of expansion. From the infinite number of possible polytropic expansions, it is worthwhile to isolate four that deserve special attention. When one of the four physical characteristics, to wit, pressure, temperature, entropy, or volume, remains constant, expansions of more than ordinary interest are denoted, since they are frequently employed in a practical way, in situations which can be subjected to thermodynamic analysis. The value of the exponent $n$of the polytropic family for each of these is:

isobaric	$n = 0$
isothermal	$n = 1$
isentropic	$n = \gamma$ (γ = ratio of specific heat at constant pressure to that at constant volume)
isometric	$n = \infty$

Note, however, that the first and last are limiting cases, since in the first the pressure remains constant, and in the fourth it approaches zero. Note also that the second applies strictly only to ideal gases.

These thermodynamic processes, as they occur in useful machines, are not often of the exact polytropic form desired. For example, an isentropic process, which is exemplified, at least theoretically, by expansion of the burned gases after the explosive combustion in the gasoline engine, is modified slightly by the interchanging of heat between gases and cylinder wall, whereas a true isentropic has no heat either added or rejected in this way. The particular polytropic curve that would suit these conditions of expansion would depart somewhat from the adiabatic form.

During a polytropic process conditions of the working medium are constantly varying, and analysis may be aimed at determining one of the following: the work done, the heat added, the variation of temperature, and the change of entropy. Some information may be obtained merely by comparing the value of the exponent n with certain other data. For example, if n lies between 0 and 1, the temperature rises during an expansion and falls during a compression; when n is greater than 1, the temperature falls during expansion and rises during compression. Also, when n is less than γ, heat must be added to obtain an expansion, whereas when it is greater than γ, heat must be expelled. From the above it will be noted that there is a certain range of polytropic expansion in which, although heat is added, the temperature falls. This may seem to some to be paradoxical, but it is readily explained. During these expansions work is being done by the gas at a rate greater than that at which heat is being added, with the result that the deficiency must be made up from within the gas. The only way that this may be accomplished is for the gas to cool and give up some of its internal energy.

The equations for work done and for heat added in the case of the general polytropic expansions are:

$$W = \frac{p_1 v_1 - p_2 v_2}{n - 1}$$

$$Q = (p_1 v_1 - p_2 v_2)\left(\frac{1}{n-1} - \frac{1}{\gamma - 1}\right)$$

Both of these are expressed in foot-pounds. Sometimes a substitution of a definite value of n in one or the other of these equations leads to an indeterminate; for example, with the isothermal,

$$W = \frac{p_1 v_1 - p_2 v_2}{1 - 1}$$

But since the equation of the isothermal for an ideal gas is

$$pv = C$$

$$p_1 v_1 = p_2 v_2$$

and the work equation becomes indeterminate,

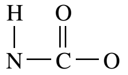
$$W = \frac{0}{0}$$

By approaching the isothermal from a different angle, however, the equation

$$W = pv \log_e \frac{v_2}{v_1}$$

may be deduced for work done.

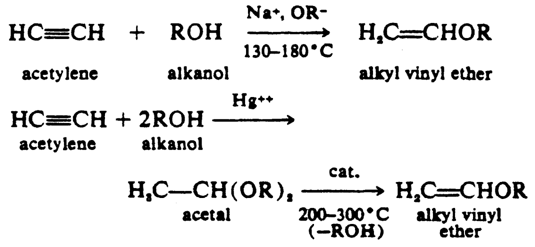
POLYURETHANES. [CAS: 9009-54-5]. These materials comprise a conglomerate family of polymers in which formation of the urethane group



is an important step in polymerization. Because the urethane linkage usually is formed by reaction of hydroxyl and isocyanate groups, urethane chemistry is the chemistry of isocyanates. The high reactivity of isocyanates and knowledge of the catalysis of isocyanate reactions have made possible the simple production of diverse polymers from low- to moderate-molecular-weight liquid starting materials. Several isocyanates (tolylene diisocyanate, hexamethylene diisocyanate, dicyclohexylmethane diisocyanate, etc.) are used in preparing polyurethanes. All are low-viscosity liquids at room temperature with the exception of 4, 4′-diphenylmethane diisocyanate (MDI), which is a crystalline solid. The aromatic isocyanates are more reactive than the aliphatic isocyanates and are widely used in urethane foams, coatings, and elastomers. The cyclic structure of aromatic and alicyclic isocyanates contributes to molecular stiffness in polyurethanes.

Flexible and rigid urethane foams, probably the most familiar of the polyurethanes, are produced in very large quantities. Foam formulations contain isocyanates and polyols with suitable catalysts, surfactants for stabilization of foam structure, and blowing agents, which produce gas for expansion. The largest volume of flexible urethane foam is used as a cushioning material. Expanding uses for flexible foam include carpet underlays and bedding. Weight reduction programs in the transportation field also take advantage of polyurethane forams for seating and trim. Rigid foams find application in insulation for appliances. Thermoplastic urethane elastomers form a widely used family of engineering materials, which appear to combine the best properties of elastomers and thermoplastics. They are tough, have high load-bearing capacity, low-temperature flexibility, and resistance to oils, fuels, oxygen, ozone, abrasion, and mechanical abuse. Possible carcinogenic properties are being studied. See also **Elastomers**; and **Urethane Polymers**.

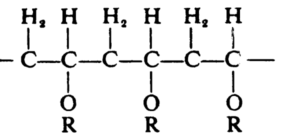
POLYVINYL ALKYL ETHERS. These products have properties which range from sticky resins to elastic solids. They are obtained by the low-temperature cationic polymerization of alkyl vinyl ethers having the general formula $ROCH{=}CH_2$. These monomers are prepared by the addition of the selected alkanol to acetylene in the presence of sodium alkoxide or mercury(II) catalyst. As shown by the following equations, the latter yields an acetal which must be thermally decomposed to produce the alkyl vinyl ether.



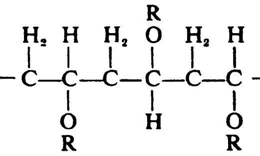
These monomers are also produced by an oxidative process in which the alkanols are added directly to ethylene and the alkyl ethers are thermally decomposed to produce hydrogen and the alkyl vinyl ethers.

Commercial polymers have been produced from methyl, ethyl, isopropyl, n-butyl, isotubtyl, t-butyl, stearyl, benzyl and trimethylsilyl vinyl ethers. The poly(methyl vinyl ether) called PVM or Resyn is produced by the polymerization of the monomer by boron trifluoride in propane at −40°C in the presence of traces of an alkyl phenyl sulfide. The polymer may have isotactic, syndiotactic or stereoblock configurations depending on the solvent and catalyst used.

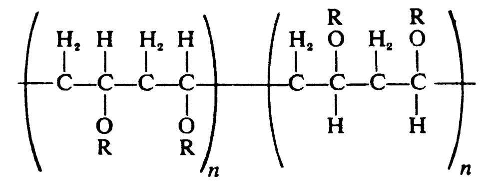
Nonpolar solvents favor the formation of ion pairs between the polymer cation and the counteranion and favor the production of isotactic polymers. Soluble catalysts, such as diethyl aluminum chloride and ethyl aluminum dichloride, also affect the stereoregularity of the polymer chains. The tendency for the formation of stereoregular polymers is decreased as the size of the alkyl group is increased. Typical structures of these polymers are shown below:



isotactic polymer



Syndiotactic polymer



stereoblock polymer

Poly(methyl vinyl ether) is soluble in cold water but becomes insoluble in a reversible process when the temperature is raised to 35°C. This sticky polymer has a glass transition temperature of −20°C. It has been used as an adhesive and as a heat sensitizer for polymer latices.

Poly(vinyl ethyl ether) is soluble in ethanol, acetone and benzene. It is a rubbery product which may be cross-linked by heating with dicumyl peroxide. Poly(vinyl isobutyl ether), has a glass transition temperature of −5°C. It has been used as an adhesive for upholstery, cellophane and adhesive tape.

The processing properties of poly(vinyl chloride) has been improved by copolymerizing vinyl chloride with a small amount of vinyl alkyl ether. Copolymers of vinyl alkyl ethers and maleic anhydride are used as water soluble thickeners, paper additives, textile assistants and in cleaning formulations.

POLYVINYL CHLORIDE (PVC). [CAS: 9002-86-2]. The manufacture of polyvinyl chloride resins commences with the monomer, vinyl chloride, which is a gas, shipped and stored under pressure to keep it in a liquid state; bp −14°C, fp −160°C, density (20°C), 0.91. The monomer is produced by the reaction of hydrochloric acid with acetylene. This reaction can be carried out in either a liquid or gaseous state. In another technique, ethylene is reacted with chlorine to produce ethylene dichloride. This is then catalytically dehydrohalogenated to produce vinyl chloride. The by-product is hydrogen chloride. A later process, oxychlorination, permits the regeneration of chlorine from HCl for recycle to the process.

Polymerization may be carried out in any of the following manners:

(1) *Suspension*: a large particle size dispersion or suspension of vinyl chloride is made in water by addition of a small quantity of emulsifying agent. The product after polymerization and drying consists of granules.

(2) *Emulsion*: a larger quantity of emulsifier is employed, resulting in a fine particle size emulsion. The polymer after spray drying, is a finely divided powder suitable for use in organosols and plastisols.

(3) *Solution*: vinyl chloride is dissolved in a suitable solvent for polymerization. The resultant polymer may be sold in solution form, or dried and pelletized.

Emulsions may be polymerized by use of a water-soluble catalyst (initiator), such as potassium persulfate, or a monomer-soluble catalyst, such as benzoyl peroxide, lauroyl peroxide or azobisisobutyronitrile. Suspension and solution polymerizations employ the monomer soluble catalysts only. In addition to the above-mentioned initiators, diisopropyl peroxydi-carbonate may also be employed, where lower-temperature polymerization may be desired, e.g., to reduce branching and minimize degradation.

Because of the low level of emulsifiers and protective colloids, the suspension polymer types are most suitable for electrical applications and end uses requiring clarity. This form is also employed in the bulk of extrusion and molding applications. Cost is lower than for emulsion and solution forms. The emulsion or dispersion resins are employed mainly for organosol and plastisol applications where fast fusion with plasticizer at elevated temperature will occur as a result of the fine particle size of the resin.

Monomers such as vinyl acetate or vinylidene chloride may be copolymerized with vinyl chloride. Up to 15% of the comonomer may be employed. Vinyl acetate increases the solubility, film formation and adhesion. Processing or forming temperatures are generally lowered. Chemical resistance and tensile strength decrease with increasing amount of vinyl acetate.

Rigid Vinyls

These have been separated into two categories according to ASTM:

Type I is rigid PVC with excellent chemical resistance, physical properties and weathering resistance such as obtained from unplasticized high molecular weight PVC.

Type II has the added feature of high impact resistance but with slightly lower chemical and physical requirements.

Perhaps the most important applications for rigid PVC will be in building. This is a rapidly growing market. Fabrication is via extrusion. Examples of applications are pipe, siding, roofing shingles, panels, glazing, window and door frames, rain gutters and downspouts.

Blow-molded bottles, which exhibit excellent product resistance, and good clarity, are also expected to become an important outlet for rigid PVC.

Formulations for extrusion generally include light and heat stabilizers, lubricants, which facilitate molding, and colorants. These materials are generally purchased in a compounded ready to use cube form, in order to minimize irregularities in blending, etc.

The outstanding characteristics of these rigid vinyls are chemical, solvent and water resistance; resistance to weathering when properly stabilized, therefore permitting long-term outdoor exposure; and low cost. Abrasion and impact resistance are satisfactory.

A major deficiency is heat sensitivity. Here, degradation begins with the split-off of HCL. The resultant unsaturation leads to cross-linking and chain cission, causing a degradation of the physical properties. Maximum service temperature for continuous exposure should not exceed 150–175°C. Cold flow or creep is another deficiency, which leads to dimensional changes in materials under constant load, e.g., water pipe under constant service pressures will tend to enlarge in diameter, resulting in decreased strength; long spans of pipe or siding may sag. Temperature accelerates this effect.

PVC has a high coefficient of expansion, one of the highest for all plastic materials, and substantially higher than metals and wood. Therefore, design allowances must be made to provide for movement in order to avoid buckling, breakage, etc.

Flexible PVC

An unusually wide variety of products and usages are possible with plasticized vinyls. Typical applications include floor and wall coverings, boots, rainwear, jackets, upholstery, garden hose, electrical insulation, film and sheeting, foams and many others.

The primary processing techniques are by means of extrusion, calendering and molding. Special techniques involve organosols and plastisols.

Plasticizers used to develop the desired flexibility and performance are selected on the basis of cost and application requirements, e.g., temperature; service life; exposure to solvents, chemicals, water, UV, food; tensile strength; abrasion resistance; flexibility; tear strength, etc.

Plasticizers must be classed as *primary*, where high compatibility is limited, thus restricting the amount that can be tolerated. The addition of secondary plasticizers may import special properties or simply reduce cost (extender plasticizer).

Primary plasticizers may be further subdivided. The *phthalate* types are by far the most popular due to cost and ease of incorporation. Dioctyl phthalate and diisooctyl phthalate are typical of this class. They exhibit good general-purpose properties. *Phosphate* plasticizers are also important for general-purpose use. Typical of these are tritolyl phosphate and trixylenyl phosphate. These plasticizers also impart fire retardant properties. *Low-temperature* plasticizers, such as dibutyl sebacate, are used where good low-temperature flexibility is required. For maximum compatibility and minimum cost, a typical plasticizer combination would be a blend of 50% DOP and 50% dibutyl sebacate.

Polymeric plasticizers are generally polyesters with a relatively low molecular weight. They are used where resistance to high temperatures and freedom from migration and extraction are required. Polymerics are more difficult to incorporate, have poor low-temperature properties, and are expensive.

Epoxy plasticizers are epoxidized oils and esters. These are generally classed with the polymerics. However, molecular weight is lower. Therefore, resistance to extraction and heat are slightly inferior. Low-temperature properties are better and epoxies are more easily incorporated.

Extender plasticizers, which are used mainly to reduce cost, consist of chlorinated waxes, petroleum residues, etc. Incorporation of excessive amounts may result in exudation on aging. The chlorinated types decrease flammability.

Organosols and Plastisols

Plastisols are dispersions of powdered PVC resin in plasticizer. A typical composition would consist of 100 parts of PVC resin dispersed in 50 parts of DOP. The resultant paste when heated to 300°F (149°C) fuses or "fluxes into a solid plastic mass. Stability of this plastisol at room temperature may range from several weeks to several months depending on the plasticizers and resins employed.

An organosol is the same mixture as described above, with the addition of solvent to reduce viscosity. These find their major applications in coatings. The solvent is evaporated before fusion of the film. Various pigments, colorants, stabilizers and fillers may be added, depending on the desired properties. Emulsion polymerization resins are generally employed because of their fast fusion rates. Coarser particle sized PVC resins would require extended time at the elevated temperature.

Plastisols allow the use of inexpensive manufacturing techniques, such as slush and rotational molding, casting, dipping, etc. They are employed for the manufacture of a large variety of parts, e.g., toys, floor mats, handles and many others.

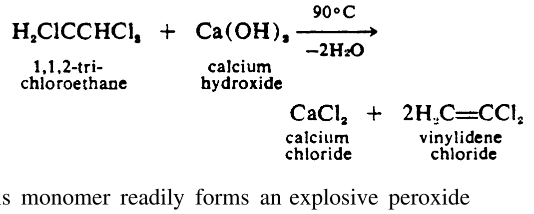
Foams are made by the addition of blowing agents to the plastisol. These may be continuously applied to a moving substrate which includes a pass at an elevated temperature where foaming occurs, followed by fusion of the plastisol.

Organosols find their major application in coatings, which may be applied by spray, dip, knife, roller, etc. Typical products are coated aluminum siding, fabrics, paper, industrial coatings, etc.

An important development was the use of plasticizers which crosslink upon application of heat and thus produce a more rigid end product. This extends the range of products obtainable by plastisol techniques into rigids. By varying the amount of crosslinking plasticizer incorporated, various levels of flexibility are obtained.

HAROLD A. SARVETNICK
Westfield, New Jersey

POLYVINYLIDENE CHLORIDE. [CAS: 9002-86-2]. A stereoregular, thermoplastic polymer is produced by the free-radical chain polymerization of vinylidene chloride ($H_2C{=}CCl_2$) using suspension or emulsion techniques. The monomer has a bp of 31.6°C and was first synthesized in 1838 by Regnault, who dehydrochlorinated 1,1,2-trichloroethane which he obtained by the chlorination of ethylene. The copolymer product has been produced under various names, including *Saran*. As shown by the following equation, the product, in production since the late 1930s, is produced by a reaction similar to that used by Regnault nearly a century earlier:



Since this monomer readily forms an explosive peroxide ,

it must be kept under a nitrogen atmosphere at −10°C in the absence of sunlight.

The copolymers were patented by Wiley, Scott, and Seymour in the early 1940s. A typical formulation for emulsion copolymerization contains vinylidene (85 g), vinyl chloride (15 g), methylhydroxypropylcellulose (0.05 g), lauroyl peroxide (0.3 g) and water (200 g). More than 95 per cent of these monomers are converted to copolymer when this aqueous suspension is agitated in an oxygen-free atmosphere for 40 hrs at 60°C. The glass transition temperature of the homopolymer is −17°C. It has a specific gravity of 1.875 and a solubility parameter of 9.8.

Because of its high crystallinity, the homopolymer (PVDV) is insoluble in most solvents at room temperature. However, since the regularity of repeating units in the chain is decreased by copolymerization, Saran is soluble in cyclic ethers and aromatic ketones. This copolymer (100 g) is plasticized by the addition of α-methyl-benzyl ether (5 g), stabilized against ultraviolet light degradation by 5-chloro-2-hydroxybenzophenone (2.0 g) and heat stabilized by phenoxypropylene oxide (2.0 g).

The poly(vinylidene chloride-co-vinylchloride) may be injection molded and extruded. Extruded pipe and molded fittings which were produced in large quantity in the 1940s have been replaced to some extent by less expensive thermoplastics. A flat extruded filament is used for scouring pads and continuous extruded circular filament is used for the production of insect screening, filter clothes, fishing nets and automotive seat covers.

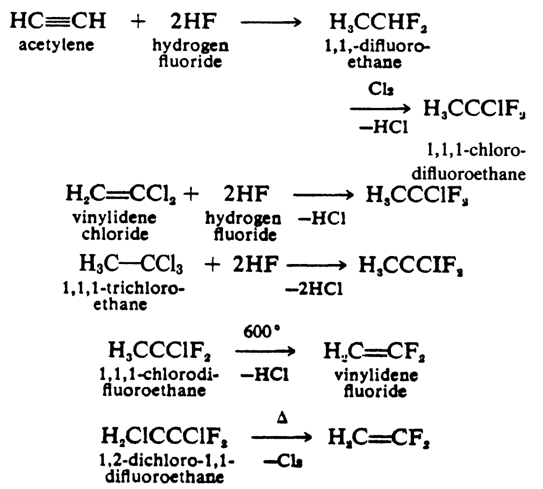
A large quantity of this copolymer is extruded as a thin tubing which is biaxally stretched by inflating with air at moderate temperatures before slitting. This product, called Saran Wrap, has a tensile strength of 15,000 psi (103 MPa). Since it has a high degree of transparency to light and a high coefficient of static friction (0.95) it is widely used for the protection of foods in the household. It has a low permeability value for gases such as oxygen and nitrogen.

Poly(vinylidene chloride-co-acrylonitrile) is widely used as a latex coating for cellophane, polyethylene and paper. Since this copolymer is soluble in organic solvents, it is also used as a solution coating. The resistance to vapor permeability and the ease of printing on polyethylene and cellophane is increased by coating with this vinylidene chloride copolymer.

The tensile strength of both film and fiber is increased tremendously by cold drawing 400–500 per cent. Thus, tensile strengths as high as 40,000 psi (276 MPa) in the direction of draw have been obtained by cold drawing.

RAYMOND B. SEYMOUR
University of Houston
Houston, Texas

POLVINYLIDENE FLUORIDE. This product is made by the free-radical chain polymerization of vinylidene fluoride ($H_2C{=}CF_2$). This odorless gas which has a boiling point of −82°C is produced by the thermal dehydrochlorination of 1,1,1-chlorodifluoroethane or by the dechlorination of 1,2-dichloro-1,1-difluoro-ethane. As shown by the following equations, 1,1,1-chlorodifluoroethane may be obtained by the hydrofluorination and



chlorination of acetylene and by the hydrofluorination of vinylidene chloride or of 1,1,1-trichloroethane.

Polyvinylidene fluoride is polymerized under pressure at 25–150°C in an emulsion using a fluorinated surfactant to minimize chain transfer with the emulsifying agent. Ammonium persulfate is used as the initiator. The homopolymer is highly crystalline and melts at 170°C. It can be injection molded to produce articles with a tensile strength of 7000 psi (48 MPa), a modulus of elasticity in tension of 1.2×10^5 psi and a heat deflection of 300°F (149°C).

Poly(vinylidene fluoride) is resistant to most acids and alkalies but it is attacked by fuming sulfuric acid. It is soluble in dimethylacetamide but is insoluble in less polar solvents. Copolymers have been produced with ethylene, tetrafluoroethylene, chlorotrifluoroethylene and hexafluoroethylene. The latter is an elastomer called Viton or Fluorel.

The homopolymer is used as a chemical resistant coating for steel, for tank linings, hose, and pump impellors. The elastomeric copolymer with hexafluoroethylene when cured with hexamethylenediamine is used as a seal, gasket, 0-ring, tubing, coating and lining.

POMERANZ-FRITSCH REACTION. Formation of isoquinolines by the acid-catalyzed cyclization of benzalaminoacetals prepared from aromatic aldehydes and aminoacetal.

PORCELAIN. ($4K_2O{\bullet}Al_2O_3{\bullet}3SiO_2$), high impact strength; impermeable to liquids and gases; resistant to chemicals except hydrogen fluoride and hot, strong caustic solutions; usable up to 1093°C but subject to heat shock. D 2.41, Mohs hardness 6–7, compression strength 100,000 psi. Porcelain is a mixture of clays, quartz, and feldspar usually containing at least 25% alumina. Ball and china clays are ordinarily used. A slip or slurry is formed with water to form a plastic, moldable mass, which is then glazed and fired to hard, smooth solid.

Uses

Reaction vessels, spark plugs, electrical resistors, electron tubes, corrosion-resistant equipment, ball mills and grinders, food-processing equipment, piping, valves, pumps, and laboratory ware.

See also **Ceramics**; **Porcelain Enamel**; and **Porcelain, Zircon**.

PORCELAIN ENAMEL. A substantially vitreous inorganic coating bonded to metal by fusion above 426°C (ASTM). Composed of various blends of low-sodium frit, clay, feldspar, and other silicates; ground in a ball mill; and sprayed onto a metal surface (steel, iron, or aluminum), to which it bonds firmly after firing, giving a glasslike fire-polished surface.

PORCELAIN, ZIRCON. ($ZrO_2{\bullet}SiO_2$). A special high-temperature porcelain used for spark plugs and furnace trays because of its high mechanical strength and heat-shock resistance. Usable up to 1700°C with high dielectric strength but rather lower power factor at high frequencies.

PORE. 1. A minute cavity in epidermal tissue as in skin, leaves, or leather, having a capillary channel to the surface that permits transport of water vapor from within outward but not the reverse. 2. A void of interstice between particles of a solid such as sand minerals or powdered metals, that permits passage of liquids or gases through the material in either direction. In some structures, such as gaseous diffusion barriers and molecular sieves, the pores are of molecular dimensions, i.e., 4–10 Å units. Such microporous structures are useful for filtration and molecular separation purposes in various industrial operations. 3. A cell in a spongy structure made by gas formation (foamed plastic) that absorbs water on immersion but releases it when stressed.

See also **Molecular Sieves**; and **Semipermeable Membrane (or Semipermeable Diaphragm)**.

POROMERIC. A term coined to describe the microporosity, air permeability, and water and abrasion resistance of natural and synthetic leather. The pores decrease in diameter from the inner surface to the outer and thus permit air and water vapor to leave the material while excluding water from the outside. Polyester-reinforced urethane resins have been used as leather substitutes with some success, primarily for shoe uppers.

PORPHYRIN. Any of several physiologically active nitrogenous compounds occurring widely in nature. The parent structure is comprised of four pyrrole rings, shown in I, II, III, and IV in Fig. 1, together with

four nitrogen atoms and two replaceable hydrogens, for which various metal atoms can be readily substituted. A metal-free porphyrin molecule has the structure shown in the diagram. Porphyrins of this type have been made synthetically by passing an electric current through a mixture of ammonia, methane, and water vapor. Some biochemists suggest that this phenomenon may account for the early formation of chlorophyll and other porphyrins which have been essential factors in the development of life.

The most important porphyrin derivatives are characterized by a central metal atom; hemin is the iron-containing porphyrin essential to mammalian blood, and chlorophyll is the magnesium-containing porphyrin that catalyzes photosynthesis. Other derivatives include the cytochromes, which function in cellular metabolism, and the phthalocyanine group of dyes. Porphyrins are described in considerable detail in a 20-volume set of books, The Porphyrin Handbook, Academic Press, New York, NY, 2003.

PORPHYRY. Porphyry is a textural term applied to igneous rocks in which one or more of the mineral constituents present exists as well crystallized individuals in a ground mass that is relatively of much finer grain. The derivation of the word presents an interesting study. The gasteropods of the genus *Murex* were much used for obtaining a purple dye; the Greek name for both the animal and the dye is the same. A certain Egyptian rock which was once much used for building and ornamental purposes displays very prominent crystals in a purplish groundmass and so the same Greek word was applied to it, then later came to mean all rocks of this general appearance. Modern use now restricts the term porphyry to the description of texture alone as in the case of the Egyptian rock.

PORTER, GEORGE (1920–2002). An English chemist who won the Nobel prize for chemistry in 1967 with Manfred Eigen and Ronald George Wreyford Norrish. His research concerned fast chemical reactions wand the chemistry of photosynthesis. He was educated at Cambridge University and taught there before going on to other posts.

PORTLAND CEMENT. See **Cement**; **Gypsum**.

POSITRON. The positron is one of many fundamental bits of matter. Its rest mass (9.109×10^{-31} kilogram) is the same as the mass of the electron, and its charge ($+1.602 \times 10^{-19}$ coulomb) is the same magnitude, but opposite in sign to that of the electron. The positron and electron are antiparticles for each other. The positron has spin 1/2 and is described by Fermi-Dirac statistics, as is the electron.

The positron was discovered in 1932 by C.D. Anderson at the California Institute of Technology while doing cloud chamber experiments on cosmic rays. The cloud chamber tracks of some particles were observed to curve in such a direction in a magnetic field that the charge had to be positive. In all other respects, the tracks resembled those of high-energy electrons. The discovery of the positron was in accord with the theoretical work of Dirac on the negative energy of electrons. These negative energy states were interpreted as predicting the existence of a positively charged particle.

Positrons can be produced by either nuclear decay or the transformation of the energy of a gamma ray into an electron-positron pair. In nuclei that are proton-rich, a mode of decay that permits a reduction in the number of protons with a small expenditure of energy is positron emission. The reaction taking place during decay is

$$p^+ \rightarrow n^0 + e^+ + v$$

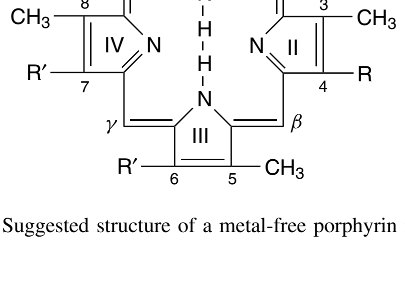


Fig. 1. Suggested structure of a metal-free porphyrin molecule

where p^+ represents the proton, n^0 the neutron, e^+ the positron, and v a massless, chargeless entity called a neutrino. See also **Neutrino**. The positron and neutrino are emitted from the nucleus while the neutron remains bound within the nucleus. Although none of the naturally occurring radioactive nuclides are positron emitters, many artificial radioisotopes that decay by positron emission have been produced. The first observed case of positron decay of nuclei was also the first observed case of artificial radioactivity. An example of such a nuclear decay is

$$_{11}\text{Na}^{22} \longrightarrow {}_{10}\text{Ne}^{22} + e^+ + v \text{ (half-life2.6 years)}$$

This decay provides a practical, usable source of positrons for experimental purposes.

The process of pair production occurs when a high-energy gamma ray interacts in the electromagnetic field of a nucleus to create a pair of particles—a positron and an electron. Pair production is an excellent example of the fact that the rest mass of a particle represents a fixed amount of energy. Since the rest energy ($E_{\text{rest}} = m_{\text{rest}} - c^2$) of the positron plus electron is 1.022 MeV, this energy is the gamma energy threshold and no pair production can take place for lower-energy gammas. In general, the cross section for pair production increases with increasing gamma energy and also with increasing Z number of the nucleus in whose electromagnetic field the interaction takes place.

The positron is a stable particle (i.e., it does not decay itself), but when it is combined with its antiparticle, the electron, the two annihilate each other and the total energy of the particles appears in the form of gamma rays. Before annihilation with an electron, most positrons come to thermal equilibrium with their surroundings. In the process of losing energy and becoming thermalized, a high-energy positron interacts with its surroundings in almost the same way as does the electron. Thus, for positrons, curves of distance traversed in a medium as a function of initial particle energy are almost identical with those of electrons.

It is energetically possible for a positron and an electron to form a bound system similar to the hydrogen atom, with the positron taking the place of the proton. This bound system has been called "positronium" and the chemical symbol Ps has been assigned. Although the possibility of positronium formation was predicted as early as 1934, the first experimental demonstration of its existence came in 1951 during an investigation of positron annihilation rates in gases as a function of pressure. The energy levels of positronium are about one-half those of the hydrogen atom, since the reduced mass of positronium is about one-half that of the hydrogen atom. This also causes the radius of the positronium system to be about twice that of the hydrogen atom.

In principle, positronium can be observed through the emission of its characteristic spectral lines, which should be similar to hydrogen's except that the wavelengths of all corresponding lines are doubled. Positronium is also the ideal system in which the calculations of quantum electrodynamics can be compared with experimental results. Measurement of the fine-structure splitting of the positronium ground state has served as an important confirmation of the theory of quantum electrodynamics.

It is possible for a positron–electron system to annihilate with the emission of one, two, three, or more gamma rays. However, not all processes are equally probable.

POSITRONIUM. A quasi-stable system consisting of a positron and a negatron bound together. Its set of energy levels is similar to that of the hydrogen atom (electron and proton). However, because of the different reduced mass, the frequencies associated with the spectral lines are less than half of those of the corresponding hydrogen lines. The mean life of positronium is at most about 10^{-7} seconds, its existence being terminated by negatron-positron annihilation. See also **Positron**.

POTASSIUM. [CAS: 7440-09-7]. Chemical element, symbol K, at. no. 19, at. wt. 39.098, periodic table group 1 (alkali metals), mp 63.3°C, bp 760°C, density 0.86 g/cm^3 (20°C). Elemental potassium has a body-centered cubic crystal structure. Potassium is a silver-white metal, can be readily molded, and cut by a knife, oxidizes instantly on exposure to air, and reacts violently with H_2O, yielding potassium hydroxide and hydrogen gas, which burns spontaneously in air with a violet flame due to volatilized potassium element, is preserved under kerosene, burns in air at a red heat with a violet flame. Discovered by Davy in 1807.

There are three naturally occurring isotopes, ^{39}K through ^{41}K, of which ^{40}K is radioactive with a half-life of 1.3×10^9 years. In ordinary potassium, this isotope represents only 0.0119% of the content. There are four other known isotopes, all radioactive, ^{38}K and ^{42}K through ^{44}K, all with relatively short half-lives measured in minutes and hours. In terms of abundance, potassium ranks seventh among the elements occurring in the earth's crust. In terms of content in seawater, the element ranks eighth, with an estimated 1,800,000 tons of potassium per cubic mile (388,000 metric tons per cubic kilometer) of seawater. First ionization potential 4.339 eV; second, 31.66 eV. Oxidation potential $K \longrightarrow K^+ + e^-$, 2.924 V. Other important physical properties of potassium are given under **Chemical Elements**.

Potassium does not occur in nature in the free state because of its great chemical reactivity. The major basic potash chemical used as a source of potassium is potassium chloride, KCl. The potassium content of all potash sources generally is given in terms of the oxide K_2O. The majority of potash produced comes from mineral deposits that were formed by the evaporation of prehistoric lakes and seas which had become enriched in potassium salts leached from the soil. In addition to natural deposits of potassium salts, large concentrations of potassium also are found in some bodies of water, including the Great Salt Lake and the Salduro Marsh in Utah, the Dead Sea between Israel and Jordan, and Searles Lake in California. All of these brines are used for the commercial production of potash.

The main potassium minerals are sylvite, KCl, sylvinite, KCl/NaCl, carnallite, $KCl \cdot MgCl_2 \cdot 6H_2O$, kainite, $MgSO_4 \cdot KCl \cdot 3H_2O$, polyhalite, $K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$, langbeinite, $K_2SO_4 \cdot 2MgSO_4$, jarosite, $K_2Fe_6\ (OH)_{12}(SO_4)_4$, leucite, $K_2O \cdot Al_2O_3 \cdot 4SiO_2$, alunite, $K_2Al_6(OH)_{12}\ (SO_4)_4$, microcline, $K_2O \cdot Al_2O_3 \cdot 6SiO_2$, muscovite, $K_2O \cdot 3Al_2O_3 \cdot 6SiO_2 \cdot 2H_2O$, bio tite, $H_2K(Mg, Fe)_3(Al, Fe)(SiO_4)_3$, and orthoclase, $K_2O \cdot Al_2O_3 \cdot 6SiO_2$. See also **Alunite**; **Biotite**; and **Polyhalite**. The principal workable mineral deposits are in Stassfurt, Germany, Alsace, New Mexico, Saskatchewan, the former Soviet Union, Spain, Poland, Italy, the Atlantic Seaboard of the United States, and Utah. There are significant potassium reserves in many other parts of the world, notably in Canada and the former Soviet Union. World consumption of potash is about 18 million tons annually. Potassium metal is obtained by electrolysis of fused potassium hydroxide or chloride fluoride mixture in a specially designed cell.

Uses

Like so many of the chemical elements, the compounds of potassium are far more important than elemental potassium—by several orders of magnitude. The uses for metallic potassium are extremely limited, mainly because metallic sodium serves about the same needs and is much less costly. Sodium production, for example, exceeds potassium production by a factor of at least 1,000. A large amount of elemental potassium is used to produce the superoxide, KO_2 which finds application in gas-mask canisters. The compound also goes into the production of a sodium-potassium alloy, which is used as a heat-exchange medium. This alloy also has been used in magnetohydrodynamic power generation and as a catalyst for the removal of CO_2, H_2O, and oxygen from inert-gas systems. The handling precautions for potassium metal are similar to those for sodium metal. See also **Sodium**.

Chemistry and Compounds

Potassium is more electropositive than sodium in many of its reactions, as is consistent with its position in group 1. Its reaction with H_2O is more vigorous and it reacts violently with liquid bromine, and readily on heating with solid iodine.

Because of the ease of removal of its single 4s electron (4.339 eV) and the difficulty of removing a second electron (31.66 eV) potassium is exclusively monovalent in its compounds, which are electrovalent. (Some experimental work indicates that the potassium alkyls may be covalent, but even they form conducting solutions in other metal alkyls.)

Potassium solutions in liquid NH_3 react readily with the elements on the further right side of the periodic table to produce normal and poly compounds such as potassium sulfide, K_2S, and tetrapotassium plumbide, K_4Pb, in the first instance and K_2S_6 and K_4Pb_9 in the second. Ammoniates are not formed by potassium as readily as by sodium or lithium and solubility of salts exhibits a minimum at the cation: anion radius ratio of 0.75 (potassium fluoride, KF, 16 moles per kilogram, potassium chloride, KCl, 0.0177 moles per kilogram, potassium bromide, KBr, 2.26 moles per kilogram, potassium iodide, KI, 11.09 moles per kilogram). Potassium nitrate reacts in liquid ammonia with potassium amide, KNH_2 to form the azide, KN_3.

Like the other alkali metals, potassium forms compounds with virtually all the anions, organic as well as inorganic. Like sodium bicarbonate, the reactivity of potassium bicarbonate with many metallic oxides permits of the preparation of many compounds (such as the meta- and pyroarsenates) which are unstable in aqueous solution. For a general discussion of these reactions, and for a general picture of the inorganic salts of potassium, see the discussion of the compounds of sodium, which differ principally in their greater degree of hydration and greater number of hydrates. However, potassium, rubidium, and cesium coordinate with large organic molecules even though they do not with water. Potassium, like the others, coordinates with salicylaldehyde. It is believed to have two coordination numbers, 4 and 6. The tetracoordinate compounds of potassium (and sodium) are the most stable. The following reasons are given: (1) Increasing atomic number carries with it increasing electropositiveness and ease of ionization, which diminishes the tendency to coordinate. (2) The increasing distance of the nucleus from the coordinating electrons with increasing atomic volume makes it less likely that additional electrons will be held with ease. (3) On the other hand, there is an increase in the maximum coordination number with the elements of higher atomic number. These factors are in keeping with a maximum stability for the tetracoordinate compounds occurring with potassium.

Charge Density Waves in Potassium

Frequently, because of their relatively simple electronic structure, the alkali metals are selected as a basis for the study of the behavior of electrons in solids. As early as 1964, Overhauser (Purdue University) predicted the existence of "charge density waves," a phrase coined by Overhauser, in the potassium atom. This conclusion was the result of calculations made by Overhauser to the effect that K, in its lowest energy or ground state, does not exhibit a uniform distribution of its free electrons (which cause K to behave as a metal), but rather the electron density varies sinusoidally with a characteristic wavelength—and that this usually is not an integral multiple of the crystal lattice constant. This concept, of course, was not in agreement with the traditional conclusion that free electrons are uniformly distributed. The reasoning—the sinusoidal clumping lowers the electron energy, which in turn causes the lattice to distort and, as explained by Robinson (1986), this distortion is an attempt to reduce the huge electric fields generated by the separation between the positive charge of the K ions and the negative charge of the electrons.

At the time of Overhauser's work in 1964, experimental examples were not available and the concept was generally considered academic. Several years later, however, investigators working with layered materials (electrons essentially move in only two directions) and with linear conductors (motion is essentially in one direction) attributed a charge density wave phenomenon to what has been termed the Pierls instability. The latter effect, which involves lowering electron energy and lattice distortion, currently is not believed to apply to the simple, three-dimensional metals (K etc.). In summary, the Pierls instability and the Overhauser charge density waves concept appear to be similar, but different.

In 1985, Giebultowicz (National Bureau of Standards), Overhauser, and Werner (University of Missouri) conducted a neutron diffraction study and tentatively proved the Overhauser concept. Some solid-state physicists are seeking further evidence. If the concept is fully confirmed, some

modifications in the thinking of how electrons behave in solids may be required.

Salt-Forming Properties. One major difference between potassium and sodium in their salt-forming properties is the much greater ability of potassium to form alums, although potassium does not form quite as many types of these compounds as do the higher alkali metals, or ammonium or monovalent thallium.

Potassium also differs from sodium, and especially from lithium, in the greater stability of its salts of polarizable polyatomic anions, such as peroxide, superoxide, azide, polysulfide, polyhalides, etc. The rubidium and cesium salts, on the other hand, are even more stable.

Among the other inorganic compounds of potassium are the following:

Bromate. Potassium bromate, [CAS: 7758-01-2], $KBrO_3$, white solid, soluble, mp 434°C, upon heating oxygen is evolved and the residue is potassium bromide; formed by electrolysis of potassium bromide solution under proper conditions. Used as a source of bromate and bromic acid.

Carbonate. Potassium carbonate, [CAS: 584-08-7], potash, pearl ash, K_2CO_3, white solid, soluble, formed (1) in the ash when plant materials are burned, (2) by reaction of potassium hydroxide solution and the requisite amount of CO_2. Used (1) in making special glasses, (2) in the making of soft soap, (3) in the preparation of other potassium salts (a) in solution, (b) upon fusion; potassium hydrogen carbonate, potassium bicarbonate, potassium acid carbonate, $KHCO_3$, white solid, soluble, (4) in vat dyeing and textile printing, (5) in titanium enamels, (6) in boiler water treating compounds, (7) in photographic chemical formulations, (8) in electroplating baths, and (9) as an important absorbent for CO_2 in the process industries.

Chlorate. Potassium chlorate, [CAS: 3811-04-9], chlorate of potash, $KClO_3$, white solid, soluble, mp about 350°C, powerful oxidizing agent, and consequently a fire hazard with dry organic materials, such as clothes, and with sulfur; upon heating oxygen is liberated and the residue is potassium chloride; formed by electrolysis of potassium chloride solution under proper conditions. Used (1) in matches, (2) in pyrotechnics, (3) as disinfectant, (4) as a source of oxygen upon heating. (Hazardous! Use of potassium perchlorate is recommended instead.)

Chloride. Potassium chloride, [CAS: 7447-40-7], KCl, colorless or white crystals; strong saline taste. Occurs naturally as sylvite. Soluble in water; slightly soluble in alcohol. Sp. gr. 1.987; mp 772°C; sublimes at 1500°C; noncombustible; low toxicity. Used in fertilizers, as a source of potassium salts; pharmaceutical preparations; photography; spectroscopy; plant nutrient; salt substitute; laboratory reagent. See also **Fertilizer**.

Chloroplatinate. Potassium chloroplatinate, [CAS: 16921-30-5]. K_2PtCl_6, yellow solid, insoluble, formed by reaction of soluble potassium salt solution and chloroplatinic acid. Used in the quantitative determination of potassium.

Chromate. Potassium chromate, [CAS: 7789-00-6], K_2CrO_4, yellow solid, soluble, formed by reaction of potassium carbonate and chromite at a high temperature in a current of air, and then extracting with water and evaporating the solution. Used (1) as a source of chromate, (2) in leather tanning, (3) in textile dyeing, (4) in inks.

Cobaltinitrite. Dipotassium sodium cobaltinitrite, $K_2NaCo(NO_2)_6 \bullet H_2O$, golden yellow precipitate, formed by reaction of sodium cobaltinitrite solution in acetic acid with soluble potassium salt solution. Used in the detection of potassium.

Cyanate. Potassium cyanate, [CAS: 590-28-3], KCNO, white solid, soluble, formed along with lead metal by reaction of potassium cyanide and lead monoxide solids upon heating. Source of cyanate.

Cyanide. Potassium cyanide, [CAS: 151-50-8], cyanide of potash, KCN, white solid, soluble, very poisonous, formed by reaction of calcium cyanamide and potassium chloride at high temperature. Used as a source of cyanide and for hydrocyanic acid, but usually replaced by the cheaper sodium cyanide. Also used in metallurgy, electroplating, extraction of gold from ores, as a pesticide and fumigant, in photography and analytical chemistry. Upon acidification, produces dangerous HCN gas.

Dichromate. Potassium dichromate, [CAS: 7778-50-9], chromate of potash, $K_2Cr_2O_7$, red solid, soluble, powerful oxidizing agent, formed by acidifying potassium chromate solution and then evaporating. Used (1) in matches, (2) in leather tanning and in the textile industry, (3) as a source of chromate, (4) in pyrotechnics, (5) in colored glass, (6) as an important laboratory reagent, (7) in blueprint developing, and (8) in wood preservation formulations.

Hydroxide. Potassium hydroxide, [CAS: 1310-58-3], caustic potash, potassium hydrate, KOH, white solid, soluble, mp 380°C, formed (1) by reaction of potassium carbonate and calcium hydroxide in H_2O, and then separation of the solution and evaporation, (2) by electrolysis of potassium chloride under the proper conditions, and evaporation. Used in the preparation of potassium salts (1) in solution, and (2) upon fusion. Also used in the manufacture of (3) soaps, (4) drugs, (5) dyes, (6) alkaline batteries, (7) adhesives, (8) fertilizers, (9) alkylates, (10) for purifying industrial gases, (11) for scrubbing out traces of hydrofluoric acid in processing equipment, (12) as a drain-pipe cleaner, and (13) in asphalt emulsions.

Hypophosphite. Potassium hypophosphite, [CAS: 7782-87-8], KH_2PO_2, white solid, soluble, formed (1) by reaction of hypophosphorous acid and potassium carbonate solution, and then evaporating, (2) by reaction of potassium hydroxide solution and phosphorus on heating (poisonous phosphine gas evolved).

Iodate. Potassium iodate, [CAS: 7758-05-6], KIO_3, white solid, soluble, melting point 560°C, formed (1) by electrolysis of potassium iodide under proper conditions, (2) by reaction of iodine and potassium hydroxide solution, and the fractional crystallization of iodate from iodide. Used as a source of iodate and iodic acid.

Manganate. Potassium manganate, K_2MnO_4, green solid, soluble, permanent in alkali, formed by heating to high temperature manganese dioxide and potassium carbonate, and then extracting with water, and evaporating the solution. The first step in the preparation of potassium manganate and permanganate from pyrolusite.

Nitrate. Potassium nitrate, [CAS: 7757-79-1], saltpeter, niter, KNO_3, white solid, soluble, mp 333°C, formed by fractional crystallization of sodium nitrate and potassium chloride solutions. Used (1) in matches, explosives, pyrotechnics, (2) in the pickling of meat, (3) in glass, (4) in medicines, (5) as a rocket-fuel oxidizer, and (6) in the heat treatment of steel. See also **Fertilizer**.

Nitrite. Potassium nitrite, [CAS: 7758-09-0], KNO_2, yellowish-white solid, soluble, for med (1) by reaction of nitric oxide plus nitrogen tetroxide and potassium carbonate or hydroxide, and then evaporating, (2) by heating potassium nitrate and lead to a high temperature and then extracting the soluble portion (lead monoxide insoluble) with H_2O, and evaporating. Used as a reagent (diazotizing) in organic chemistry.

Oxides. See discussion later in entry.

Perchlorate. Potassium perchlorate, [CAS: 7778-74-7], $KClO_4$, white solid, very slightly soluble, mp 610°C, but above 400°C decomposes with evolution of oxygen gas and formation of potassium chloride residue; formed (1) by electrolysis of potassium chlorate under proper conditions, (2) by heating potassium chlorate at 480°C and then fractional crystallization. Used (1) as a convenient and safe (preferred to use of potassium chlorate) method of preparing oxygen by heating, (2) in the determination of potassium in soluble salt solution.

Periodate. Potassium periodate, [CAS: 7790-21-8], KIO_4, white solid, very slightly soluble, mp 582°C, formed by electrolysis of potassium iodate under proper conditions.

Permanganate. Potassium permanganate, [CAS: 7722-64-7], permanganate of potash $KMnO_4$, purple solid, soluble, formed by oxidation of acidified potassium manganate solution with chlorine, and then evaporating. Used (1) as disinfectant and bactericide, (2) in medicine, (3) as an important oxidizing agent in many chemical reactions.

Persulfate. Potassium persulfate, [CAS: 7727-21-1], $K_2S_2O_8$, white solid, slightly soluble, formed by electrolysis of potassium sulfate under proper conditions. Used (1) as a bleaching and oxidizing agent, (2) as an antiseptic.

Silicate. Potassium silicate, K_2SiO_3, colorless (when pure) glass, soluble, mp 976°C, formed by reaction of silicon oxide and potassium carbonate at high temperature, similar in properties and uses to the more common sodium silicate.

Sulfates. Potassium sulfate, [CAS: 7778-80-5], sulfate of potash, K_2SO_4, white solid, soluble. Common constituent of potassium salt minerals. Used (1) as an important potassium fertilizer, (2) in the preparation of potassium or potash alums; potassium hydrogen sulfate, $KHSO_4$, white solid, soluble; potassium pyrosulfate, $K_2S_2O_7$, white solid, soluble, formed by heating potassium hydrogen sulfate to complete loss of H_2O. See also **Fertilizer**.

Sulfides. Potassium sulfide, [CAS: 1312-73-8], K_2S, yellowish to reddish solid, soluble, formed by heating potassium sulfate and carbon to a high temperature; potassium hydrogen sulfide, potassium bisulfide, potassium acid sulfide KHS, formed in solution by reaction of potassium hydroxide or carbonate solution and excess H_2S.

Sulfite. Potassium sulfite, [CAS: 10117-38-1], $K_2SO_3 \cdot 2H_2O$; potassium hydrogen sulfite, $KHSO_3$; white solids, similar in properties and formation to the corresponding sodium sulfites.

Thiocarbonate. Potassium thiocarbonate, K_2CS_3, yellow solid, soluble, formed by reaction of potassium sulfide and CS_2.

Thiocyanate. Potassium thiocyanate, [CAS: 333-20-0], potassium sulfocyanide, potassium sulfocyanate, potassium rhodanate, KCNS, white solid, soluble, mp about 170°C, formed by fusing potassium cyanide and sulfur, and then crystallizing. Used as a source of thiocyanate.

In addition to the inorganic salts, potassium forms such binary compounds as a phosphide, K_3P, by direct union with phosphorus, a boride, KB_6, by electrolysis of fused fluorides and borates in the presence of a metal boride, a nitride, and the oxides. Of the latter, direction reaction of potassium and oxygen yields the superoxide, KO_2, a paramagnetic, orange-colored substance. The likelihood of KO_2 having a monomeric structure is supported by these properties, since the O_2^- ion would have an odd electron, which would confer paramagnetism and color upon the compound. The lower oxides of potassium, K_2O and K_2O_2, which are less stable in air than the superoxide, have been prepared, as have their hydrates. K_2O unites explosively with the oxygen of the air. One other oxide, K_2O_3, has been reported, but this appears to be a double salt of KO_2 and K_2O_2. The properties of potassium hydroxide are in keeping with its position in Group 1; thus its heat of solution is somewhat lower than that of rubidium hydroxide, RbOH, or cesium hydroxide, CsOH, and much higher than that of lithium hydroxide, LiOH, and NaOH.

The organic compounds of potassium include many oxycompounds, such as salts of organic acids, alcohols and phenols (alkoxides, phenoxides, etc.). A few potassium-carbon linked compounds have been reported, such as a phenylisopropyl potassium, $C_6H_5C_3H_7K$, and a carbonyl compound of unknown composition, $K_x(CO)_x$. The adduct of ethyl potassium and diethyl-zinc is a true salt, $K_2[Zn(C_2H_5)_4]$, potassium tetraethylzincate.

Health and Safety Factors

Reactions of potassium with water and oxygen are hazardous and safe handling is a concern. Potassium oxidizes slowly in air at room temperature, and it usually ignites if it sprays hot into the air. The peroxide and superoxide products may explode in contact with free potassium metal or organic materials including hydrocarbons. Thus, packaging (qv) under oils is less desirable than packaging under an inert cover gas or in a vacuum. Potassium can react with entrapped air in oils to form the superoxide. The encrustation of potassium with superoxide (as a yellow crust) developed during storage has been known to detonate by friction from cutting. Potassium encrusted with a peroxide and superoxide layer should be destroyed immediately by careful, controlled disposal.

Potassium forms corrosive potassium hydroxide and liberates explosive hydrogen gas upon reaction with water and moisture. Airborne potassium dusts or potassium combustion products attack mucous membranes and skin causing burns and skin cauterization. Inhalation and skin contact must be avoided. Safety goggles, full face shields, respirators, leather gloves, fire-resistant clothing, and a leather apron are considered minimum safety equipment.

POTASSIUM AND SODIUM (In Biological Systems). Potassium and sodium play major roles in biological processes. Because of the numerous parallels between these two elements in metabolism, they are treated in a single entry, with appropriate distinctions made.

Potassium is required by both plants and animals. Although the total amount of potassium in most soils is usually rather high, the level of available or soluble forms of the element is frequently too low to meet the needs of growing plants. Deficiencies of plant-available potassium are more frequent in the soils of the eastern rather than of the western United States. See also **Soil**. Potassium in the form of soluble potassium salts is a very common constituent of fertilizers. See also **Fertilizer**.

Many plants will not grow at normal rates unless the plant tissues, especially the leaves, contain as much as 1 or 2% potassium and, for some plants, even higher concentrations are required. Therefore, if a plant grows at all, it will nearly always contain sufficient potassium to meet the requirements of the people or animals that consume the plant. Potassium deficiencies do occur in humans and animals, but these are largely due to metabolic upsets and illnesses that interfere with the utilization of potassium in the body, or via excessive losses of potassium from the body, rather than due to inadequate levels of dietary potassium.

The general role of potassium fertilizers in improving human and animal nutrition is to help increase food and feed supplies rather than to improve the nutritional quality of the crops produced. Excessive use of potassium fertilizers may decrease the concentration of magnesium in crops. Sodium is essential to higher animals that regulate the composition of their body fluids and to some marine organisms, but it is dispensable for many bacteria and most plants except for the blue-green algae. Potassium, on the other hand, is essential for all, or nearly all forms of life. The importance of these cations for all forms of life has been related to the predominance of sodium and potassium in the ocean where primitive forms of life are thought to have originated and developed. During most of the period of evolvement of living organisms, there has been little change in the sodium and potassium content of seawater, either as to proportion or total amount. The body fluids of sea animals are, in most instances, similar to seawater in sodium and potassium level and ratio. In freshwater and terrestrial animals, the sodium and potassium level of body fluids is usually somewhat lower, and the ratio is likely to vary from the 40:1 ratio of seawater. Most fresh waters contain small and variable amounts of sodium and potassium, usually in a ratio of from 1:1 to 4:1.

Despite the higher level of sodium in natural water, potassium is universally the characteristic cation found within both plant and animal cells. Although sodium is not an absolute requirement for most plants and bacteria, it is found in these organisms and is essential to higher animals where it is the principal cation of the extracellular fluids. Sodium and potassium are important constituents of both intra- and extracellular fluids. Generally, the best external and internal medium for function of cells not adjusted to low salt levels is a medium involving a balance of sodium and potassium.

Beyond the osmotic effects depending on the sum of the concentration of the ions in the solution, Ringer found in 1882 that to maintain the

contractility of an isolated frog heart, it was necessary to perfuse it with a medium containing sodium, potassium, and calcium ions in the proportion of seawater. It has since been recognized that the normal life activities of tissues and cells may depend on a proper balance among the inorganic cations to which they are exposed. Sodium is required for the sustained contractility of mammalian muscle, while potassium has a paralyzing effect. Thus, a balance is necessary for normal function. Other investigators have found that the antagonism among univalent and divalent cations observed by Ringer is demonstrable with various simpler or more complicated organisms or biological systems.

Excessive salt in soil, such as soils recently soaked with seawater, is toxic to most plants, although there are many plants, e.g., those of the salt marshes and the sea, which are adapted to a high salt concentration. Ingestion of seawater by man as the only source of water is eventually fatal because of the inability of the body to eliminate salt at a concentration comparable to that of seawater. This results in accumulation of salt, with severe toxic effects and eventually fatal results.

It is probable that potassium is absorbed by the plant roots from the soil by an active transport mechanism which carries it through the cell wall structure. Similarly, potassium and sodium if required, are accumulated by animals also by active transport. The actual cellular content of potassium and sodium is likewise controlled by transport mechanisms that specifically move potassium in and sodium out of the cell against the concentration gradient. The energy for this is derived from the metabolic processes of the cell. The nature of these transport mechanisms has not been fully determined.

Ions and Transport Mechanisms

Potassium differs from most other essential constituents of plant and animal cells in that it is not built into the cell as a part of an organic compound, but is rather an ion from a soluble inorganic or organic salt. Potassium ions may chelate with cellular constituents, such as polyphosphates. The ion is of the correct size to fit into the water lattice adsorbed by the protein in the cell. In general, the potassium and sodium ions are attracted to protein or other colloidal or structural units having a negative charge. Mucopoly-saccharides within the cell, on the cell surfaces and of the intercellular structures, are of particular importance in holding cations, such as potassium and sodium. Active centers of other configurational features of the proteins in the cell may be affected or altered by the potassium held by electrostatic or covalent binding. There are several enzyme systems activated by potassium.

In general, most of the sodium and potassium in the animal is in a dynamic state, being exchanged between different parts of the cell, between the cell and the extracellular fluid, and intermixing with ingested sodium and potassium in body fluids.

Most cellular constituents do not selectively bind potassium in preference to sodium. Myosin of muscle fibers, for example, will bind either. But, in contrast, the mitochondria and ribosomes are organized cellular organelles able to selectively take up or extrude potassium. This accounts for only a part of the potassium held in the cell.

In blue-green algae and some yeasts, sodium may in part replace cellular potassium. While potassium is usually the principal cation concerned with the maintenance of the osmotic pressure within the cell, sodium contributes appreciably to the total, and amino acids and other organic compounds may help make up any deficit, particularly in marine invertebrates.

The sodium content of the body extracellular fluids of marine invertebrates from the coelenterate through the arthropod phyla is approximately that of seawater. In freshwater and terrestrial invertebrates, the sodium of body fluids varies over a wide range and there is considerable variation among vertebrates. There are both fish and crustaceans so highly adaptable that they are able to live in either fresh or salt water.

Osmotic Pressure Regulation

The regulation of osmotic pressure within the cell and the control of the passage of water into or out of the cell is dependent to a considerable extent on the control of the potassium and sodium in the cell by the transport systems of the cell wall. The cell wall itself is of protein-lipid composition and is in general impermeable to the passage of water and inorganic salts. Recent studies of the cell walls with electron microscopes and with the use of other investigative techniques indicate that the cell wall contains pores connecting the cell contents with the extracellular fluid, or in some plants, with other cells. In cells having an endoplasmic reticulum, the intracellular vacuolar system may have openings through the cell wall communicating with the extracellular fluid. The ease with which water passes in or out of the cell in response to changes in external or internal osmotic pressure varies over an extreme range, from easy passage to rigid control, depending on the cell and its functions.

Phagocytosis and pinocytosis may bring salts and water, as well as other substances, into the cell.

In some unicellular organisms, osmotic equilibrium may be maintained by a contractile vacuole, which collects water; in other organisms, water may be excreted through the cell wall. The kidney and sweat glands of higher animals, gills of fish and salt glands of birds serve to excrete salt. Most animals, through control of sodium and potassium excretion and loss, are able to adapt to a wide range of intake.

The importance of sodium chloride in nutrition has been recognized from the beginning of history. Agricultural populations that lived on cereal grains, nuts, berries, and other vegetable foods poor in sodium, experienced a hunger for salt which led them to go to great lengths to obtain the mineral. This was particularly true if they lived in a hot climate with the attendant increased loss of salt in perspiration. Similarly, herbivorous animals will travel long distances to supply their need for additional salt. In contrast, peoples or animals subsisting on meat, milk and other foods receive quite appreciable amounts of sodium salts in the diet, and experience no special desire or hunger for salt. See also **Sodium Chloride**.

In plants, the meristematic tissues in general are particularly rich in potassium, as are other metabolically active regions, such as buds, young leaves, and root tips. Potassium deficiency may produce both gross and microscopic changes in the structure of plants. Effects of deficiency reported include leaf damage, high or low water content of leaves, decreased photosynthesis, disturbed carbohydrate metabolism, low protein content and other abnormalities.

Since potassium is found abundantly in most natural foods consumed by animals, deficiency is ordinarily no problem. With prolonged maintenance through parenteral (intravenous) feeding when normal oral feeding is not possible, potassium must be supplied.

Role of Kidney

Experimental potassium deficiency in rats results in stunted growth, loss of chloride with hypochloremic acidosis, loss of potassium and increase of sodium in muscle. In man, disease of the gastrointestinal tract, involving loss of secretions through vomiting or diarrhea, may result in serious loss of both sodium and potassium. Trauma, surgery, anoxia, ischemia, shock and any damage to or wasting away of tissues may result in loss of cellular potassium to the extracellular fluid and plasma, and the loss from the body through kidney excretion. Recovery with rapid uptake or potassium by the tissues may result in low plasma levels. Low extracellular potassium concentration may cause muscular weakness, changes in cardiac and kidney function, lethargy, and even coma in severe cases. There are no reserve stores of either sodium or potassium in the animal body, so any loss beyond the amount of intake comes from the functional supply of cells and tissues. The kidney is the key regulator of the sodium and potassium content of higher animals and makes possible adaptation to wide variations of intake. In the glomerulus of the kidney nephron (or individual unit), an ultrafiltrate containing the smaller molecules of plasma is normally produced. As this ultrafiltrate passes down the kidney tubule, 97.5% or more of the sodium is actively resorbed, along with nearly all of the potassium. The remaining 2.5% of the sodium is sufficient to account for even the maximum sodium excretion. Potassium is added to the filtrate in the distal tubule through exchange for sodium. Control of this exchange appears to be the principal mode of action of aldosterone, which thus exerts a final control over sodium excretion. Aldosterone is a steroid hormone from the adrenal cortex, secretion of which seems to result from lowering of the Na/K ratio in the blood. Water is passively resorbed with the electrolytes along the length of the tubule.

Water excretion is further controlled by the antidiuretic hormone from the posterior pituitary gland which acts to increase water resorption in the kidney through making the collecting tubule permeable to water for additional resorption beyond what took place in the tubule. The posterior pituitary gland secretes the hormone as a rapid and sensitive response

to a rise in the osmotic pressure of the extracellular fluid. The osmotic pressure of the extracellular fluid is, of course, principally due to its sodium chloride content.

With low intake of sodium, excretion is reduced to a very low level to conserve the supply in the body. Potassium is not so efficiently conserved.

The kidney regulates the acid-base balance of the body by control over resorption of sodium ions, which may exchange for hydrogen ions in the kidney tubule. Since most dietaries are of acid-ash, the urine is usually more acid than the original plasma filtrate and much of the phosphate excreted is thus changed to the acid monosodium salt. Within the range of normal variability, with an alkaline ash diet, the urine may become alkaline, and in extreme instances, some sodium bicarbonate may be excreted.

The salts of the buffer pairs responsible for control of the pH of plasma and extracellular fluid involve sodium as the principal cation, while the cellular buffers involve potassium salts. See also **Acid-Base Regulation (Blood)**; and **Diuretic Agents**.

POTENTIATOR. A term used in the flavor and food industries to characterize a substance that intensifies the taste of a food product to a far greater extent than does an enhancer. The most important of these are the 5′-nucleotides. They are approved by the FDA. Their effective concentration is measured in parts per billion, whereas that of an enhancer such as MSG is in parts per thousand. The effect is thought to be due to synergism. Potentiators do not add any taste of their own, but intensify the taste response to substances already present in the food.

POUND, ROBERT (1919–). Pound is a Canadian-born American physicist who pioneered many fruitful ideas and is especially remembered for co-discovering, with Purcell, nuclear magnetic resonance (NMR) and establishing it as one of physics' most valuable analytical techniques. NMR is used as an analytical technique in chemical research, medical diagnosis, and a number of other fields.

Pound worked with his associate, Glen A. Rebka, Jr., carrying out an experiment using the Mossbauer effect to measure the gravitational effects of electromagnetic radiation and to test the predictions of Einstein's theory of general relativity. Pound's experiments continued and results predicted the Red Shift discovery.

During WW II, Pound worked at the Submarine Signal Company and then at MIT's radiation laboratory helping to develop radar and microwave technology. After the war, he became a professor at Harvard in 1948 and stayed until his retirement in 1989. Among his many awards have been the Thompson Memorial Award of the Institute of Radio Engineers in 1948, The Eddington Medal of the Royal Astronomical Society in 1965, and the National Medal of Science in 1990.

J.M.I.

POUR POINT. 1. The lowest temperature at which a liquid will flow when a test container is inverted. 2. The temperature at which an alloy is cast.

POUR POINT DEPRESSANT. An additive for lubricating and automotive oils that lowers the pour point (or increases the flow point) by 11.0°C. The agents now generally used are polymerized higher esters of acrylic acid derivatives. They are most effective with low-viscosity oils.

See also **Petroleum**.

POWDER. Any solid, dry material of extremely small particle size ranging down to colloidal dimensions, prepared either by comminuting larger units (mechanical grinding), combustion (carbon black, lampblack), or precipitation via a chemical reaction (calcium carbonate, etc.). Powders that are so fine that the particles cannot be detected by rubbing between thumb and forefinger are called *impalpable*. Typical materials used in powder form are cosmetics, inorganic pigments, metals, plastics (molding powders), dehydrated dairy products, pharmaceuticals, and explosives. Metal powders are used to make specialized equipment by sintering and pressing (powder metallurgy), as well as sprayed coatings and paint pigments (aluminum, bronze). Thermoplastic polymers in powder form are used in a technology known as powder molding. Thermosetting polymers are used in the sprayed coatings field for autos, machinery, and other industrial applications in which they have many advantages over sprayed solvent coatings.

See also **Carbon Black**; and **Powder Metallurgy**.

POWDER METALLURGY. Powder metallurgy (PM) embraces the production of finely divided metal powders and their union through the use of pressure and heat into useful articles. The temperatures required are below the fusion point of the principal constituent, and bonding depends on interdiffusion of the metal particles in the solid state. It is necessary to provide intimate contact between particles, hence reducing atmospheres are provided in the sintering process to prevent formation of oxide films. Readily oxidized powders such as aluminum require special technique.

Probably the most important applications of powder metallurgy are those in which a product is made which cannot be duplicated by other methods. There are many examples of this kind. The melting point of tungsten, 6,100°F (3.371°C), is much too high for ordinary melting and casting methods and the only way in which filaments for electric lights can be made is to draw them from rods of compacted and sintered tungsten powder. The cemented carbide cutting tools are another important product of refractory nature readily made by powder metallurgy.

Self-lubricating bronze bearings having controlled porosity are products that can be made only by powder metallurgy. The pores are impregnated with oil, and flow to the bearing surface is maintained by capillary action. Graphite is incorporated with the metal powder in one type of oil-less bearing. A material made from powdered copper and graphite is used for electric-current collector brushes, and tungsten-copper or tungsten-silver combinations are used for electric contact points. In contrast to these high-conductivity materials, a high-resistance element is produced from a mixture of copper and porcelain powders, combining a metal with a nonmetallic substance.

Advances in PM Technology

Particularly during the past decade, remarkable progress was made in PM technology. Major trends in the early 1990s included: (1) rapid solidification processing (RSP), (2) liquid-dynamic compaction (LDC); (3) self-propagating high-temperature synthesis (SHS); (4) greater use of intermetallics and additives in PM products; (5) advancements in PM injection molding; and (6) improvements in heat treating PM parts—not to mention the appearance of PM in products and structures traditionally made by other metallurgical processes, such as seamless tubing.

Rapid Solidification Processing. RSP holds high promise for producing engineering alloys with refined microstructures, improved chemical homogeneity, extended solute solubility, and possible retention of metastable phases. RSP usually involves cooling rates greater than 100°C/second (212°F/s). For high cooling rates, RSP products must have a large surface-to-volume ratio, and thus are commonly in the form of powder, flakes, or ribbon. To be commercially acceptable, such rapidly solidified particulates must be consolidated into fully dense, metallurgically bonded forms suitable for engineering applications. RSP properties are quite sensitive to heat treatment and the desired properties can easily be lost without careful control over the consolidation process. Among the consolidation methods currently in commercial or near-commercial use include hot extrusion, hot isostatic pressing, vacuum or inert-atmosphere pressing or sintering, and powder forging. Unfortunately, these processes require elevated temperatures for relatively long times, which may destroy the benefits achieved by RSP. A major problem involves the tenacious oxide that forms on the surface of many RSP materials, particularly aluminum, nickel, and stainless steels.

A shock wave moving through the medium at velocities in excess of that of sound appears to be one solution to this problem. The shock wave can greatly exceed the yield stress. Passage of the

shock wave causes plastic flow, interparticle melting and bonding, and can produce a fully dense, metallurgically bonded product. Three methodologies have evolved for introducing a shock wave: (1) use of a gas gun incorporating propellants or compressed gas; (2) direct application of explosives; and (3) impact of a projectile accelerated by explosives.

Guns are available of several designs. In one configuration, a high-pressure burst of gas launches a projectile down an evacuated tube where the projectile imparts a shock wave by driving a punch into the powder bed. As pointed out by Wright, the gun may be in the form of a high-impact press in which a reusable piston is accelerated in an evacuated chamber by introducing a rapid burst of gas into the breach. The impact of the ram produces a pressure pulse.

Hitchcox (1986) describes a process being developed at the Massachusetts Institute of Technology, which uses high-velocity pulses of an inert gas to atomize a stream of molten metal. Semisolid droplets of the metal are collected as rapidly solidified "splats" on a chilled metallic substrate. (This liquid dynamic compaction (LDC) process is attractive from a cost standpoint.) Substrates can be flat surfaces, molds, or shaped containers. The splats build up rapidly, forming high-density bodies suitable for further processing. Because the splats are thin, they cool at relatively high rates (1000°C/second; 1800°F/s). It is claimed that the LDC process improves ductility and fracture toughness because oxides and powder particle boundaries are minimized. Although in an early stage of development, materials such as high-strength aluminum and superalloys and (FeCo)-Nd-B have been produced with the process. Grant (MIT) reports that rapidly solidified material may exhibit grain sizes as fine as 0.2 micrometer (8 microinches) after crystallization of glasses. The fine grain size allows superplastic forming of aluminum alloys, stainless steels, and other materials.

Self-Propagating High-Temperature Synthesis. SHS usually involves an exothermic reaction producing temperatures in excess of 2500°C (4532°F). In essence, a mixture of compressed powders is ignited with a heat source in air or an inert atmosphere and in an instant, a refractory compound or multicomponent material results. SHS eliminates the need for high-temperature furnaces as required by conventional processes. Processing time is shortened to seconds or minutes versus hours and days as required with normal sintering. The products are usually of a higher purity, some having less than 0.2% (wt) of unreacted elements. This is the result of vaporizing volatile contaminants during the "explosion." SHS has been used to produce borides, carbides, and other difficult materials and is considered to have much potential for making ceramic matrix composites with unique microstructures.

In SHS, there are fundamentally two types of reactions: (1) *thermite*, where oxidation-reduction produces multiphase products, such as cermets; and (2) *compound formation*, as resulting from the starting elements, such as $Ti + 2B = TiB_2$. A combination of the two types of reaction also can be used. SHS requires a strong exothermic reaction where the heat of reaction is at least 40 kcal/mole (168,000 Joules/mole). The adiabatic temperature must be greater than the melting point of the product in order to produce a liquid phase for enhancing diffusion. Sheppard also breaks the reactions into (1) propagating, and (2) bulk. *Propagating reactions* are initiated locally, so that a synthesis wave of reactants, or, conversely, chemical activators can be added to accelerate the reaction. Also, if a higher reaction temperature required, preheating of the reactants is practiced.

Examples of products made by the SHS process include borides, carbides, chalcogenides, hydrides, intermetallic compounds, nitrides, silicides, carbonitrides, sulfides, cemented carbides (cermets), and various heterogeneous mixtures (microcomposites).

PM Intermetallics and Additives. An example of improved materials for which PM technology may solve past metallurgical processing problems is found in turbine parts, where high-temperature performance and oxidation resistance is mandatory. Aluminides of iron, nickel, and titanium have received consideration for a number of years, not only because they appear to meet the two foregoing criteria, but also because of their relatively low density, high strength, and corrosion resistance. Conventional casting of these materials results in unacceptable inhomogeneities. This has led to the evaluation of several PM methodologies, including hot isostatic pressing (HIP), vacuum hot pressing (VHP), injection molding, transient liquid-phase sintering, reactive sintering, and hot extrusion. Of considerable promise, reflecting research at Rensselaer Polytechnic Institute, is *reactive sintering*. This process involves a transient liquid phase. The reaction takes place above the lowest eutectic temperature in the system, but still at a temperature at which the compound remains in the solid phase. Research has shown that a transient liquid forms at the lowest eutectic temperature and spreads through the compact during heating. Actually, the reaction is approximately spontaneous because heat is liberated due to the thermodynamic stability of the compound's high melting temperature. In terms of the reaction of nickel and aluminum powders, a temperature over 550°C (1020°F) is the optimum. The time required for processing is relatively short (about one-half hour). Densities over 97% (of theoretical) are obtained. Even with the presence of some residual porosity, the ductility and strength of the product are good, which properties are retained after subsequent high-temperature exposure.

Researchers at Case Western Reserve University and the NASA Lewis Research Center, both located in Cleveland, Ohio, have evaluated *hot extrusion* as a candidate process. In essence, the process consists of canning the powder (prealloyed aluminide powders [FeAl, NiAl, and Ni_3Al]) and then extruding the material at a temperature and area-reduction ratio sufficiently high to produce satisfactory material flow and efficient filling of interparticle spaces, the latter for eliminating porosity and to encourage grains to recrystallize dynamically.

A basic advantage of PM technology has been that of minimizing or eliminating machining in making a final part. Nevertheless, some machining operations may be required. Traditionally, the machinability of sintered PM steels, for example, is poor, mainly due to porosity, hardness, and low thermal conductivity, Porosity causes an interrupted cut and causes tool wear—with the possible results of both higher tool costs and poorer surface finish. In recent years, PM techniques have been improved by the incorporation of additive, notably manganese sulfide (MnS), to enhance machinability.

Powder metallurgy also is playing a major role in the pioneering but rapidly developing technology of *nanofabrication*. Melding the technologies of PM and electronic components manufacture are reducing operational minute machine parts to submicron levels. See Fig. 1.

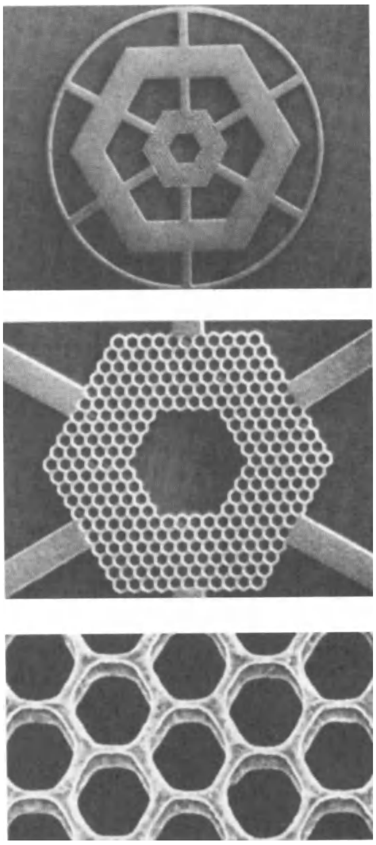

Fig. 1. Representative cross sections of tiny (submicrometer) mechanical parts that can be produced by nanofabrication technology. (*Cornell University*)

POWER (Nuclear). See **Nuclear Reactor**.

PPB. Parts per billion. One part per billion is a frequently used dimension for expressing the composition and analysis of substances—as found in air, water, food substances, etc. Instrument developments and other assay techniques perfected during the past decade or so have made the determination of such minute quantities a practical possibility for many materials. One part per billion is approximately equivalent to 1 drop in a 10,000-gallon (37,850-liter) tank.

PPM. Parts per million. One part per million is a common dimension for expressing the composition and analysis of substances—as found in air, water, raw materials, food substances, etc. One part per million is approximately equivalent to about 1/32 ounce (1 gram) in 1 ton of substance. One gram is exactly one-millionth of a metric ton.

PRANDTL NUMBER. A dimensionless number equal to the ratio of the kinematic viscosity to the thermometric conductivity (or thermal diffusivity). For gases, it is rather under one and is nearly independent of pressure and temperature, but for liquids the variation is rapid. Its significance is as a measure of the relative rates of diffusion of momentum and heat in a flow and it is important in the study of compressible flow and heat convection. See also **Heat Transfer**.

PRASEODYMIUM. [CAS: 7440-10-0]. Chemical element symbol Pr, at. no. 59, at. wt. 140.91, second in the Lanthanide Series in the periodic table, mp 934°C, bp 3,512°C, density 6.769 g/cm^3 (20°C). Elemental praseo dymium has a close-packed hexagonal crystal structure at 25°C. The pure metallic praseodymium is silver-gray in color, the luster dulling rapidly upon exposure to air and forming a nonadherent oxide which hastens the process of oxidation. When pure, the metal is soft and workable with ordinary tools. Processing and handling require storage under a nonreactive liquid or inert atmosphere or vacuum. Finely-divided praseodymium is pyrophoric, burning at a red heat. There is only one isotope of the element in nature ^{141}Pr. It is not radioactive and has a low acute-toxicity rating. Fourteen artificial isotopes have been produced. Of the light (or cerium-group) rare-earth metals, praseodymium is the fourth most plentiful and ranks 59th in abundance of the elements in the earth's crust, exceeding tantalum, mercury, bismuth, and the precious metals, excepting silver. The element was first identified by C.A. von Welsbach in 1885. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^2 5s^2 5p^6 5d^1 6s^2$$

Ionic radius, Pr^{3+} 1.01 Å, Pr^{4+} 0.90 Å. Metallic radius, 1.828 Å. First ionization potential, 5.42 eV; second, 10.55 eV. Other important physical properties of praseodymium are given under **Rare-Earth Elements and Metals**.

Primary sources of the element are bastnasite and monazite, which contain from 4 to 8% praseodymium. Plant capacity involving liquid-liquid or solid-liquid organic ion-exchange processes for recovering the element is in excess of 100,000 pounds Pr_6O_{11} annually. Metallic praseodymium is obtained by electrolysis of Pr_6O_{11} in a molten fluoride electrolyte, or by a calcium reduction of PrF_3 or $PrCl_3$ in a sealed-bomb reaction.

For many years, praseodymium has been a component of light rare-earth mixtures used in mischmetal, a pyrophoric alloy used in cigarette-lighter "flints." Mixtures of cerium, lanthanum, neodymium, and praseodymium, as oxides and fluorides, are used in the cores of arc carbons for the production of light of greater intensity. Similar mixtures of rare-earth oxides, including praseodymium, are used in optical glass polishing formulations. Mixtures of the lanthanide compounds, including about 5% praseodymium, find application as catalysts in petroleum cracking processes. A mixture containing 10% Pr, 30% Nd, and 60% La is used for cracking crude oil and comprises the largest single use of the element as well as of all other Lanthanide elements. Use of elemental praseodymium as a colorant for glass was one of the early applications. The color ranges from clear yellow to green and finds use in sunglasses, protective glasses for industry, art objects of glass, tableware, and optical filters. In the manufacture of ceramic tile, a praseodymia-zirconia yellow stain is used. Metallurgically, the most important intermetallic compound is $PrCo_5$, which has unsurpassed permanent magnetic properties. The compound has a very high resistance to demagnetization and has a high magnetic saturation value. PrNi5 has been used for adiabatic magnetization cooling of samples down to the milli-Kelvin range for low-temperature research. Investigations continue into further electronic and optical uses of the element and its compounds.

PRECIPITATE. (↓, ppt). Small particles that have settled out of a liquid or gaseous suspension by gravity, or that result from a chemical reaction. Precipitated compounds, such as blanc fixe (barium sulfate, are prepared in this way, for example, by the reaction $BaCl_2 + Na_2SO_4 \longrightarrow NaCl + BaSO_4$. In formulas, a downward vertical arrow, ↓, or "ppt" is sometimes used to indicate a precipitate. A class of organic pigments called *lakes* are made by precipitating an organic dye onto an inorganic substrate. Colloidal particles dispersed in a gas, as flue dust in industrial stacks, can be precipitated by introducing an electric charge opposite to that which sustains the particles.

See also **Sedimentation**.

PRECIPITATION HARDENING. A large number of alloys are hardenable by a heat treating procedure known as precipitation hardening. Hardening is accomplished by the controlled precipitation of many minute particles of a second crystalline phase (or phases) inside the crystals of the primary metal. In order that the precipitation may be effected, the hardening constituent must be more soluble at higher temperatures than it is at lower

temperatures, so that heating of the solid metal at an elevated temperature causes the second phase to dissolve into the matrix. If a precipitation hardening alloy is heated and held at an elevated temperature so as to dissolve the hardening phase and then is quenched to room temperature, a supersaturated solid solution is obtained. This heating and quenching operation is known as the solution treatment. The second phase of precipitation hardening is known as the aging treatment wherein the second phase is precipitated out of the supersaturated solid solution by holding the metal either at room temperature or some intermediate temperature well below the temperature employed in the solution treatment. The various stages involved in the formation of the nuclei of the precipitation particles may be very complex. In general, however, the aim of the aging process is to obtain a distribution of the precipitated particles that produces maximum hardness. This will usually occur when the particles are submicroscopic in size and extremely numerous. Their hardening effect on the crystal lattice of the matrix crystals is believed to result from local strains that they produce in the matrix. These latter hinder the normal easy motion of dislocations, thereby hardening the metal. The term age hardening is synonymous with precipitation hardening, but when so used generally refers to metals aged at room temperature.

PRECURSOR. In biological systems, an intermediate compound or molecular complex present in a living organism which, when activated physiochemically, is converted to a specific functional substance. Sometimes the prefix "pro" is used to indicate that a compound in question plays the role of a precursor. Examples from the history of vitamin and other essential chemical developments include: ergosterol (pro-vitamin D2), which is activated by ultraviolet radiation to form vitamin D; carotene (pro-vitamin A) is a precursor of vitamin A; prothrombin forms thrombin upon activation in the blood-clotting mechanism.

PREFERENTIAL. Descriptive of the selectivity of action, either chemical or physiochemical, exhibited by a substance when in contact with two other substances; it may be due either to chemical affinity or to surface phenomena. An example of a preferential chemical combination is that of hemoglobin with carbon monoxide, with which it unites 200 times as readily as it does with oxygen when expose to a mixture of the two. Such phenomena as adsorption, corrosion, and the wetting of dry powders by liquids are other examples.

PREGESTOGENS AND PROGESTINS. See **Steroids**.

PREGEL, FRITZ (1869–1930). An Austrian chemist who won the Nobel prize in 1923. He was also a medical doctor who worked in micromechanical analysis and developed determinations for hydrogen, carbon, nitrogen, and organic groups using micromethods. He was educated at Tubingen, Leipzig, and Berlin.

PREHNITE. Prehnite is a hydrous silicate of calcium and aluminum, $Ca_2Al_2Si_3O_{10}(OH)_2$, crystallizing in the orthorhombic system. Usual occurrence as intergrown crystals of reniform, stalactitic character, and as rounded groups of such crystals; hardness, 6–6.5; specific gravity 2.90–2.95; luster, vitreous to pearly; color, various shades of light green to gray or white; translucent. Though not a zeolite it is found associated with them and with datolite and calcite, in veins and cavities of basic rocks, sometimes in granites, syenites, or gneisses. It is found in Austria, Italy, the Harz Mountains, France, Scotland, and the Republic of South Africa, where it was originally discovered. Magnificent crystal casts after an unknown mineral have been found in a single large cavity in the basaltic rocks near Bombay, India. In the United States well-known localities are Somerville, Massachusetts; Farmington, Connecticut; Paterson, New Jersey; and Keweenas County, Michigan. Named for Colonel Prehn, its discoverer, who was an early Dutch Governor of the Cape of Good Hope colony.

PRELOG, VLADIMIR (1906–1998). A Swiss organic chemist who won the Nobel prize for Chemistry in 1975 along with John W. Cornforth for his research into the stereochemistry of organic molecules and reactions. Although educated in Yugoslavia, he spent many years in Zurich.

PREMIX MOLDING. A mixture of plastic ingredients prepared in advance of the molding or extruding operation and stored in bags or bins until required. It is made by mixing the components (resin, filler, fibrous materials such as glass and necessary curatives) in a dough blender. Storage life may be from a few days to a year or more, depending on formulation. Such mixtures are then calendered or extruded after warming to suitable temperature.

PRENENOLONE. See **Steroids**.

PREPOLYMER. An adduct or reaction intermediate of a polyol and a monomeric isocyanate, in which either component is in considerable excess of the other. A polymer of medium molecular weight having reactive hydroxyl and −NCO groups.

See also **Polymers**.

PRESERVATIVE. Any agent that prolongs the useful life of a material. Food products are preserved by; (1) low temperature, (2) ionizing radiation (X and Y rays), (3) antioxidants, (4) fungicides, (5) aldehydes, (6) paints and others.

See also **Food Additives**.

PRESSURE. If a body of fluid is at rest, the forces are in equilibrium or the fluid is in static equilibrium. The types of force that may act on a body are shear or tangential force, tensile force, and compressive force. Fluids move continuously under the action of shear or tangential forces. Thus, a fluid at rest is free in each part from shear forces; one fluid layer does not slide relative to an adjacent layer. Fluids can be subjected to a compressive stress, which is commonly called *pressure*. The term may be defined as force per unit area. The pressure units may be dynes per square centimeter, pounds per square foot, torr, mega-Pascals, etc. Atmospheric pressure is the force acting upon a unit area due to the weight of the atmosphere. Gage pressure is the difference between the pressure of the fluid measured (at some point) and atmospheric pressure. Absolute pressure, which can be measured by a mercury barometer, is the sum of gage pressure plus atmospheric pressure.

Pascal's law states that the pressure in a static fluid is the same in all directions. This condition is different from that for a stressed solid in static equilibrium. In such a solid, the stress on a plane depends upon the orientation of that plane. A liquid in contact with the atmosphere is sometimes called a free surface. A static liquid has a horizontal free surface if gravity is the only type of force acting.

Imagine a body of static fluid in a gravitational field. The mass of the fluid is m (in grams) and the weight of the fluid is mg (as dynes) where g is the local gravitational acceleration. Figure 1 shows a large region of any static fluid with a very small or infinitesimal element. Figure 2 indicates the element in detail. The vertical distance z is measured positively in the direction of decreasing pressure (up); dA is an infinitesimal area; p is the pressure acting on the top surface; and $(p + dp)$ is the pressure acting on the bottom surface. The pressure difference is due only to the weight of the fluid element. Let r represent density, which is mass per unit volume (as grams per cubic centimeter). Thus the weight of the element is $\rho\ g\ dz\ dA$. Considering the element as a free body, an accounting of forces in the vertical direction gives:

$$dpdA = -\rho gdzdA; dp = -\rho gdz \qquad (1)$$

As z is measured positively upward, the minus sign indicates that the pressure increases with an increase in height. This fundamental equation

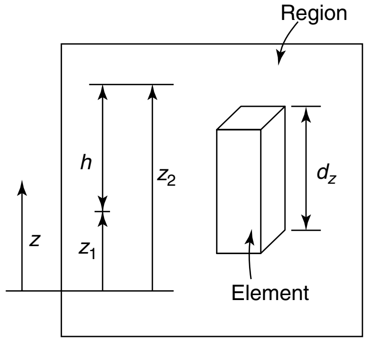

Fig. 1. Large region of any static fluid

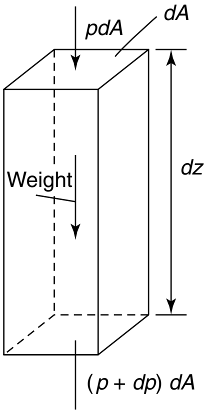

Fig. 2. Vertical forces on infinitesimal element

of fluid statics can be applied to all fluids. In integral form, Equation (1) becomes:

$$\int_1^2 \frac{dp}{g} = \int_1^2 dz = -(z_2 - z_1) \qquad (2)$$

where 1 refers to one level and 2 refers to another level. The functional relation between pressure p and the combination ρg must be established before Equation (2) can be integrated. There are two major cases: (a) incompressible fluids, in which the density ρ is a constant; and (b) compressible fluids, in which the density ρ varies.

Liquids can be considered as incompressible in many cases. For small differences in height, a gas might be regarded as incompressible. For an incompressible fluid, with constant g, Equation (2) becomes:

$$p_2 - p_1 = -\rho g(z_2 - z_1) \qquad (3)$$

The term $(z_2 - z_1)$ may be called a static "pressure head," and it can be expressed in feet or inches of water, or some height of any liquid. For example, barometric pressure can be expressed in inches of mercury.

A manometer is a device that measures a static pressure by balancing the pressure with a column of liquid in static equilibrium. Many types of manometers are used. The common mercury barometer is essentially a manometer for measuring atmospheric pressure; a mercury column in a glass tube balances the weight of the air above the mercury. Figure 3 illustrates a manometer in which the left leg is open to the atmosphere; the liquid has a specific weight (weight per unit volume) $\rho_2 g$. In the other leg is a liquid of specific weight $\rho_1 g$. Starting with the left leg, the gage pressure p_A is:

$$p_A = h_2\rho_2 g$$

Since the fluid is in static equilibrium, the pressure p_B at point B equals the pressure at point A. Thus:

$$p_A = p_B = h_2\rho_2 g$$

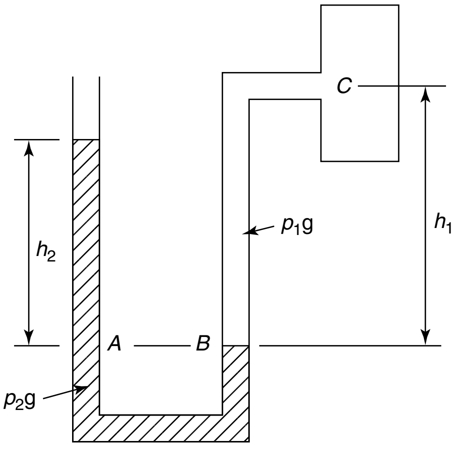

Fig. 3. Manometer

The pressure p_C at point C is less than that at B. Thus:

$$p_B - p_C = h_1\rho_1 g$$

Then the gage pressure at point C is:

$$p_C = g(h_2\rho_2 - h_1\rho_1)$$

When a body of any kind is partly or fully immersed in a static fluid, every part of the body surface in contact with the fluid is pressed on by the fluid. The pressure is greater on the areas more deeply immersed. The resultant of all these fluid pressure forces is an upward or buoyant force. The pressure on each part of the body is independent of the body material. Archimedes' principle states that the buoyant force equals the weight of the displaced fluid.

Equation (3) is for the special case of an incompressible fluid. As an example of a compressible fluid, consider an isothermal or constant-temperature layer of gas. The equation of state for such a gas can be written:

$$p = \rho R T_1 \qquad (4)$$

where T_1 is the given absolute temperature and R is a gas constant or gas factor depending upon the gas. Assuming a constant g, Equation (2) gives:

$$\frac{RT_1}{g}\int_1^2 \frac{dp}{p} = -(z_2 - z_1)$$
$$z_2 - z_1 = \frac{RT_1}{g}\log_e \frac{p_1}{p_2} \qquad (5)$$

Equation (5) is sometimes called a "barometric height" relation. For an isothermal atmosphere, a measurement of the temperature T_1 and the static pressure (as with a barometer) at two different levels will provide data for the calculation of the height difference.

Other pressure designations include:

Vacuum. A gage pressure below atmospheric.

Hydrostatic Pressure. The pressure at a point below a liquid surface due to the height of fluid above it.

Tons-on-Ram. The force that acts over a given area as in various types of hydraulic machinery.

Partial Pressure. The pressure exerted by one component in a system, usually one gas or vapor in a mixture.

Internal Pressure. The effect of the attractive forces of the molecules of a substance, which is called pressure because its result is the same as that of an added external pressure. In liquids, its effect appears as the ability of liquids to stand substantial negative pressures without rupture.

Cohesion Pressure. A term in Van der Waal's equation introduced to take care of the effect of molecular attraction. It is usually expressed as a/V^2, where a is a constant and V is the volume of the gas.

Pressure Measurement. Liquid-column elements, such as the manometer, are commonly used for pressure measurement. A variety of diaphragm and other elastic elements is used to measure pressure. A metallic diaphragm element is primarily a device for measuring relatively low pressures. It consists of a single diaphragm or of one or more capsules connected together, so that upon pressure application, each capsule deflects. The total deflection is the sum of the deflections of all capsules. A variety of bellows elements is similarly used in pressure gages. One of the most common forms of pressure gage makes use of a bourdon-spring element. Gages for medium-to-high vacuums usually incorporate an electronic type transducer. See also **Vacuum Gages.** Electrical transducers, such as strain gages, moving-contact resistance elements, inductance, reluctance, capacitative, and piezoelectric devices also are used in pressure detection systems. Pressure not only is important as a key variable for direct measurement, but differential pressures are commonly measured in connection with various flowmeters that use a differential-producing element, such as an orifice plate, to measure flow. Manometers and other pressure sensors are also used in liquid-level measuring devices.

High-Pressure Technology. Until the mid-1970s, the limit to most high-pressure experimentation was confined to about 300 kilobars.

As of 1988, the maximum pressure created in the laboratory by the diamond anvil pressure cell approximates 5 million atmospheres.

Theoretical estimates, however, forecast that diamond is stable up to 23 million atmospheres with respect to any phase transition. Although plastic deformation would limit its capability, predictions for the diamond anvil cell are for pressures somewhere between 5 and 23 million atmospheres.

PRIESTLEY, JOSEPH (1733–1804). Priestley was an English chemist who researched relationships among plants, air, and animals. After meeting Benjamin Franklin he became interested in science and the two men became lifelong friends. Priestley started doing chemical experiments as a hobby, but it soon became a passion. He had little scientific education but his observations were very keen.

Priestley lived near a brewery and his curiosity about how it operated and about the gases involved lead him to discover a gas (carbon dioxide) was heavier than air. He found water and this heavy "air" made a great drink and in 1773 he was awarded a medal by the Royal Society for his invention of soda water. In 1774, he announced the results of his experiment, which described the unusual properties of a new "air", this was in fact, the discovery of oxygen. His experiments with "air" and gases were important for leading to the first ballooning flights.

Priestley also researched relationships among plants, air, and animals. He observed the respiration of plants, by which they take in carbon dioxide and produce oxygen. His observation helped others understand the process. He observed "green matter", which now we know as photosynthesis.

He was a strong religious and political leader and was persecuted for his support of the American Revolution. He came to America in 1794 and spent his last years experimenting in his laboratory. His research in America resulted in the discovery of carbon monoxide (1799).

See also **Oxygen**.

J.M.I.

PRIGOGINE, IIYA (1917–2003). A Belgian chemist who won the Nobel prize for chemistry in 1977 for his contributions to nonequilibrium thermodynamics particularly the theory of dissipative structures. The main theme of the scientific work of Ilya Prigogine has been a better understanding of the role of time in the physical sciences and in biology. He has contributed significantly to the understanding of irreversible processes, particularly in systems far from equilibrium. His education was at the University of Brussels. The Center for Statistical Mechanics and Thermodynamics at the University of Texas bears his name. order.ph.utexas.edu/research/glimpse.html

PRILLS. Small, round, or acicular aggregates of a material, usually a fertilizer, that are artificially prepared. In the explosives field, prills-and-oil consists of 94% coarse, porous ammonium nitrate prills and 6% fuel oil.

PROGESTERONE. See **Hormones**; **Steroids**.

PROMETHIUM. [CAS: 7440-12-2]. Chemical element symbol Pm, at. no. 61, at. wt. 145 (mass number of the most stable isotope), fourth in the Lanthanide Series in the periodic table, mp 1042°C, bp 3000°C (estimated), density 7.26 g/cm^3 (20°C). Elemental promethium has a double hexagonal closepacked crystal structure at 25°C. The pure metallic promethium is silverwhite in color, is soft, and can be cast or machined. The naturally occurring isotope ^{147}Pm is radioactive with a half-life of 2.52 years. Consequently, the element must be handled within a shielded area. Eighteen artificially produced isotopes, ranging from ^{140}Pm to ^{146}Pm and from ^{148}Pm to ^{158}Pm have been identified, all with very short half-lives. Many of the properties of promethium remain classified by the United States Atomic Energy Commission, or are known by other proprietary sources. Although first identified as an element by J.A. Marinsky, L.E. Glendenin, and C.D. Coryell in 1947, the element was not available on more than a gram-scale for several years. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^4 5s^2 5p^6 5d^1 6s^2$$

Ionic radius 0.98 Å. Other important physical properties of promethium are given under **Rare-Earth Elements and Metals**.

^{147}Pm is extracted from the wastes of uranium or plutonium reactors, the most important source of the element. ^{146}Pm and ^{148}Pm also are derived from reactor wastes. In 1970, ^{147}Pm became available in kilogram quantities. ^{147}Pm has been under intensive study as a heat and power source; however, before it can be used for this, ^{146}Pm and ^{148}Pm, which produce penetrating gamma radiation, must be eliminated. The desirable property of ^{147}Pm is that it decays by beta emission only, at a low energy level compared with most fission products, and thus requires only light to moderate shielding. ^{147}Pm has been used to activate luminescent phosphors. Beads (Microspheres®, 3 M Company) containing ^{147}Pm mixed with a phosphor provide a long-lived, reliable green light and were used by astronauts to assist in docking and other maneuvers in outer space. Commercial applications of ^{147}Pm as a power source include beta-voltaic cells for surgical implant with heart pumps and pacemakers.

PROMOTER. 1. A substance that, when added in relatively small quantities to a catalyst, increases its activity, e.g., aluminum and potassium oxide are added as promoters to the iron catalyst used in facilitating a combination of hydrogen and nitrogen to form ammonia.

2. In ore flotation, a substance that provides the minerals to be floated with a water-repellent surface that will adhere to air bubbles. Such reagents are generally more or less selective toward minerals of certain classes.

PROOF. The ethanol content of a liquid at 15.5 C, stated as two times the percentage of ethanol by volume. One gallon of 95% alcohol is therefore equivalent to 1.9 gallons of proof alcohol. In the U.S., the alcohol tax is based on the number of proof gallons.

PROPANE. [CAS: 74-98-6], $CH_3 \cdot CH_2 \cdot CH_3$, formula weight 44.09, colorless gas, mp −187.1°C, by −42.2°C, sp gr 0.585 (at −45°C). The gas is slightly soluble in H_2O, moderately soluble in alcohol, and very soluble in ether. Although a number of organic compounds which are important industrially may be considered to be derivatives of propane, it is not a common starting ingredient. The content of propane in natural gas varies with the source of the natural gas, but on the average is about 6%. Propane also is obtainable from petroleum sources.

Liquefied propane is marketed as a fuel for outlying areas where other fuels may not be readily available and for portable cook stoves. In this form, the propane may be marketed as LPG (liquefied petroleum gas) or mixed with butane and pentane, the latter also constituents of natural gas (1.7% and 0.6%, respectively). LPG also is transported via pipelines in certain areas. The heating value of pure propane is 2520 Btu/ft^3 (283 Calories/m^3); butane 3260 Btu/ft^3 (366 Calories/m^3); and pentane 4025 Btu/ft^3 (452 Calories/m^3). Propane and the other liquefied gases are clean and appropriate for most heating purposes, making them very attractive where they are competitively priced.

PROSTAGLANDINS. A group of physiologically active compounds (PGs) derived from fatty acids with 20 carbon atoms (approximate formula, $C_{20}H_{36}O_5$). The compounds originally were isolated as lipid-soluble extracts from sheep and human prostates. Later studies have shown that prostaglandins are found in most mammalian tissues. There are numerous prostaglandins, individually named by the substituents present on the cyclopentane ring that is part of the parent molecule, prostanoic acid. Thus, they are identified as PGA_1, PGE_1, PGI_2 (prostacyclin), etc. The chemical structure and metabolic functions of the prostaglandins have been established, in most cases, with considerable accuracy. Some have been synthesized. Each prostaglandin has specific effects. The compounds participate in pulmonary circulation and hypertension, with

varying vasodilator and vasoconstrictor effects. Prostaglandins of the E series have been implicated as a cause of hypercalcemia—they resorb fetal bone in vitro, urinary prostaglandin metabolites are elevated in certain hypercalcemic patients with malignancy, and clinically very important, in certain cancer patients with hypercalcemia. Chemical improvement has been seen after treatment with indomethacin, which inhibits prostaglandin synthesis. Prostaglandins also are implicated in systemic mastocytosis, due partly to marked overproduction of prostaglandin D_2. Prostacyclin plays an important role in platelet function, acting as an effective antiaggregating agent. The prostaglandins are involved in the biochemical pathways that participate in bronchial asthma. PGs are synthesized ubiquitously in the body from unsaturated fatty acid precursors with high rates of production by the seminal vesicles and renal medulla. The metabolism of prostaglandins occurs mainly in the lungs, renal cortex, and liver, with the metabolites excreted in the urine. The most prolific source of natural prostaglandins is a marine organism (gorgonian sea whip) found in great numbers in coral reefs, notably in the Caribbean area. Intermediates and chemical analogs derived from this organism are sometimes referred to as *syntons*.

PROTACTINIUM. [CAS: 7440-13-13]. Chemical element, symbol Pa, at. no. 91, at. wt. 231.036, radioactive metal of the Actinide Series, mp is estimated at less than 1600°C. All isotopes are radioactive. The most stable isotope is ^{231}Pa with a half-life of 3.43×10^4 years. The latter is a second-generation daughter of ^{235}U and a member of the actinium $(2n + 3)$ decay series. See also **Radioactivity**. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^2 6s^2 6p^6 6d^1 7s^2$$

Ionic radii Pa^{4+} 0.91 Å; Pa^{3+} 1.06 Å. See also **Chemical Elements**.

The probable existence of protactinium was predicted as early as 1871 by Mendeleev to fill up the space on his periodic table between thorium (at. no. 90) and uranium (at. no. 92). He termed the unconfirmed element *ekatantalum*. In 1926, O. Hahn predicted the properties of the element in considerable detail, including descriptions of its compounds. In 1930, Aristid v. Grosse isolated 2 milligrams of what then was termed ekatantalum pentoxide and showed that element 91 differed in all reactions with comparable amounts of tantalum compounds with exception of precipitation by NH_3. However, credit for the discovery of protactinium generally is attributed to Lise Meitner and Otto Hahn in 1917.

Protactinium-231 yields actinium-227 by α-particle emission and has a half-life of 3.43×10^4 years. Its other isotopes include two isomers of mass number 234: uranium X_2 with a half-life of 1.17 minutes, and uranium Z with a half-life of 6.7 hours, the former being an excited state which undergoes de-excitation to give the latter. Other nuclear species have mass numbers 225–230, 232, 233, 235 and 237.

Protactinium (of mass number 231) is found in nature in all uranium ores, since it is a long-lived member of the uranium series. It occurs in such ores to the extent of about $\frac{1}{4}$ part per million parts of uranium. An efficient method for the separation of protactinium is by a carrier technique using zirconium phosphate which, when precipitated from strongly acid solutions, coprecipitates protactinium nearly quantitatively. Then the protactinium is separated from the carrier by fractional crystallization of zirconium oxychloride.

Isotopes of protactinium can also be produced artificially, i.e., by the nuclear reactions of other elements with such particles as deuterons, neutrons, and alpha-particles. Thus, when thorium is bombarded with deuterons of various high energies, five of the reactions are: $^{232}Th(d, 4n)^{230}Pa$, $^{232}Th(d, 6n)^{228}Pa$, $^{232}Th(d, 7n)^{227}Pa$, $^{232}Th(d, 8n)^{226}Pa$, and $^{230}Th(d, 3n)^{229}Pa$.

Quantitative methods of obtaining protactinium start from the carbonate precipitate from the treatment of the acid extract of certain uranium ores. After this carbonate precipitate is dissolved, the protactinium remains in the silica gel residue, from the solution of which it is obtained on a manganese dioxide carrier. An alternate method effects final separation of the protactinium by formation of a complex compound, protactinium-cupferron, and its extraction with amyl acetate.

The methods of purification include the use of ion exchange resins, the precipitation of protactinium peroxide and the extraction of aqueous solutions of protactinium salts by various organic solvents.

Protactinium metal is prepared: (1) by reducing the tetrafluoride with metallic barium at about 1,500°C; (2) by heating the halide, usually the iodide, under a high vacuum; and (3) by bombardment of the oxide under high vacuum with 35-keV electrons for hours at a current strength of 0.005–0.010 Amperes.

As early as 1965, investigators at Los Alamos (Fowler et al., 1965) reported that protactinium metal is superconductive below 1.4 K. In 1972, researchers at Harwell (Mortimer, 1972) reported no superconductivity of the metal down to approximately 0.9 K. An exchange of information to resolve the differences in data was conducted over the next few years (Fowler, 1974; Hall et al., 1977). Smith, Spirlet, and Mueller (1979) reported that differences in experimental research were due to problems with the crystal structure of the metal and sample purity that arise when dealing with radioactive material. These investigators observed very-high-purity protactinium, produced by the Van Arkel procedure, and observed an extremely steep superconductivity transition at 0.42 K in protactinium in the presence of rather high self-heating. The superconducting transition temperature and upper critical magnetic field of protactinium were measured by alternating-current susceptibility techniques. Inasmuch as the superconducting behavior of protactinium is affected by its $5f$ electron character, it has been further confirmed that protactinium is a true actinide element.

The predominant oxidation state of the element is (V). There is some evidence that the (IV) state is obtained under certain reduction conditions. When the pentapositive form is not in the form of a complex ion it may exist in solution as PaO_2^+. The compounds are very readily hydrolyzed in aqueous solution yielding aggregates of colloidal dimensions, thus showing marked similarity to niobium and tantalum in this respect. These properties play a dominant role in the chemical properties of aqueous solution, because the element is so easily removed from solution by hydrolysis and adsorption. Protactinium coprecipitates with a wide variety of substances, and it seems likely that the explanation for this lies in the hydrolytic and adsorptive behavior.

The element is difficult to maintain in aqueous solution in the form of simple salts. Solubility data seem to indicate that such amounts as can be dissolved probably do so entirely by formation of complex ions. Fluoride ion strongly complexes protactinium, and it is due to this that protactinium compounds are in general soluble in hydrofluoric acid.

Protactinium oxide may be prepared from the hydrated oxide or the oxalate by ignition. The product is a dense white powder with a very high melting point; the ignited material is not hygroscopic and maintains a constant weight upon exposure to the air. The formula Pa_2O_5 has been determined indirectly, and there is evidence for the existence of $PaO_{2.25}$ (air oxidation) and PaO_2 (reduction of P_2O_5 by H_2).

Volatile protactinium pentachloride has been prepared in a vacuum by reaction of the oxide with phosgene at 550°C or with carbon tetrachloride at 200°C. Reduction of this at 600°C with hydrogen leads to protactinium(IV) tetrachloride, $PaCl_4$, which is isostructural with uranium(IV) tetrachloride, UCl_4. The pentachloride can be converted into the bromide or iodide by heating with the corresponding hydrogen halide or alkali halide.

The volatile fluoride protactinium(V) fluoride, PaF_5, or possibly protactinium(V) oxyfluoride, $PaOF_3$, is formed at relatively low temperatures such as 200°C from the action of agents such as bromine tri- or pentafluoride, BrF_3 or BrF_5, on one of the protactinium oxides. At higher temperatures, treatment of Pa_2O_5 with hydrofluoric acid and hydrogen yields PaF_4.

The reduction of protactinium to the (IV) state in aqueous solution can be accomplished by reducing agents, such as zinc amalgam, and polarographically.

PROTEASE. A proteolytic enzyme that weakens or breaks the peptide linkages in proteins. They include some of the more widely known enzymes such as pepsin, trypsin, ficin, bromelin, papain, and rennin. Being water soluble they solubilize proteins and are commercially used for meat tenderizers, bread baking, and digestive aids.

See also **Enzyme**; and **Proteins**.

PROTECTIVE COATING. A film or thin layer of metal glass of paint applied to a substrate primarily to inhibit corrosion, and secondarily for decorative purposes. Metals such as nickel, chromium, copper, and tin are electrodeposited on the base metal; paints may be sprayed or brushed on. Vitreous enamel coatings are also used; these require baking. Zinc coating are applied by continuous bath process in which a strip of ferrous metal is passed through molten zinc.

PROTEIN CALORIE MALNUTRITION (PCM). See **Proteins**

PROTEIN HYDROLYSATE. Solutions of protein hydrolyzed into its constituent amino acids.

PROTEINS. Along with the carbohydrate and lipid[1] components of the animal diet, protein substances are a major source of nutrition and energy for the living system. Because of his high regard for the proteins, but well before they were really understood, the Dutch chemist Gerardus Mulder (1802–1880) pioneered the use of the term *protein*, derived from the Greek word meaning "to come first." Although proteins furnish energy to the body and thus can be considered body fuels, as are the carbohydrates and fats, the major nutritional roles of the proteins reside in other functions, usually of a highly specific nature. Thus, there are structural, contractile, process-activating, and transport proteins, among others, which essentially are responsible for the chemical workability of the animal system.

Considering the research tools available, the amount of qualitative and quantitative information pertaining to proteins collected over several decades of effort has been tremendous. The data amassed have been highly beneficial to the medical and health sciences, notably in terms of dietary requirements and protein deficiency diseases, to biologists, and, of course, to organic chemists. Past protein research has led to the development of many useful protein substances for industry and commerce. Scientists stretched the limitations of their available instrumental techniques (crystallography, electron microscopy, chromatography, electrophoresis) in their efforts to better understand protein structure and protein function. With the advent of molecular biology (studying proteins at the molecular level), the potential for learning more pertaining to structure and of what proteins do and how they behave in living organisms increased, conservatively speaking, by an order of magnitude or more. As of the later 1980s, protein science has progressed just a little beyond the initial efforts to reduce protein studies to the molecular level. Highlights are summarized in the latter portion of this article. There are several keys to expanding protein knowledge, two of the most important of which are continued mapping of organism genomes, notably mapping the human genome; and the continuing development of improved instrumental and procedural techniques. In using this newly acquired knowledge to manipulate protein structures, the term "protein engineering" is sometimes used. Protein engineering largely lies in the future.

Protein Requirements

In the growing animal body, a significant portion of proteins consumed is required for the creation of new tissue. This results in an increasing requirement for proteins in the diet of humans, for example, up to about the age of 20 years, at which time the protein requirement tends to level off to a fairly stable figure. After body maturity, the portion of proteins needed for tissue maintenance is greater than the need for new tissue building. It must be emphasized, however, that immediately at the commencement of life both new tissue building and tissue maintenance take place and even as the body grows older, the two needs continue—only the proportions between the two roles change.

Proteins, on a weight basis, are second only to water in their presence in the human body. If the factor of water is discounted, then about 50% of the body's dry weight is made up of numerous protein substances, distributed about as follows: 33% in muscles; 20% in bones and cartilage; 10% in skin; the remaining 37% in numerous other body tissues. With exception of the urine and bile in the normal healthy individual, all other body fluids contain from small to relatively large portions of protein substances.

Chemically, proteins are distinguished from other body substances in that all proteins contain nitrogen. Some contain sulfur, phosphorus, iron, iodine, cobalt, and other elements, some of which are generally not thought of as components of the life process, but which nevertheless do play extremely important roles (e.g., as catalysts), even if present only in very minute quantities.

In considering the importance of proteins to building and maintaining body functions, it must be emphasized that proteins consumed essentially are raw materials that contain the building blocks for the creation of different proteins. These building blocks are the amino acids of which the protein molecules consumed are constructed and of which the proteins restructured in the body (after consuming or metabolizing the raw materials) are also constructed. Thus, the desirability of proteins for the diet is based upon the best combination of amino acids present. Therefore, some foods are desirable from a protein nutrition standpoint not only because, with relation to their carbohydrate and fat content, they contain a high percentage of protein, but also because they contain most or all of the amino acids needed to form new proteins within the body. See also **Amino Acids**.

Examples of this situation (desirable versus less desirable proteins) popularly cited are the soybean proteins and the grain proteins. With exception of the sulfur-bearing amino acids, notably methionine, the amino acid balance of soybean proteins is reasonably good. With exception of the amino acid lysine, the amino acid balance of grain proteins is reasonably good. By mixing protein substances from these two sources, an excellent source of protein for the human diet is obtained, this explaining growing trends toward fortification of wheat and other cereal flours with soy flour. There are scores of examples of this type which are representative of the trend toward so-called *fabricated foods*.

From years of experience in studying the dietary needs of humans, nutritionists and biologists established the hen egg as having the most perfect balance of amino acids in a natural protein substance. Against this standard, other foods can be rated in their performance. In naming the following food substances in order of their diminishing chemical score, it should be stressed that these foods are arranged only in terms of this one nutritional criterion: fish (70), beef (69), cow's milk, whole (60), brown rice (57), polished white rice (56), soybeans (47), green leaves (45), brewer's yeast (44), groundnuts (peanuts) (43), whole grain maize (corn) (41), cassava (manioc) (41), common dry beans (34), white potato (34), white wheat flour (32). The foregoing food items were selected *randomly* to provide a sense of the spectrum of foods from this one particular standpoint. The Figures represent only the chemical balance of amino acids present and not the total amount of protein available as a weight percentage of food intake, or from the standpoint of protein utilization, once ingested.

In looking at a number of food substances, again a random selection, from the standpoint of total protein (with no regard to quality) in an average serving, the following amounts of protein (grams) are present: fried chicken breasts (27.8); canned tunafish (24), cooked round roast of beef (24), roasted leg of lamb (22), oven-cooked pork loin (21), dry cooked soybeans (13), whole milk (1 cup) (9), canned red beans (7.5), cheddar cheese (1 ounce = 28 grams) (7), fresh cooked lima beans (6.5), egg (medium size) (6), vanilla ice cream (6), fried crisp bacon (5), baked potato (3), cooked broccoli (2.5), cooked oatmeal (2.5), enriched white bread (1 slice) (2), cooked green snap beans (1), lettuce (1/4 head) (1), and reconstituted frozen orange juice (1).

[1] Fats, oils, fatty acids, phospholipids, and sterols.

Consequences of Protein Deficiency. Because proteins are so important to numerous and very complex bodily functions, years of research have just commenced to provide some understanding of most of the mechanisms involved. As would be expected, recognition of the extreme manifestations of protein deficiencies has taken place, at least to the extent of providing new guidelines for assisting millions of inadequately fed people in several regions of the world. As further experience is gained in researching the gross problem, the important subtleties of protein performance within the body will become more apparent.

Exemplary of a better understanding and appreciation of protein nutrition is a comparison of the 1945 report of the Food and Agriculture Organization (United Nations) with more recent findings, recommendations, and nomenclature used. In the first *World Food Survey*, the terms *undernourishment* and *malnourishment* were used throughout the report. The general interpretation of undernourishment was taken to mean an inadequate caloric intake, i.e., insufficient energy input to support normal body functions and activities, with body weight loss the inevitable result. Similarly, *malnourishment* was taken to mean a deficiency of one or all of the protective nutrients, such as proteins, vitamins, and minerals. During the last few years, inasmuch as these two problems are so interrelated, the term *protein-calorie malnutrition* (PCM) has come into wide use. PCM of early childhood, particularly in regions that are a part of some of the less developed countries, is quite widespread. PCM apparently is manifested in minor ways at first, but when prolonged very severe syndromes become evident. These include the conditions known as *kwashiorkor* and *marasmus*.

Kwashiorkor usually occurs in the second or third year in the life of a child. Edema is the principal symptom. The condition arises from a combination of circumstances, but the primary cause appears to be a weaning diet that is both inadequate and indigestible and, notably, is lacking of protein. The principal calories are supplied by carbohydrate. The condition is accelerated by repeated infections of a bacterial, parasitic, or vital nature. Without treatment, the disease is fatal in most cases.

Nutritional marasmus is a severe manifestation of PCM and is a condition that usually occurs during the first year of life. Again, it arises from a combination of conditions, frequently widespread in many regions, of feeding an overly diluted formula of cow's milk, thus reducing the protein input well below minimum needs. The condition is accelerated by filthy surroundings and contaminated bottles. Characteristic of the syndrome are a wasting of muscle and subcutaneous fat, a body weight that may be only 60% of standard, and diarrhea. Children who have access to human milk usually are protected against marasmus and diarrheal disease.

A more recent finding and term now used for a protein deficiency syndrome is *PCM-plus*, or *infantile obesity*. This is a condition that occurs among the more affluent populations where an infant is bottlefed, where hygiene is adequate, and where funds are adequate. Overfeeding of an improperly balanced formula can cause the condition. The condition does not occur with breast feeding because the volume of intake is regulated by the infant's appetite and thirst.

Sources of Proteins

The two basic categories of protein sources for the animal diet are other *animals* (living or dead) and *plants*. Thus, in the animal category as a source of human and pet protein foods, there are what might be called terminal sources or nonreplenishing sources, in which the living animal is killed and disassembled into its protein-containing parts. The most common examples including the meaty flesh and organs of beef cattle, pigs, sheep, and horses and goats, as well as the more occasional sources of meat, such as deer, elephant, hippopotamus, etc., depending upon availability and regional eating preferences. To these sources are added the flesh and organs of birds (chickens, ducks, turkeys, pheasants, etc.) and of fish caught in saline and fresh waters. In the overall animal protein category, one also would include those less conventional and essentially unexplored categories, such as earthworms and single-cell proteins (produced by microorganisms) and algae. Renewable or repeating protein sources from living animals, of course, include the milk from dairy cows and buffaloes and the eggs from hens, from which hundreds of high-protein foods (cheese, for example) are prepared. And, to this category, must be added the excellent source of protein provided by human milk to the nursing infant.

Plants, of course, also require protein to build and maintain their life processes and, consequently, are protein sources for the animal diet. In the case of herbivores, plants are essentially the exclusive source of proteins, energy, and all other dietary elements.

In terms of percentage of protein content of basic sources, the animal sources far excel the plant sources. For example, the protein content of some typical unfortified foods is as follows: 20–30% for cooked poultry and meats; 19–30% for cooked or canned fish; 25% for cheese; 13–17% 17% for cottage cheese; 16% for nuts; 13% for whole eggs; 7–14% for dry cereals; 8.5–9% for white bread; 7–8% for cooked legumes; and about 2% for cooked cereals.

Of course, in achieving the higher protein contents of meat from poultry and cattle, a rather costly two-step production process is involved, wherein the animal first converts plant proteins (as from grasses) into animal protein. In a sense, the animal both converts and concentrates the protein source for humans. Several economic factors enter into the picture—the utilization of land, the costs of labor, the additional costs of feed materials, and the costs related to a greater time span of production, among others. As a case in point, an animal must be fed between 3 and 10 pounds (1.4 and 4.5 kilograms) of grain to produce 1 pound (0.45 kilogram) of meat. All of these factors in recent years, particularly in consideration of protein shortages in many regions of the world, have given rise to conflicting opinions pertaining to the ever-increasing production and consumption of meat, not only in several of the western nations of the world, but in the developed nations of the Orient as well. A few authorities have suggested that the western countries should cut back on meat production, thus making more land, skills, etc. available to increasing vegetable protein production to the level where a generous excess supply would be available to underdeveloped countries as well as amply supplying the protein needs of the developed countries. Quickly, these arguments penetrate not only into technological and economic factors, but psychological considerations as well—because any moves of this type necessarily require drastic changes in eating habits, and to bring them about successfully would require much more governmental regulation and policing than any system of private enterprise is likely to tolerate. Further, attitudes tend to swing rather widely from times of grain surplus to times of grain shortage.

Fortunately, as of the early 1980s, it appeared that protein-processing techniques were providing a very satisfactory compromise, even though the industry is just getting underway toward a large-scale operation. Protein meat extenders, for example, wherein meat and vegetable protein are blended to produce an edible product that retains much of what is desired of meats, including their good protein content, are finding acceptance. The wide acceptance of vegetable protein in analogue meat products has many hurdles to overcome, but it appears that a solid start has been made. The hurdles not only include acceptability in the marketplace, but also some justifiable resistance on the part of cattle and poultry producers. For many reasons, the transition, if it ultimately takes place, will occur over quite a long period of time. Because of continuing economic inflation, the earlier cost advantages that tended to favor blends of meat and vegetable proteins have become less significant.

An early impetus to soy protein foods was given when the United States introduced soy protein products into its overseas donation program in 1966 as a component of foods formulated to meet special needs of certain population groups. Chief among these were children in developing nations, especially the weanling infant and preschool child whose requirements for growth put special demands on diet composition. Pregnant and lactating mothers also had dietary needs frequently not met in countries where food supplies were marginal. Beyond these needs, there were nutrient deficiencies in large population groups, which could be best overcome by enrichment or fortification of commonly eaten foods.

Shortages in the domestic supply of nonfat dry milk, which developed in 1965, stimulated the development of high-protein formulated foods which would serve as supplements in the diets of the children or in the emergency feeding of adults. These formulations had to pass rigid specifications, one of the principal criteria being the recommended daily dietary allowance for protein, vitamins, and minerals. The U.S. Department of Agriculture and the U.S. Agency for International Development developed the guidelines and designed various formulated foods. Among these formulations were Corn-Soy Milk (CSM), Corn-Soy Blend (CSB), and Wheat-Soy Blend (WSB).

Further impetus was given to protein blends in foods when such products were introduced into the domestic food assistance program in the United States. Soy protein foods were introduced into school lunch and breakfast programs for which federal assistance has been given in the form of a subsidy administered by the federal government. Soy-fortified foods also were distributed to needy families through a family food distribution program.

Textured soy protein products in their use as meat alternatives have become increasingly popular in school lunch programs since their introduction in 1971. A soy-modified macaroni was introduced into the family food assistance program a number of years ago.

Less Conventional Sources of Protein. In addition to the traditional animal sources of protein already described and the very large amounts of vegetable protein derived from the soybean, other sources of protein on a large scale for the future are under intense study. Among these are (1) oil-seed crops, such as rapeseed and cottonseed; (2) leaf proteins; (3) algae; and (4) single-cell protein.

Rapeseed, one of the five most widely produced oilseeds, is cultivated mainly in India, Canada, Pakistan, France, Poland, Sweden, and Germany. Past objections to using rapeseed as a source of edible protein has been its content of deleterious glucosinolates. Considerable research has been conducted in Sweden to develop a rapeseed protein concentrate. The first full-scale production plant using a new process was installed in Alberta, Canada. The plant, with a capacity of 5000 tons/year produces a material containing 65% protein. Rapeseed is rich in essential amino acids, with exception of methionine, which soybeans also lack.

Cottonseed offers an attractive source of protein provided that certain objectionable ingredients can be removed. One of these is gossypol, a substance in cottonseed gland that is harmful to humans. A process developed by the U.S. Department of Agriculture has been designed to turn out a satisfactory edible cottonseed protein product. Employing solvent-extraction techniques, the first plant was built in Texas. Cottonseed flour extrudes easily and can be water-extracted to produce a nearly 100% protein isolate. The product has been used as a bland extender and fortifier for processed meats, baked goods, candies, and cereals. Research of a different approach has been used in Central America. In this approach, iron compounds are used to tie up the gossypol in nontoxic form without having to remove it.

Leaf Protein Concentrates. Laboratories in Hungary, Japan, the United Kingdom, and the United States, among other countries, have been engaged in perfection of a leaf protein concentrate process, with emphasis upon increasing yields and palatability and reducing flavor problems and cost. To date, alfalfa appears to be most attractive as a source of leaf protein. Alfalfa will produce more protein per unit of land than most other crops—up to 2800–4000 pounds/acre (3136–4480 kilograms/hectare). It has been estimated that the raw material costs for edible protein from alfalfa would be about 50% that for soybean meal. Several processes have been worked out, ranging from a green curd containing 52% protein to a white powder containing about 90% protein.

Single-Cell Protein. The advantages of single-cell protein (SCP) made from growing microorganisms are several: (1) SCP is independent of agricultural or climatic conditions; (2) SCP doubles in mass rapidly for high production rates and fast genetic experimentation; (3) the crop is free of surface-area limitations, and (4) the protein in microbial cells is generally of a high nutritional quality. Many of the processes proposed and tested, some with limited operating experience, commence with hydrocarbon feedstocks—gas oil and normal paraffin substrates. Two objections have been raised. The first is the possibility that carcinogenic polyaromatic materials present in gas oil may be passed along to the final protein product. The second is an adverse public reaction. A more recent, third objection is the proposition that perhaps technology should be concentrating on manufacturing fuels from farm products rather than food from petroleum products.

Some of the more recent SCP process concepts start with other materials, such as ethanol, acetic acid, starches, sugars, and cellulosic products that may be more available and particularly so in the protein-needy developing countries.

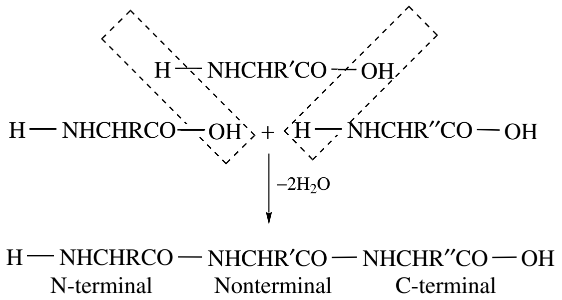
Algae have the highest intrinsic rates of photosynthesis and growth found among green plants. Human food and animal feed are being produced from algae. In Japan, a full plant-scale production harvests algae from open ponds to yield green powder extract that can be used for animal or human consumption. The genus *Chlorella* has perhaps received the most research to date.

Conservation Sources of Protein. Tightening pollution restrictions have forced cheese makers in many regions to end a long-time practice of dumping whey (with its high biological oxygen demand) as a liquid waste. Although many of these manufacturers are now evaporating or spray-drying whey to produce a whole-solids product, several fractionation techniques have been devised to separate a concentrated protein. In the United States, whey as a byproduct of cheese making totals well over 30 billion pounds (13.6 billion kilograms) per year. From 6.5 to 7% of the whey is solids, of which 0.9% is protein. Some authorities believe that whey and other milk-based protein ingredients offer a high growth potential among all of the non-soybean sources.

Fish protein concentrate is regarded by some authorities as having a high long-term potential. A major restraint is competition for the whole fish. As fish food sources become increasingly competitive, fishes currently considered "trash" fishes from a fresh marketing viewpoint may ultimately become more desirable for table use. Animal-feed fish meal also will be a strong contender for available fish. In terms of processes required for preparing fish-protein concentrate, extraction processes using single or mixed solvents of isopropanol, ethylene dichloride, ethanol, and hexane already have been developed. Experiments with enzymatic processing also are underway.

Chemical Nature of Proteins

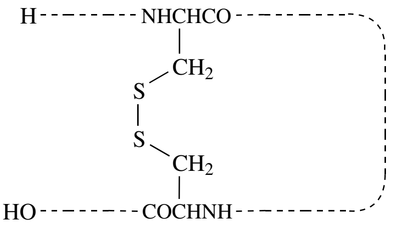
In defining a protein structurally, it is first necessary to define a peptide. Peptides are compounds made up of two or more amino acids covalently bound in an amide linkage. The characteristic amide linkage, in which the carboxyl group of one amino acid joins with the amino group of the next amino acid, is called a peptide bond. A peptide is a chain of amino acid residues. Provided that the chain is not circular or blocked at either of the ends, the peptide has an N-terminal amino acid, bearing a free amino group, and a C-terminal amino acid, bearing a free carboxyl group. This is illustrated as follows:



Usually a form of shorthand is used to represent the structure of a peptide. For example, H-Val-Gly-Ala-OH, represents a peptide where abbreviation for each amino acid is given in terms of three letters each (Val = valine; Gly = glycine; Ala = alanine). Abbreviations for other amino acids are given in entry on **Amino Acids**. The H denotes the amino terminal (N-terminal) and the suffix OH denotes the carboxyl terminal (C-terminal). Peptides may consist of from two to eight amino acid residues and thus are known as dipeptides, tripeptides, or oligopeptides (eight), depending upon the number of residues contained. A peptide consisting of ten or more amino acid residues and with a molecular weight in the range of $1–5 \times 10^3$ is called a polypeptide. Emil Fischer, father of protein chemistry, proposed early in the twentieth century that proteins are peptide in nature. Actually, no sharp demarcation exists between large polypeptides and small proteins. Examples of small proteins include insulin (hormone protein), protamine, and some components of histone (basic proteins of chromosomes).

Almost all proteins are comprised of amino acid residues, more than 100 in number, and their molecular weight may range from 10^4 to 10^7. A few examples include: Insulin (6×10^3); ribonuclease (13×10^3); lysozyme (eggwhite) (15×10^3); chymotrypsinogen (21×10^3); ovalbumin (43×10^3); serum albumin (66×10^3)—all of the foregoing being single peptide chains. Multiple chains include: Hemoglobin (68×10^3); gamma globulin (IgG) (160×10^3); fibrinogen (340×10^3); urease (460×10^3); thyroglobulin (640×10^3); myosin (850×10^3); hemocyanin (octopus) ($2{,}800 \times 10^3$); hemocyanin (snail) ($8{,}900 \times 10^3$); and tobacco mosaic virus ($40{,}000 \times 10^3$). Proteins of huge molecular weight (millions) are enormous aggregates of protein subunits, each of which may be so large (molecular weight = $1.5–10 \times 10^4$) in most instances. The independent peptide chains that constitute a protein molecule are often held by the disulfide bridges of cystine residues. From the diagram below, it will be seen that in a single chain the bridges may hold together two quite distant points in terms of

the linear amino acid sequence, forming a large loop structure:



Although more than 200 amino acids have been found in living organisms, only 20 alpha-amino acids of the L configuration have been found serving as the building units for proteins and related peptides. These 20 amino acids occur in varying proportions in different proteins. Some proteins are fully lacking in one or more of them. Some amino acids occur only in some of the proteins. For example, hydroxyproline has been found only in collagen and elastin (proteins of animal connective tissue) and in gelatin derived from collagen.

Numerous classifications of proteins have been proposed over the years. In terms of function, there are:

a. *Structural Proteins.* Proteins that support the skeletal structures, maintain the form and position of organs, impart the structural rigidity to walls of containers for biological fluids, and often form part of the external tissues. In keeping with their functions, they are insoluble in many liquids, especially body fluids, and are otherwise relatively resistant to biochemical reactions. The proteins of nails, horn, hoofs, and hair are familiar examples.
b. *Contractile Proteins.* Those substances that have the property of undergoing a change in configuration, which results in a change in length or shape. Thus they give the organism the power to move itself, its parts, or other objects. The proteins of muscles are prominent examples.
c. *Process-Activating Proteins.* As used here, the term *process* includes the biochemical reactions, which are catalyzed by enzymes, and in some of which the cytochromes play an intermediate role; it also includes the endocrine reactions activated by the hormones, some of which are proteins.
d. *Transport Proteins.* Proteins which transport an essential substance or factor, from that part of the organism where it becomes available from a source external to the organism to the point where it is used. Examples are many of the chromoproteins, such as hemoglobin, or the blue hemocyanins (from mollusks) which contain copper instead of iron as does hemoglobin, or the chlorophyll-protein complexes of plants.

Another basis of classification is that of solubility, which has been applied to proteins from all sources, plant and animal. (a) Thus the albumins were soluble in water and coagulable by heat. They included serum albumin, egg albumin, lactalbumin (from milk), leucosin (from wheat), and legumelin (from legumes, chiefly peas). (b) The globulins are soluble in neutral salt solutions and in strong acids and alkalies. They include blood globulin (which has been separated by electrophoresis into alpha, beta, and gamma fractions, and is further discussed later in this entry), ovoglobulin (from egg yolk), edestin (from hempseed), phaseolin (from beans), arachin (from peanuts), and amandin (from almonds). (c) The glutelins, such as glutenin from wheat, are soluble in dilute acids and alkalies, and insoluble in neutral salt solutions. (d) The scleroproteins are quite insoluble, and the structural proteins (group I mentioned above) belong to this group. All these groups, and several others not included here, are simple proteins, i.e., they consist only of polypeptide chains of amino acids. The many conjugated proteins must then be classified upon the basis of their nonprotein portions: glycoproteins which contain carbohydrate groups, lipoproteins which contain lipid groups, chromoproteins which contain metal-containing complexes that are usually colored, as hemoglobin contains heme.

Still another classification places proteins into three major categories: (a) Simple proteins; (b) conjugated proteins; and (c) derived proteins. The last classification embraces all denatured proteins and hydrolytic products of protein breakdown and no longer is considered a general class.

A relatively simplistic concept of a protein structure is indicated in Fig. 1. The molecular weight for the hemoglobins is on the order of 68,000. They are conjugated proteins and consist of four heme groups and the globin portion. The heme group is a porphyrin in which the metal ion coordinated is iron, which may be Fe^{3+} or Fe^{2+}, but only in the latter case (ferrohemoglobin) can the molecule bond molecular oxygen and be effective in respiration, i.e., by forming oxyhemoglobin. The globin portion of the molecule consists of four polypeptide chains. These chains are designated as alpha, beta, gamma, etc. according to their amino acid composition. Normal adult hemoglobin consists of two alpha chains and two beta chains. The composition and conformation of the beta chain are shown in the diagram, together with the point of attachment of the heme groups: Note that they are attached to histidine groups. It has been learned that the central iron atom in heme, which is chelated to the porphyrin ring by four bonds, is attached to the polypeptide chain in adult human hemoglobin by three imidazole ligands of the globin chain, which belong to the histidines at positions 58, 87, and 89 of the alpha chain. See also **Hemoglobin**.

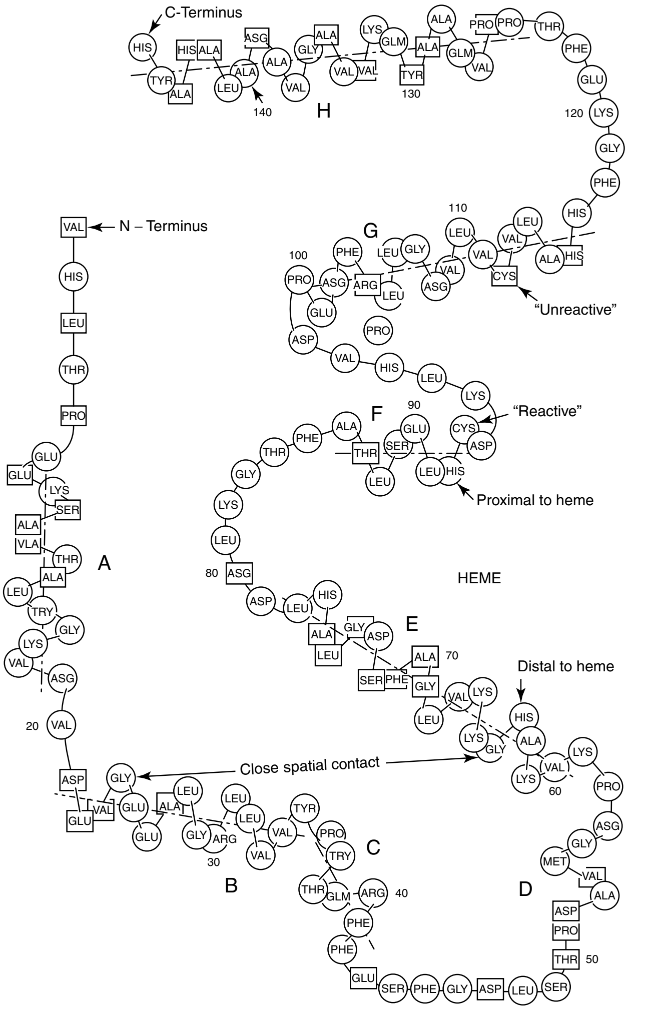


Fig. 1. Simplified representation of the beta chain of human hemoglobin A

Besides hemoglobin, other proteins of blood are of considerable importance. They are the plasma proteins, serum albumin and fibrinogen, and the globulins. Serum albumin is responsible for the major part of the osmotic pressure of human plasma. Its molecular weight is on the order of 68,000. It is a typical globular protein, having nearly one-half helical character. Although not as nearly symmetrical as hemoglobin or myoglobin, it has a symmetry indicated by its molecular dimensions of 150 Å long and 38 Å wide. It is the smallest, and most abundant, of the plasma proteins; for this reason, and also because of its relatively low isoelectric point, it undergoes migration rapidly in an electric field. See also **Electrophoresis**. By this method it may be separated into two types of molecules, similar in composition except for the presence of a single cysteine residue in one and not the other. However, it contains cystine residues, which form seventeen disulfide bridges cross-linking the polypeptide chain, i.e., the molecule of serum albumin consists of a single polypeptide chain.

Another plasma protein to be discussed here is fibrinogen, which is the chief substance involved in the process of blood clotting. Its molecular

weight is on the order of 330,000. It contains all twenty of the amino acids described in that entry as the most general in proteins, although it is relatively low in cysteine, and highest in the acidic amino acids (aspartic and glutamic acids). The process of clotting occurs in three major steps. In the first the substance prothrombin, a blood glycoprotein containing about 5% carbohydrate as glucosamine and a hexose sugar, is converted to the clotting enzyme thrombin. (The latter is unstable, and hence must be formed when needed.) The conversion process is catalyzed by the calcium ion and a group of substances known as thromboplastins. In the second step the enzyme thrombin catalyzes the transformation of fibrinogen to an activated form, called profibrin, with an altered pattern of electric charge. This change is considered to be due to the liberation of two short-chain polypeptides (one bearing 18 amino acid residues and the other 20), and a corresponding change in the character of the remainder of the fibrinogen molecule, which collectively constitute the substance profibrin. In the third step, this mixture of substances undergoes spontaneous polymerization to form the substance fibrin, which has been shown in electron microscope photographs to consist of a network of striated fibers. This polymerization occurs in stages, and in some views of the process they are divided into two steps, polymerization and clotting, the former being regarded as the formation of linear polymers, and the latter as their cross-linking by an enzymatic reaction whereby disulfide bonds are formed.

Animal organisms generally require effective assistance of intestinal flora, as in ruminants to assimilate inorganic nitrogen into a very wide variety of foreign substances, called antigens.

The life span of individual proteins in living organisms is relatively short—about 4 months for hemoglobin and but a week or two for serum albumin. The aged proteins are digested by proteolytic enzymes of tissues, such as cathepsin. A significant portion of the recovered amino acids may be available for the biosynthesis of new proteins, but another part is catabolized and the nitrogen is excreted as urea in mammals, uric acid in birds, reptiles, and insects, or ammonia in organisms of lower classes. For the maintenance of nitrogen balance and for growth, the human organism requires a daily intake of from 70 to 80 grams of proteins. The present world population thus requires 3×10^7 tons of animal proteins and 10×10^7 tons of plant proteins annually.

Living organisms can synthesize their own proteins from amino acids. In terms of the ability to carry out the de novo synthesis of amino acids, however, there are wide variations among different organisms. Plants, for example, can synthesize amino acids from nitrogen in the form of ammonium salts or nitrate and other simple compounds. The annual production of cereal and vegetable proteins so assimilated from inorganic nitrogen over the world is estimated to be about 10×10^7 tons. Of this, 4×10^7 tons are provided by wheat; 2×10^7 tons by rice; and 1×10^7 tons by corn and other sources. Lactic acid and some other microorganisms require preformed amino acids for growth, lacking some ability to synthesize. However, some microorganisms perform well with ammonium sulfate and carbohydrate as the sole sources of nitrogen, sulfur, and carbon. In some cases, they accumulate particular amino acids in a process referred to as amino acid fermentation.

Animal organisms generally require effective assistance of intestinal flora, as in ruminants, to assimilate inorganic nitrogen into body protein. This accounts for the human needs of a daily requirement of 70–80 grams of protein. However, over half of the protein-constituent amino acids can be derived from other amino acids by their own enzymic reactions. Thus, amino acids are classified as essential or nonessential. Amino acid requirements vary with the physiological state of the animal, age, and possibly with the nature of the intestinal flora.

The Food and Agricultural Organization (FAO) established the following essential amino acids in the ratios indicated:

	Percent of Crude Protein
Isoleucine	4.2
Leucine	6.2
Lysine	4.2
Methionine	2.2
Phenylalanine	2.8
Threonine	2.8
Tryptophan	1.6
Valine	5.0

A distribution of amino acids in dietary proteins can be obtained accordingly by taking both animal and plant proteins at a ratio of 1:3–4. Although plant proteins are lower cost, they are markedly deficient in some essential amino acids. Their protein efficiency is low without addition of deficient amino acids. Enrichment of human and animal diets with free amino acids, such as lysine, methionine, threonine, and tryptophan, as a substitute for animal proteins, has proved successful.

Excesses of amino acids are not harmful—with few exceptions. An imbalance of amino acids can result in a few instances. For example, a rat that feeds on eggwhite proteins with threonine or isoleucine added in high concentrations can experience an undesirable imbalance.

Several industries are based upon proteins as exemplified by the keratins of wool, feather, or horn; the fibroin of silk; the collagenous tissues as leather; proteins in milk, wheat, soybean, egg, and numerous other natural substances. Making cheese from milk casein and flavor seasonings from plant or fish proteins are old processes. Gelatin derived from collagen has been used widely in processed foods and as an adhesive material and in photography. Gluten in cereal is a protein. Major proteins in meat are *myosin*; in egg, *ovalbumin*; in rice, *oryzenin*; in soybean, *glycinin*; and in corn, *zein*.

Protein Quality and Evaluation. Protein quality relates to the efficiency with which various food proteins are used for synthesis and maintenance of tissue protein. Food industry evaluators of protein nutritional quality must operate on several levels of awareness. In particular, manufacturers of processed foods must measure the biological value of the protein content of a variety of processed foods for several reasons: (1) to comply with various governmental regulations; (2) to satisfy nutrition labeling regulations; and (3) an accurate knowledge of protein effectiveness is required in developing new food products and in controlling sources of protein ingredients. Protein quality is also very important in the formulation of animal feedstuffs.

In a number of countries, including the United States, the stipulated measurement of protein quality is the so-called protein efficiency ratio (PER), which may be defined as the *gain in weight* divided by the *weight of protein consumed* by experimental laboratory animals. As of the early 1980s, the AOAC (Association of Official Analytical Chemists) method, defined in 1975, is only one of the codifications of PER work since the concept was first proposed in 1919. More specifically, the PER is the ratio of the weight gained by a group of ten weanling rats fed a diet containing about 10% protein, to the weight of protein consumed over a 28-day period. No sample to be studied should contain less than 1.8% nitrogen according to the AOAC method, and the diet should supply 1.6% nitrogen. Since the samples are not analyzed for protein, but rather for nitrogen, and since protein efficiency ratio rather than nitrogen efficiency ratio is reported, it is important to be clear about whether one of the specific nitrogen factors or the conventional 6.25 figure is used to calculate the protein in the final diet.

Advances in Protein Chemistry

For many years, research was directed to a better understanding of the structure of proteins, notably based upon X-ray crystallography. Remarkable structural details were evidenced. But this avenue of research tended to regard proteins as being static in nature, whereas more recent findings show that indeed proteins are dynamic and that, if they were rigid, they simply could not function. The internal motions that underlie their workings are best explored in computer simulations. As pointed out by Karplus and McCammon, it is now recognized that the atoms in a protein molecule are in a state of constant motion. Thus, what the crystallographer finds is at best a representation of a protein's average structure. The chemical bonds between the atoms along the polypeptide chain in a protein act much like springs. There are also weaker forces between unbonded atoms, including forces that prevent more than one atom from occupying the same point in space at any given time. Thus, in a protein consisting of many atoms, the total force acting on any one atom at any given time depends upon the positions of all the others. Not surprising, the solution of Newton's equations of motion for determining the positions and velocities of all the atoms in a protein requires a high-speed computer. Such calculations constitute what is called a *molecular-dynamics simulation*.

In summarizing their recent research, Karplus (Harvard University) and McCammon (University of Houston) observe that, from future research, much will be learned regarding how to calculate the rates of enzymatic reactions, and the binding of small molecules to large ones, as well as the role of flexibility and fluctuations in the function of macromolecules. For example, it should become possible to determine how particular solvent

conditions and amino acid sequences produce certain patterns of protein fluctuations. Such information will become useful in applying new genetic technologies in a practical way.

Protein research of this kind is important because all enzymes are proteins. They catalyze the speed of essential reactions in living systems, including the synthesis of proteins themselves. Knowledge of the dynamics of proteins will assist in better understanding those proteins that transport small molecules, electrons and energy to specific parts of an organism where they are needed. Those proteins of a structural nature, which make up fibrous tissue and muscle, also will be better understood.

As pointed out by Phillips, the level of understanding of enzyme (protein) action has been achieved for many enzymes through the use of chemical, crystallographic, and spectroscopic methods. Gene science, however, has enormously advanced protein studies. By using cellular machinery for protein synthesis, proteins can be manufactured with any primary structure and then introducing whatever changes seem useful in the chemical constitution of naturally occurring proteins. With further knowledge, at some future date it most likely will be possible to design and manufacture fully novel proteins with new and useful properties.

Currently, the most useful advances are being made by the detailed modification of existing protein structures. A very small change, often involving only a single base, is made of the DNA coding for the protein. This is followed by use of natural cellular machinery (frequently bacteria) to synthesize the modified protein. The method is known as *site-directed mutagenesis*, which was first used in 1982. Classical chemical modification of protein structure still is used, but the site-directed mutagenesis approach is usually more straightforward and reliable.

Phillips has projected an imaginary oligopeptide with side chains grouped in accordance with their properties to illustrate intricacies of structure and regions of specializing functions. See Fig. 2.

Much progress is being made in connection with *fibronectins*, those adhesive proteins that act as biological organizers by holding cells in position and guiding their migration. Studies are now revealing the molecular bases for the functions of fibronectins. As observed by Hynes, within the complex architecture of a multicellular organism most normal cells remain reasonably stationary. They are anchored to basement membranes and connective tissue, which is made up mainly of a fibrous mesh of proteins and other substances. In the adults of most species, only

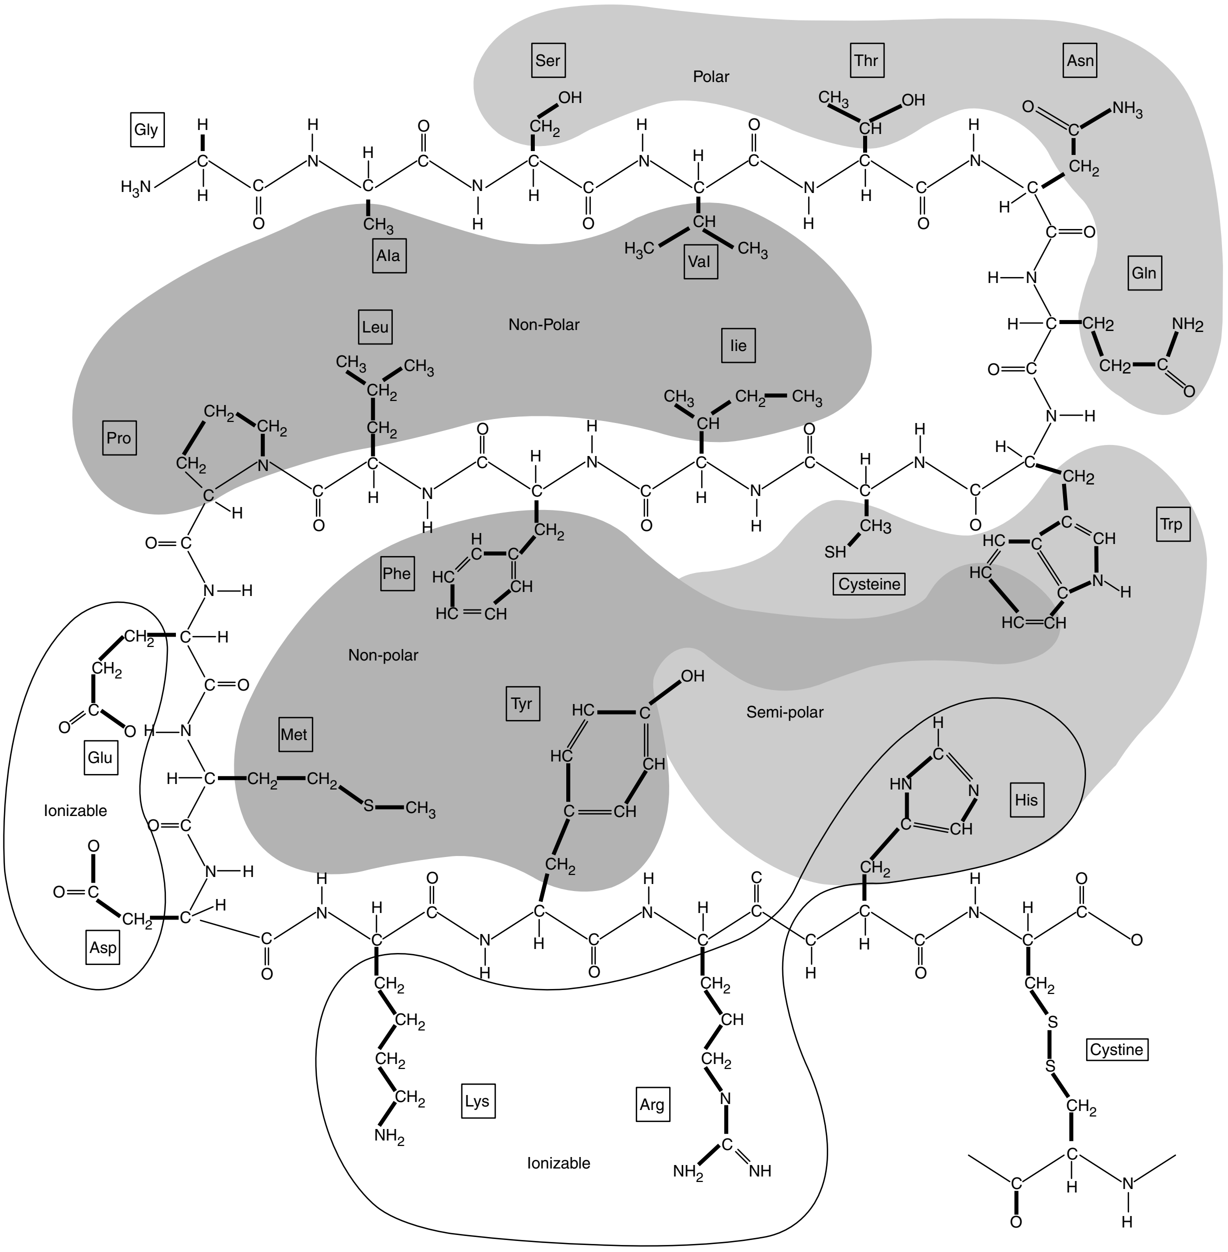

Fig. 2. Facsimile depiction of an imaginary oligopeptide with side chains grouped in accordance with their properties as proposed by Phillips (1987) in an excellent summary of "Protein Engineering" in the new and exceptional publication, *Scientific & Technology Review (The University of Wales)*. All twenty amino acids are represented as shown by three-letter abbreviations in the boxes on the diagram. Polar, semipolar, nonpolar, and ionizable portions of the hypothetical oligopeptide are indicated by shaded and dotted areas. Also, note disulfide bridge shown. (*After Phillips*)

a few cell types will routinely move through this extracellular matrix. It is known that during embryonic development and wound healing, some cells migrate extensively and usually unerringly. The question is asked—how can the organization of these cells be both fixed and dynamic? Glycoproteins (those with attached sugars) may be part of the answer. Of these glycoproteins, the fibronectins are currently the best understood. These molecules have several functions—they can assemble into fibrils, bind to cells, and link cells to other kinds of fibrils in the extracellular matrix. Fibronectin, of course, is a critical component of the blood clotting function. Several lines of research are now being followed in fibronectin studies. These are well described and illustrated in the Hynes reference. It has been suggested that, inasmuch as cancer most frequently involves metastasis (migration of tumor cells to unrelated tissues elsewhere in the body), there may be some connection with fibronectins, because their currently best understood role is that of keeping cells in place and when they move they control their migration.

W.R. Schaffer (University of California, Berkeley) and colleagues have been investigating what are known as *isoprenoids*. These compounds are structurally related lipophilic molecules that perform a wide variety of essential cellular functions. These lipids include such functionally diverse molecules as cholesterol, ubiquinone, dolichols, and chlorophyll, yet isoprenoids are derived from a common precursor, mevalonic acid. These studies may lead to a better understanding of the Ras oncogenic proteins.

In recent years, molecular biologists have found that proteins, in their various roles (binding of receptors, assembling into cellular structures, catalyzing metabolic reactions, etal) depend largely on their three-dimensional structure. For quite some time, biologists have been successful with their techniques for sequencing the amino acids that make up a given protein. In contrast, progress was slow toward determining how the protein chain of components folds into a three-dimensional structure.

It was not until quite recently that neural computers have been used to solve the protein-folding problem. Some proteins have been described in the past as being contorted into "tangled" structures, sometimes likened to a twisting telephone cord. Attempts to predict a folding pattern would require the computation of each part of a chain and its effect on adjacent parts of the chain, a computation process of great magnitude. Further, protein crystals are difficult to develop, thus eliminating or at least reducing the effectiveness of x-ray crystallography. Nuclear magnetic resonance (NMR) also has been used, but unfortunately tends to be limited to the smaller proteins and requires much computer time. Although several thousand proteins have been amino acid sequenced, only a few hundred structures have been determined.

In 1988, researchers T.J. Sejnowski and N. Olan (Johns Hopkins University) reasoned that a computer (NETtalk), that had been designed to pronounce written English words might be applied to the protein structure problem—because NETtalk also depended upon deciphering that occurs at the junctions of numerous separations in a word (as it may appear hyphenated) and that this analysis may be similar to the occurrence of a multi-hyphenated structure exhibited by proteins. The researchers explain that a learning rule modifies the network so that eventually the network will produce the correct phoneme a large percentage of the time. Further work along these lines resulted in a network that could correctly predict over 64% of a test sequence.

S. Brunak and R.M.J. Cotterill (Technical University of Denmark) pursued the approach further, based upon data inputs from NMR and x-ray diffraction. The neural network approach remains very active so that encoding of the intricacy of interconnections may be achievable.

In addition to studying the structure (folding) of proteins for fundamental knowledge, the study of enterotoxins has the additional incentive where life-threatening diseases are concerned, particularly toward the development of improved vaccines.

In research conducted at the University of Groningen (Netherlands) over a 14-year period, scientists succeeded in developing a pure crystal of the cholera toxin. Over 25,000 diffraction measurements of pure crystals, it became possible to generate a computer image of the cholera toxin. It has been observed that all bacterial toxins act in the same manner—one component is an enzyme that performs the invasive function and another component performs destruction once it enters the cell.

Research also has indicated that *E. coli* and diphtheria toxin perform in a similar manner. Active research programs currently are being conducted at Harvard University and the University of California, Los Angeles.

Similar structural determination studies are going forward to determine enzyme structures. In 1991, S. Taylor, D. Knighton, J. Sowadski, and colleagues (University of California, San Diego) announced their development of the three-dimensional structure of a protein kinase.

As aptly put by Doolittle (1985)—"If DNA is the blueprint of life, then proteins are the bricks and mortar."

PROTHROMBIN. See **Anticoagulants**; **Blood**.

PROTIUM. The lighter isotope of hydrogen, with a single proton and electron, and constituting 98.51% of ordinary hydrogen is termed protium.

PROTON. The proton is the atomic nucleus of the element hydrogen, the second most abundant element on earth. Positively charged hydrogen atoms or "protons" were identified by J.J. Thomson in a series of experiments initiated in 1906. Although the structure of the hydrogen atom was not correctly understood at that time, several properties of the proton were determined. The electric charge on the proton was found to be equal but opposite in sign to that of an electron. The traditionally accepted proton mass is 1836 times the electron rest mass, or 1.672×10^{-24} grams.[1]

An estimate of the size of the proton and an understanding of the structure of the hydrogen atom resulted from two major developments in atomic physics: the Rutherford scattering experiment (1911) and the Bohr model of the atom (1913). Rutherford showed that the nucleus is vanishingly small compared to the size of an atom. The radius of a proton is on the order of 10^{-13} centimeter as compared with atomic radii of 10^{-8} centimeter. Thus, the size of a hydrogen atom is determined by the radius of the electron orbits, but the mass is essentially that of the proton.

In the Bohr model of the hydrogen atom, the proton is a massive positive point charge about which the electron moves. By placing quantum mechanical conditions upon an otherwise classical planetary motion of the electron, Bohr explained the lines observed in optical spectra as transitions between discrete quantum mechanical energy states. Except for hyperfine splitting, which is a minute decomposition of spectrum lines into a group of closely spaced lines, the proton plays a passive role in the mechanics of the hydrogen atom. It simply provides the attractive central force field for the electron.

The proton is the lightest nucleus, with atomic number one. Other singly charged nuclei are the deuteron and the triton, which are nearly two and three times as heavy as the proton, respectively, and are the nuclei of the hydrogen isotopes deuterium (stable) and tritium (radioactive). The difference in the nuclear masses of the isotopes accounts for a part of the hyperfine structure called the isotope shift.

In 1924, difficulties in explaining certain hyperfine structures prompted Pauli to suggest that a nucleus possesses an intrinsic angular momentum or "spin" and an associated magnetic moment. The proton spin quantum number I is $\frac{1}{2}$, and the angular momentum is given by $[I(I+1)h^2/(2\pi)^2]^{1/2}$, where h is Planck's constant. The intrinsic magnetic moment is 2.793 in units of nuclear magnetons (0.50504×10^{-23} erg/gauss), which is about a factor of 660 less than the magnetic moment of the electron.

Two types of hydrogen molecule result from the two possible couplings of the proton spins. At room temperature, hydrogen gas is made up of 75% orthohydrogen (proton spins parallel) and 25% parahydrogen (proton spins antiparallel). Several gross properties, such as specific heat, strongly depend upon the ortho or para character of the gas.

See also **Particles (Subatomic)**.

[1] Particularly since the early 1970s, physicists have been seeking a grand unification theory to explain all the elementary particles of matter and all the forces acting between them. Although this goal continues to be elusive, work toward that end is producing many new findings and revised concepts. In the main part of this entry, the traditional viewpoints on the proton are described. Some of the more recent postulations are given toward the end of the entry.

PROTON-PROTON REACTION. A thermonuclear reaction in which two protons collide at very high velocities and combine to form a deuteron. The resultant deuteron may capture another proton to form tritium and the latter may undergo proton capture to form helium. The proton–proton reaction is now believed to be the principal source of energy within the sun and other stars of its class. A temperature of the order of five million degrees Kelvin and high hydrogen (proton) concentrations are required for this reaction to proceed at rates compatible with energy emission by such stars.

PROUSTITE. This ruby-silver mineral crystallizes in the hexagonal system; its name is a product of its scarlet-to-vermilion color when first mined. It is a silver arsenic sulfide. Ag_3AsS, of adamantine luster. Hardness of 2–2.5; specific gravity of 5.55–5.64. Usual crystal habit is prismatic to rhombohedral; more commonly occurs massive. Conchoidal to uneven fracture; transparent to translucent; color, scarlet to vermilion red. Light sensitive; must be kept in dark environment to maintain its primary character. A product of low-temperature formation in most silver deposits. Notable world occurrences include the Czech Republic and Slovakia, Saxony, Chile and Mexico. Found in minor quantities in the United States; the most exceptional occurrence at the Poorman Mine, Silver City District. Idaho where a crystalline mass of some 500 pounds (227 kilograms) was recovered in 1865. It was named for the famous French chemist, Louis Joseph Proust.

PROVITAMIN. The precursor of a vitamin. Examples are carotene and ergosterol, which upon activation become Vitamin A and Vitamin D, respectively.

See also **Vitamin**; **Vitamin A**; and **Vitamin D**.

PSEUDOMORPH. In mineralogy and geology, a mineral, having the crystal form of one species and the chemical composition of another. Typical pseudomorphs are malachite in the form of cuprite, barite in the form of quartz, limonite in the form of pyrite. In such cases of pseudomorphism the evidence seems to be that there has been a complete chemical and molecular change but without any change of the original outward form. See also **Mineralogy**.

PSEUDOPLASTIC SUBSTANCES. See **Rheology**.

PSILOMELANE. Psilomelane is a massive black mineral, essentially a basic oxide of barium with divalent and quadrivalent manganese, corresponding to the formula $BaMn^{2+}Mn^{4+}O_{16}(OH)_4$. It crystallizes in the monoclinic system, but is found only in massive, botryoidal or reniform to earthy habits; hardness, 5–6, less in earthy varieties; specific gravity, 6.45; color, black to gray; opaque; submetallic to dull luster. It is a product of secondary weathering of manganese carbonates and silicates. Of widespread occurrence, usually associated with pyrolusite. Major world occurrences include Michigan in the United States, Scotland, Sweden, France, Germany, and India. It is a major source of manganese. The word psilomelane is derived from the Greek words meaning smooth and black, in reference to the smooth black surfaces so often exhibited.

PSI PARTICLE. Discovery of this subatomic particle in 1974 was announced independently by Ting (Brookhaven National Laboratory) who named it the *J particle* and by B.D. Richter (Stanford) who named it the *psi particle*. The discovery of this particle resolved a number of important problems in particle physics. Intensive research on the psi particle was carried out by Richter and the Stanford group during 1975 and 1976 and is reported firsthand by Richter (*Science*, **196**, 1286–1297,1977). As pointed out by Richter, the four-quark theoretical model became much more compelling with the discovery of the psi particles. The long life of the psi is explained by the fact that the decay of the psi into ordinary hadrons requires the conversion of both c and $\bar{c}$ into other quarks and antiquarks. See also **Particles (Subatomic)**.

PSYCHOACTIVE DRUGS. See **Enkephalins and Endorphins**.

PTOMAINE. A group of highly toxic substances (derivatives of ethers of polyhydric alcohols) resulting from the putrefaction or metabolic decomposition of animal proteins. Examples that have been isolated and prepared synthetically are cadaverine (1,5-diaminopentane), muscarine (hydroxyethyltrimethylammonium hydroxide), putrescine (tetraethylenediamine), and neurine (trimethylvinyl-ammonium hydroxide).

Note: The term *ptomaine poisoning* is usually a misnomer for other types of food poisoning.

PULP (Wood) PRODUCTION AND PROCESSING. Pulps can be defined as fibrous products derived from cellulosic fiber-containing materials and used in the production of hardboard, fiberboard, paperboard, paper, and molded-pulp products. With suitable chemical modification, pulps can be used in the manufacture of rayon, cellulose acetate, and other familiar products. Pulps can be produced from any material containing cellulosic fiber; but in North America and several other regions of the world, wood is the predominant source of pulp. This description is confined to the production and processing of wood pulp.

Wood is a cellular substance chemically composed of roughly 70% holo cellulose, 25% lignin, and 5% water and ethyl alcohol-benzene soluble extractives. These percentages are based on oven-dry wood.

The chemical composition and physical character of wood vary from species to species, within species grown in different geographical locations, and within a given tree, depending upon the location of the fiber cell in the tree. Both lignin (noncarbohydrate) and holocellulose (carbohydrate) are polymeric substances. Holocellulose is composed of approximately 70% alpha cellulose and 30% hemicellulose, the long-chained alpha cellulose being characterized by nonsolubility in alkali; whereas the shorter-chained hemicellulose is alkali-soluble, the degree depending upon the alkali concentration. Lignin concentration in wood substance is greatest in the middle lamella (the zone around each individual fiber cell), decreasing in concentration through the cross section of the fiber, and reaching a concentration of about 12% at the inner layer of the fiber adjacent to the fiber cavity, or lumen. It is the middle-lamella material (lignin and hemicellulose) that cements the fiber cells together, thus giving rigidity to the fibrous wood structure.

The objective of wood pulping is to separate the cellulose fibers one from another in a manner that preserves the inherent fiber strength while removing as much of the lignin, extractives, the hemicellulose materials as required by pulp end-use considerations. Wood pulp to be used for the manufacture of hardboard, for example, requires only the removal of water-soluble wood sugars and sufficient fiberization, i.e., separation of fibers, to permit effective felting of the fibers in a sheet-forming operation. In a subsequent operation in which the felted fiber sheet is subjected to high pressure and heat, the lignin in the fiber mass softens and flows, ultimately acting as a bonding agent cementing the fibers together into a coherent hardboard. At the other extreme, wood pulp to be used for rayon manufacture must be of a high alpha-cellulose content ($\sim$ 88–93%), have extremely low amounts of noncarbohydrate material, and be well fiberized to permit uniform reactions during chemical processing.

Pulping Processes

Wood is converted to pulp by mechanical and chemical actions, which constitute the pulping process. Their selection depends upon the type of wood supply available and the pulp qualities desired. Pulps can be characterized on the basis of the unbleached pulp yields achieved by the pulping process used, i.e., the yield of oven-dry (OD) pulp obtained from oven-dry debarked wood.

Five major types, or classes, of pulps, related to pulp yield ranges normally considered to define each class of pulp, are shown in Fig. 1. Pulp yield is a direct indication of degree of chemical action (delignification and chemical attack on carbohydrate and other nonligneous material). Also shown in this figure are the degrees of defibration effected by chemical and mechanical action utilized to produce the pulp, although this representation is not strictly correct. For example, in producing a full chemical pulp, wood chips are subjected to chemical action (digestion or cooking) in a pressure vessel. When digestion is completed, the cooked and softened chips retain the same physical form as the raw chips originally charged to the digester. But they separate into essentially discrete fibers as a result of mechanical action occurring upon sudden release of the chips from the pressure vessel into a receiving tank, which ordinarily is at atmospheric pressure.

At the other extreme, no chemicals are used in the production of mechanical pulp, and defibration is effected by subjecting wood to a mechanical grinding or attrition action. In this instance, the defibration is aided by some small degree of chemical change and solubilization of wood substance occasioned by heat generated by the grinding operation.

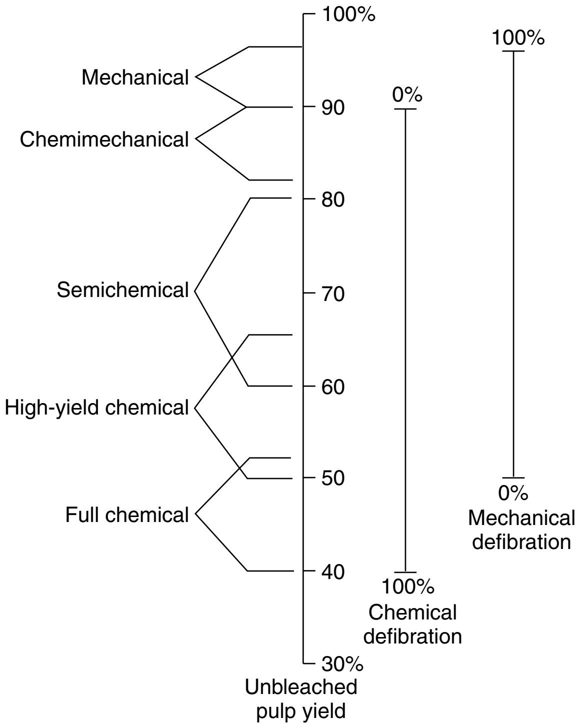

Fig. 1. Wood pulp characterized on basis of yield

The pulps listed in Fig. 1 are characterized on an unbleached basis as produced by processes conventionally called *pulping processes*. In many instances, these pulps must be further treated chemically to remove residual lignin, hemicellulose, and color bodies before they can be considered suitable for use in specific applications. This further treatment is called *bleaching*, and the bleaching operation is actually an extension of the pulping process.

Customarily, pulping processes and bleaching processes are considered separately, although the choice of bleaching process is highly dependent upon the pulping process used. With this distinction between pulping and bleaching in mind, it will be understood that the pulping processes that are briefly described here pertain only to the production of *unbleached* pulps.

The soda, kraft, and sulfite pulping processes are used to prepare full chemical pulps. The soda process, which uses sodium hydroxide as the cooking chemical for delignification purposes, has largely been superseded by the kraft process, which is characterized by its use of sodium hydroxide and sodium sulfide as active delignification agents in the chip-cooking phase of the process.

Chip-digestion parameters are digester pressure and temperature, digestion time to and at maximum temperature, amount of active alkali used per unit weight of OD wood (percent active alkali), percentage ratio of sulfide to active alkali (percent sulfidity), and weight ratio of cooking liquor (including chip moisture) to OD wood weight. No two kraft pulp mills use the same set of parameter values. Such values must be frequently adjusted, even within a given mill, because of variations in incoming wood and pulp-quality requirements.

Kraft processes are applicable to nearly all species of wood, and effective means of recovering spent cooking chemicals for recycle in the process have been developed. Some sodium and sulfur losses do occur and are replenished in the cooking-liquor system by adding sodium sulfate at the recovery boiler, where it is converted to sodium carbonate and sulfide. In order to maintain a proper sulfur-to-sodium ratio in the recovered chemicals, other chemicals, such as sodium carbonate, sodium sulfite, and sulfur, are sometimes used for chemical makeup.

In contrast to the highly alkaline (pH 11–13) kraft processes, sulfite pulping processes are acidic in nature and are of two general types: (1) the *acid sulfite processes* utilize calcium, sodium, magnesium, or ammonium bisulfite in combination with free or excess sulfur dioxide as

cooking chemicals (pH 1.7–2.3). (2) The *bisulfite processes* use sodium, magnesium, or ammonium bisulfite (pH 3.5–5.5) for chip digestion.

Several sulfite processes are multistage and use various combinations of acid sulfite and bisulfite cooking stages and can even use the alkaline kraft cook as one of the multistages. Although spent calcium acid sulfite cooking liquor can be incinerated, there is no recovery of calcium or sulfur. The sodium and magnesium bases can be recovered with or without sulfur recovery, and spent ammonium base liquor can be burned with recovery of sulfur as an option.

High-yield chemical pulps can be produced by the soda, kraft, or sulfite processes, in which chemical use and digestion time and/or temperature are suitably reduced to effect a milder cook than used for full chemical pulps. Mechanical defibrators are used to complete the separation of wood fibers not accomplished by the chemical action.

Semichemical pulps are usually prepared by the neutral sulfite semichemical (NSSC) process, although modifications of the full chemical processes can be used. Active pulping chemicals are (in the sodium-base NSSC process) sodium sulfite buffered with sodium bicarbonate (pH 7.0–9.0) and (in the ammonium-base NSSC process) ammonium sulfite with ammonium hydroxide used as a buffer. Defiberization is usually accomplished by attrition mills of the disk type.

Mechanical pulps are produced by two basic processes: (1) *stone groundwood pulp* (SGW) is produced by the defibration action of natural or artificial grindstones rotated at moderate speeds (200–300 rpm) against bark-free bolts of roundwood axially aligned across the peripheral face of the stone in the presence of water. By air-pressurization of the grinder, a *pressurized groundwood pulp* (PGW) of improved quality can be produced. (2) *Refiner mechanical pulp* (RMP) is produced by the attrition action upon raw wood chips of an open (atmospheric) discharge disk refiner. By preheating the chips in a pressurized vessel via direct steaming at temperatures of 120°C or higher and fiberizing the heated chips in either a pressurized or atmospheric disk refiner, *thermomechanical pulp* (TMP) is produced.

Chemimechanical pulps (CMP) are produced by processes in which roundwood or chips are treated with weak solutions of pulping chemicals, such as sulfur dioxide, sodium sulfite, sodium bisulfite or sodium hydrosulfite, followed by mechanical defibration. By presteaming chemically treated chips before attrition, *chemithermo-mechanical pulps* (CTMP) are produced. The mild chemical action, augmented by heat, softens wood lignin and promotes easier defibering with less fiber damage than achieved by the purely mechanical processes.

Wood Pulping Operations. The preceding description of pulps and pulping processes were given as a background to the following descriptions of the various operations involved in the preparation of wood pulp. The pulping system of a typical kraft linerboard mill, as indicated in the simplified flow diagram in Fig. 2, is illustrative of that required for the preparation of both full and high-yield chemical pulps. Linerboard normally is two-layered. The base, or primary sheet, is formed from a high-yield chemical pulp (50–54% yield) and the top, or secondary sheet, is formed from a full chemical pulp, either unbleached (48–50% yield) or bleached (46–48% unbleached yield), laid upon the wet primary sheet on the sheet-forming wire.

Pulp, paper, and paperboard mills are characterized by high capital investment costs and use of high tonnage and rugged but precisely engineered machinery capable of continuous operation with minimum maintenance. A modern kraft linerboard mill with a capacity of 1000 short tons per day (900 metric tons) will have an installed cost, excluding woodlands, of from $275,000 to $325,000 (1986 dollars) per daily on of board produced. Indication of machinery sizes will be given in the following paragraphs.

Wood-Chip Preparation. As indicated in Fig. 2, pulping operations begin with receipt of wood at the mill site. Pulpwood is supplied in log form (roundwood) or chips in accordance with specifications set by the pulp mill. Roundwood is usually received with bark on and in lengths and diameters suitable for proper handling in the wood-preparation equipment at the mill. It has been customary for mills to specify multiple lengths of pulpwood, i.e., 4 feet (1.2 meters) and 8 feet (2.4 meters) as standard receipts, but there is a trend to the procurement of tree-length logs, up to 70 feet (21 meters) in length, either exclusively or in combination with short logs. Another trend has been to the use of chips already prepared, except perhaps for final screening, by independent suppliers or by satellite wood yards operated by the pulp mill itself.

Although linerboard mills formerly used only softwoods (coniferous) for pulping, continued improvements in pulping and board-making technology have permitted the inclusion of up to 20% or more of hardwoods (deciduous) in the wood furnished to the mill, with improved utilization of woodlands as a beneficial result. Softwood and hardwood species are processed through the chipping operation and stored separately; they are either blended into the digester and cooked together, or they are processed separately and the respective pulps blended just ahead of the linerboard machine.

Former practice was to store pulpwood receipts in either a debarked or unbarked condition in stacks or random piles in the wood yard and to reclaim the yard wood for processing into chips just a few hours in advance of chip needs at the digester. A common practice today is to convert the wood into chips immediately after pulpwood receipt and to place the chips, usually by belt or air conveyance, in chip piles built up on concrete or asphalt pads. Separate piles are provided for softwood and hardwood chips, and storage capacities of 40,000 cords or greater can be maintained.

Pulp logs are conveyed to the debarking area, where they are cut to proper length, if necessary, and sorted. Accepted logs are mechanically fed into one end of a large horizontal, cylindrical drum, usually consisting of one or more sections constructed of spaced steel plates, channels, or bars mounted in carrying rings and supported on trunnions and driven by ring gears or suspended from an overhead structure by heavy chains, one or more of which are motor driven. This *barking drum rotates* at a speed of 5–8 rpm, and as the logs tumble about in passing from the intake to the discharge end of the drum, bark removal is effected by the logs rubbing against each other or against the bars or plates constituting the drum shell. Provision can be made for introduction of steam into the feed-end for log de-icing when needed.

Bark removal also can be accomplished by use of a *ring barker* or *hydraulic barkers* which employ high-pressure water jets for bark stripping. Bark removed is collected, shredded in a hog or hammer mill, and used as fuel in steam boilers, where it contributes about 3863 kJ/kg (9000 Btu/pound) of dry solids.

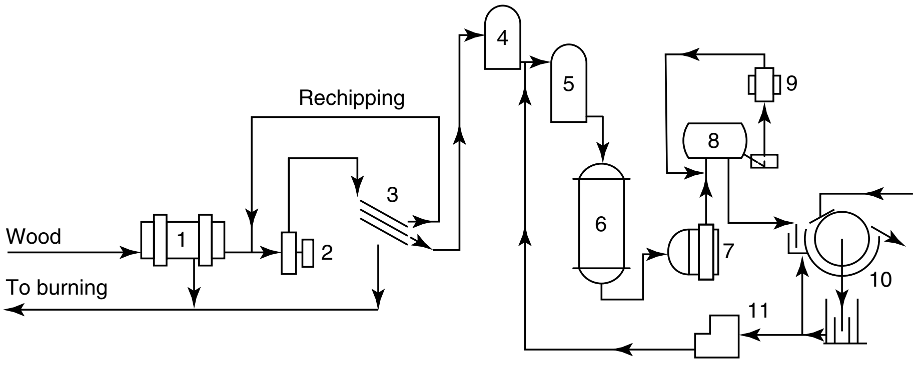

Fig. 2. Flow diagram of kraft pulp mill: (1) debarking, (2) chipping, (3) screening, (4) steaming, (5) impregnating, (6) digesting, (7) fibrilizing, (8) screening, (9) fiberizing, (10) washing, (11) chemical recovery

Debarked wood is conveyed to a chipper for conversion into chips of proper length for chemical treatment in a subsequent cooking operation. Chip length of 0.5–1.0 inch (12.7 to 25.4 millimeters) is conventional.

Chip Digestion. This cooking operation is accomplished in either a batch or continuous digester. A chip digester is essentially a large pressure vessel provided with suitable raw-chip and cooking liquor feed ports and a cooked-pulp discharge port. It is equipped with means for heating and maintaining its contents to and at a specified temperature for the required periods of time.

Batch digesters are vertical, stationary, cylindrical pressure vessels into which chips and cooking liquor are charged under atmospheric conditions. Heating of the digester, after sealing of the feed ports, is effected by direct steam addition or by continual withdrawal of liquor through screened ports and reintroduction of the liquor, after passage through external heat exchangers, onto the top (and sometimes into the bottom) of the chip mass within the vessel. Often, a combination of the direct and indirect heating methods is used. Modern batch digesters are typically 4000–6000 cubic feet (113–170 cubic meters) in volume, with height-to-diameter ratios of 3.5–5.5, and pre-cook pulp capacities of 10–12 tons (9–18 metric tons).

Continuous digesters have been developed as part of the highly successful effort to convert pulp and papermaking from a series of strictly batch operations into an integrated series of continuous operations. A number of successful types of continuous digesters range from horizontal and inclined tube (single or multiple) designs, in which the chip charge is moved through the digester by mechanical screw or bucket conveyors, to vertical digesters, in which chip movement is effected by gravity. See Fig. 3.

Screened chips are conveyed from storage to a chip supply bin in the digester house. The chip bin is designed so that low pressure steam recovered from the hot, spent cooking liquor can contact the chips, preheat them and expel most of the air from the chip interior. If hardwood and softwood chips are to be cooked together, they are blended by weight proportion during the transfer to the chip bin. The chips drop by gravity from the bin to a chip meter, either a twin-screw or a multi-pocket rotary feeder, the speed of which determines chip and cooking liquor flow rate to the digester and pulp discharge rate.

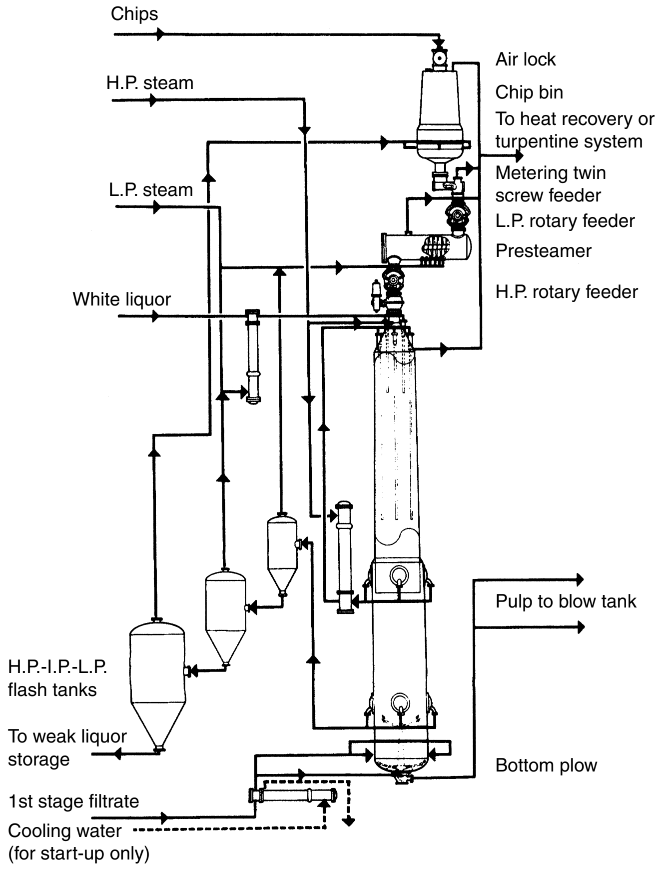

Fig. 3. Continuous digester system (*Ingersoll Rand Co.*)

Metered chips drop into a low-pressure rotary feeder valve, through which they are introduced to a steaming vessel maintained at a pressure of about 15–55 psi gage (1 to 3.5 atmospheres). There the chips are further preheated, the remaining air expelled from the chip interior, and chip moisture is leveled in preparation for impregnation of cooking liquor. Since cooked chips are continuously removed from the bottom of the digester, chips pass downward in the digester, replacing those discharged. The time of passage through the cooking zone is normally 90–120 minutes. As cooked chips reach the bottom zone of the digester, the hot, spent cooking liquor is displaced with cooler filtrate from the pulp washers, and removed via extraction strainers to a heat recovery system in which steam is generated to be used to precondition the chips being fed to the digester. As the partially cooled chips move further down the digester, they are plowed to a central well in the bottom of the digester, and are mixed with more filtrate from the pulp washers for dilution and final cooling. Mechanical forces exerted in the transfer of chips from the digester to the blow tank effect fiberization of the chips, the degree of which depends upon cooking conditions. The fibrous material in the blow tank is called pulp, and separate blow tanks are normally used to collect the several types of pulp produced alternately in the digester.

Pulp Screening and Washing. Pulp (brown stock) discharged to the blow tank is in admixture with black liquor, a water solution of spent and residual cooking chemicals and dissolved wood substance, and is at a consistency of from 10 to 18%. The term *consistency* has a meaning peculiar to the pulp and paper industry and refers to the percentage ratio of washed, dry (either oven- or air-dried) fiber to total fiber slurry weight. The fiber bundles left in the pulp after blowing must be fiberized, i.e., separated into discrete fibers, and the black liquor removed in order for the pulp to be refined (a conditioning of individual fibers) and formed into a fiber sheet on the linerboard machines.

Pulp is diluted with filtrate from the pulp washer to a consistency of about 4.5% in the lower portion of the blow tank and fed to fibrilizers, which serve the purposes of metal trapping, fiber-bundle breaking, rough screening, and pumping.

Removal of the black liquor from screened brown stock is usually accomplished on rotary-drum vacuum filters, arranged for multistage countercurrent washing, as shown in Fig. 4.

Refining is accomplished by disk mills, equipped with different plate designs or patterns than those used for defibration. During the refining operation, cellulose fibrils, which wind spirally around the fiber at various positions in its cell wall, are loosened, the cell wall swells due to water absorption, and the fiber is conditioned for sheet formation and inter-fiber binding in the paper- or board-making operation.

Chemical Recovery. Economic and environmental control factors dictate that chemical and heat values of black liquor solids be carefully

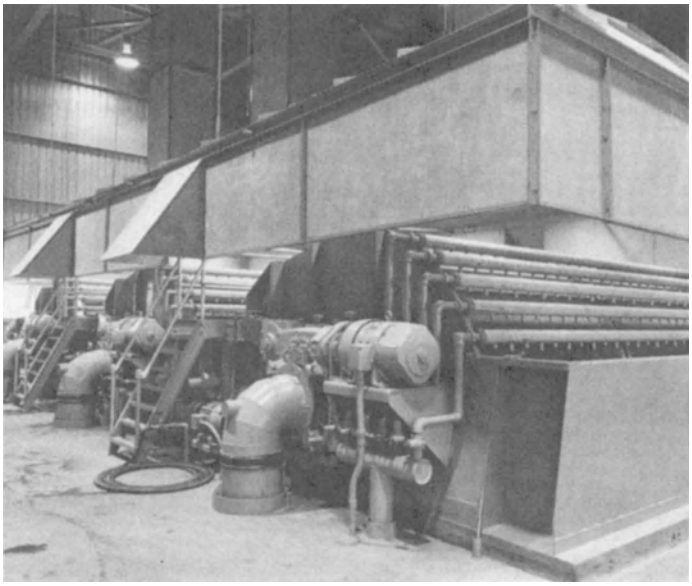

Fig. 4. Line of three brown stock washers, 9.5 feet (3 meters) in diameter and 16 feet (3 meters × 5 meters) long, equipped with multiport circumferential valve. First stage washer is shown in foreground. (*Ingersoll-Rand Co.*)

conserved, and the recovery system of the modern kraft pulp mill has developed into a highly sophisticated system with still more improvement in efficiency continually being sought. See also **Papermaking and Finishing**.

PULTRUSION. A technique for making certain products from glass-reinforced plastics, such as rods, electrical insulators, etc. It involves passage of continuous bundles of glass fiber, which have been impregnated with liquid resin through an oven at the rate of 18 inches per minute at 140°C (285°F).

PUMICE. A highly porous igneous rock, usually containing 67–75% SiO_2, and 10–20% Al_2O_3, with a glassy texture. Potassium, sodium, and calcium are generally present; insoluble in water; not attacked by acids. High gas content, when suddenly discharged by volcanic action; congeal in the form of a highly vesicular natural glass called pumice. When ground, mixed with an appropriate binder and pressed into cakes it is the "pumice stone" of commerce which is used as a light abrasive.

Uses. Concrete aggregate, heat and sound insulation, filtration, finishing glass and plastics, road construction, scouring preparations, paint fillers, absorbents, support for catalysts, and dental abrasive.

PURINE BASES. See **Nucleoproteins and Nucleic Acids**.

PURINES. [CAS: 120-73-0]. Derivatives of the dicyclodiureide of malonic and oxalic acids. The dicyclodiureide is uric acid and the parent compound is purine: so that uric acid is 2,6,8-trioxypurine or the keto form of 2,6,8-trihydroxypurine. Caffeine, theobromine, and theophylline are other important purine compounds.

Uric acid CAS: 69-93-2, ($C_5H_4O_3N_4$) is a white solid, insoluble in cold water, alcohol or ether, sparingly soluble in hot water. Uric acid is a weak dibasic acid thus forming two series of salts, most of which are very slightly soluble in water (lithium urate soluble).

Uric acid is found in the urine, blood, and muscle juices of carnivorous animals (herbivorous animals secrete hippuric acid), in the excrement of birds, serpents and insects, and is an oxidation product of the complex nitrogenous compounds of the animal organism.

Purine Metabolism

Purines are major building blocks for the nucleic acids, DNA and RNA. Adenine, also a purine, plays several important roles—as a cofactor component in energy metabolisms and in enzymatic reactions in which the coenzymes NAD^+ and $NADP^+$ are involved. The end product of purine metabolism is uric acid. It has been well established for many years that biochemical shortcomings in purine metabolism are the principal cause of gout. An average adult male will excrete between 200 and 600 milligrams of uric acid in the urine per day, representing about two-thirds of the total uric acid production in the body. Less than 10–20% of uric acid can be accounted for directly as dietary intake. When insufficient uric acid is excreted, a condition known as *hyperuricemia* will result. When the concentration of uric acid nears the saturation threshold, precipitation in tissues commences. Increased amounts of uric acid may be produced as the result of faulty enzyme activity or other abnormal factors that may occur in the purine metabolism system. Hyperuricemia may be evidenced by the development of an acute, extremely painful, swollen, inflamed joint, frequently at the base of the great toe (podagra). This condition is most commonly encountered in obese, overindulgent people. Usually this condition persists for several days to several weeks without treatment. The condition may recur periodically. The condition responds well to the administration of colchicine. See also **Alkaloids**. Treatment also includes removal of carbohydrates from the diet for a few days, as well as deprivation of alcohol and certain medications, such as thiazide diuretics. Abnormalities in purine metabolism also may create a purine nucleoside phosphorylase (PNP) deficiency, which ultimately may surface as *hypoplastic anemia*.

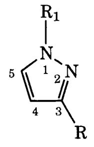
Purine, uric acid, and other associated compounds play a role in organic synthesis of industrial products.

PYCNOMETER. A device for measuring densities of liquids. It is a container, usually in the form of a bottle or a pipette-like tube, the capacity of which is accurately known and which may be completely filled with the liquid. The difference in weight when filled and when empty, together with the known volume of the liquid, gives the density. The pipette form has a mark to show how far to fill it, and is bent into a V-shape to facilitate immersion in a temperature bath. A familiar design is the "specific gravity bottle," a small flask with a ground and perforated stopper, and sometimes provided with a thermometer. In one of the most precise forms the stopper has a conical top with the capillary leading to the apex, and both neck and stopper are covered by a tight-fitting ground-glass cap to prevent evaporation.

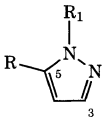
A preliminary step necessary to precise work with the pycnometer is the determination of its two volume constants; that is, the constants of the linear equation expressing the capacity as a function of the temperature. This is done by filling with distilled water and weighing accurately several times at each of two temperatures near the ends of the range for which the pycnometer is to be used. The bottle form is also adapted to the precise measurement of densities of solids. See also **Specific Gravity**.

PYRARGYRITE. An antimony-bearing silver mineral corresponding to the formula Ag_3SbS_3. It crystallizes in the hexagonal system, commonly in rhombic prismatic forms. It displays a rhombohedral cleavage; fracture, conchoidal to uneven; brittle; hardness, 2.5; specific gravity, 5.24; luster, adamantine to submetallic; color, deep red, but being light sensitive alters readily to black. In thin fragments deep red by transmitted light, otherwise practically opaque; streak, purplish red. Pyragyrite occurs with proustite, other silver minerals, and galena, and sphalerite. It is found in the Harz Mountains, in the Czech Republic and Slovakia, Bolivia, Chile, Mexico, and in the United States in Colorado, Idaho, and Nevada. In Canada it is found in the Cobalt region of the Province of Ontario. It derives its name from the Greek words meaning fire and silver.

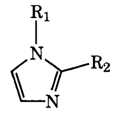
PYRAZOLES, PYRAZOLINES, AND PYRAZOLONES. The compounds of this article, i.e., five-membered heterocycles containing two adjacent nitrogen atoms, can best be discussed according to the number of double bonds present. Pyrazoles contain two double bonds within the nucleus, imparting an aromatic character to these molecules. They are stable compounds and can display the isomeric forms, (**1**) and (**2**), when properly substituted. Pyrazoles are scarce in nature when compared to the imidazoles (**3**), which are widespread and have a central role in many biological processes.



(**1**)

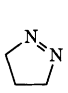


(**2**)

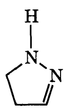


(**3**)

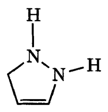
Pyrazolines have only one double bond within the nucleus and, depending on the position of the double bond, can exist in three separate forms: 1-pyrazoline (**4**), 2-pyrazoline (**5**), and 3-pyrazoline (**6**).



(**4**)

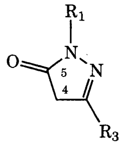


(**5**)

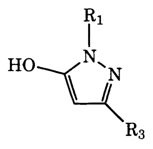


(**6**)

Pyrazolones, contain two double bonds, and are predominantly in the keto form (**7**), although they can also exist in the enol form (**8**).



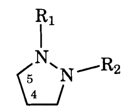
(**7**)



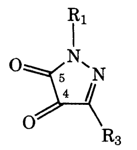
(**8**)

Neither pyrazolidines (**9**), which have no double bonds, nor pyrazoline diones (**10**), with two double bonds, and pyrazolidine triones (**11**), which

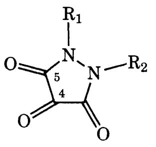
have three double bonds, are covered in this article.



(**9**)



(**10**)



(**11**)

Despite their scarcity in nature, the title compounds have found use in many applications, including pharmaceuticals, agricultural chemicals, and dyes.

Theoretical Methods

A number of theoretical studies on the reactivity of pyrazoles have been published. However, due to the difficulties involving these calculations, the studies often only approximate the actual reactions occurring in the laboratory.

Structural Elucidation

Among the modern procedures utilized to establish the chemical structure of a molecule, nuclear magnetic resonance (nmr) is the most widely used technique. Mass spectrometry is distinguished by its ability to determine molecular formulas on minute amounts, but provides no information on stereochemistry. The third most important technique is x-ray diffraction crystallography, used to establish the relative and absolute configuration of any molecule that forms suitable crystals. Other physical techniques, although useful, provide less information on structural problems.

Nuclear Magnetic Resonance Spectroscopy. The main application of nmr in the field of pyrazolines is to determine the stereochemistry of the substituents and the conformation of the ring. For pyrazolones, nmr is useful in establishing the structure of the various tautomeric forms.

X-Ray Diffraction. Because of the rapid advancement of computer technology, this technique has become almost routine and the structures of moderately complex molecules can be established sometimes in as little as 24 hours.

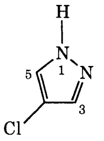
Miscellaneous Techniques. The use of ultraviolet (uv) and infrared (ir) spectroscopy has diminished drastically as newer and more powerful procedures have been introduced. However, uv is still useful in studying the tautomeric structures and ionization constants of pyrazoles.

Physical Properties

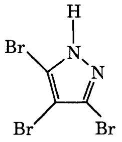
Pyrazoles in general are stable compounds, as demonstrated by pyrazole itself, which distills at 186°C at atmospheric pressure. The boiling point (bp) increases with an increase in the number of alkyl substituents on carbon. *N*-Methylation decreases both the bp and the melting point (mp) as a result of the elimination of hydrogen bonding. Pyrazoles with substituents at C_3 (C_5) are tautomeric mixtures and form azeotropes. The solubility of pyrazole in H_2O is about 1 g/mL, but it is much less soluble in organic solvents. Pyrazole is a weak base ($pK_a = 2.5$) and can be protonated by strong acids; strong bases yield metal salts. The pyrazolines resemble the pyrazoles in their physical properties. They are liquids with a high bp or low mp. Pyrazolines are basic and the ease of protonation is dependent on the position of the double bond. Most pyrazolones are solids and the mp usually decreases in the presence of substituents at N_1. Simple low molecular weight pyrazolones are soluble in hot water and the higher mol wt materials are soluble in most organic solvents. Hydrogen bonding has strong influence on the predominant tautomeric form. 3-Pyrazolones are more basic than the isomeric 5-pyrazolones.

Chemical Reactivity

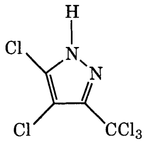
Pyrazoles. The chemical reactivity of the pyrazole molecule can be explained by the effect of individual atoms. The N-atom at position 2 with two electrons is basic and therefore reacts with electrophiles. The N-atom at position 1 is unreactive, but loses its proton in the presence of base. The combined two N-atoms reduce the charge density at C_3 and C_5, making C_4 available for electrophilic attack. Deprotonation at C_3 can occur in the presence of strong base, leading to ring opening. Protonation of pyrazoles leads to pyrazolium cations that are less likely to undergo electrophilic attack at C_4, but attack at C_3 is facilitated. The pyrazole anion is much less reactive toward nucleophiles, but the reactivity to electrophiles is increased. Chlorination of pyrazole yields 4-chloropyrazole (**12**) and bromination can produce mono-, di-, or tribromo pyrazoles (**13**). 3-Methylpyrazole on treatment with chlorine in acetic acid yields the pentachloropyrazole derivative (**14**).



(**12**)



(**13**)



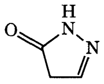
(**14**)

The pyrazole ring is resistant to oxidation and reduction. Only ozonolysis, electrolytic oxidations, or strong base can cause ring fission. On photolysis, pyrazoles undergo an unusual rearrangement to yield imidazoles via cleavage of the N_1-N_2 bond, followed by cyclization of the radical intermediate to azirine.

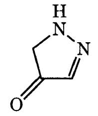
Oxidation of N_1-substituted pyrazoles to 2-substituted pyrazole-1-oxides using various peracids facilitates the introduction of halogen at C_3, followed by selective nitration at C_4. The halogen atom at C_3 or C_5 is easily removed by sodium sulfite and acts as a protecting group. Formaldehyde was used to direct the selective introduction of electrophiles at C_5 in a simple one-pot procedure.

Pyrazolines. The chemical properties of pyrazolines are governed by their relative instability. They readily undergo ring cleavage, and are easily reduced and oxidized. Loss of nitrogen occurs in pyrazolines lacking a substituent at N_1 to give a mixture of olefins and cyclopropanes, the latter being predominant. This elimination occurs near the map and can be catalyzed by uv light, aluminum oxide, and many other substances. Mild reduction of pyrazolines leads to pyrazolidines. Sodium–alcohol, tin–HCl, or Raney nickel cause ring cleavage, yielding diamines or aminonitrile derivatives. Pyrazolines are easily oxidized to pyrazoles by many reagents, such as bromine, permanganate, and lead tetraacetate. Besides pyrazole formation, rearrangements or side-chain oxidations may also occur. Oxidation with peracids produce N-oxides. Pyrazolines lacking a substituent at N_1 undergo reactions typical of secondary amines, such as acylation, benzoylation, nitrosation, carbamate, and urea formation.

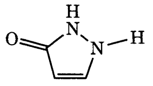
Pyrazolones. The oxo derivatives of pyrazolines, known as pyrazolones, are best classified as follows: 5-pyrazolone, also called 2-pyrazolin-5-one (**15**); 4-pyrazolone, also called 2-pyrazolin-4-one (**16**); and 3-pyrazolone, also called 3-pyrazolin-5-one (**17**). Within each class of pyrazolones many tautomeric forms are possible; for simplicity only one form is shown.



(**15**)

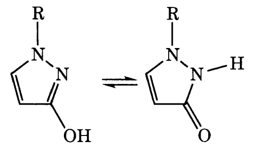


(**16**)



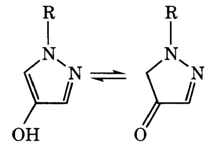
(**17**)

Substitution at N_1 decreases the possible number of tautomers: for 3-pyrazolones, two tautomeric forms are possible, (**18**) and (**19**), which in nonpolar solvents are both present in about the same ratio. 5-Pyrazolones exhibit similar behavior.



(**18**) (**19**)

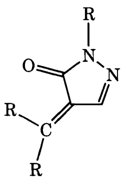
In 4-pyrazolones, the enol form predominates, although the keto form has also been observed.



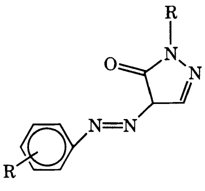
enol keto

The tautomeric character of the pyrazolones is also illustrated by the mixture of products isolated after certain reactions. Thus alkylation

normally takes place at C_4, but on occasion it is accompanied by alkylation on O and N. Similar problems can arise during acylation and carbamoylation reactions, which also favor C_4. Pyrazolones react with aldehydes and ketones at C_4 to form a carbon–carbon double bond, eg (**20**). Coupling takes place when pyrazolones react with diazonium salts to produce azo compounds, e.g. (**21**).



(**20**)

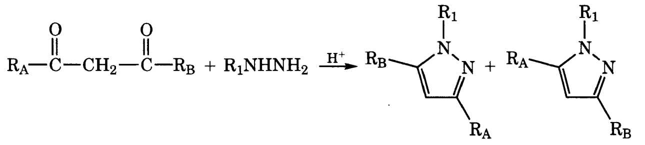


(**21**)

Compounds of type (**21**) are widely used in the dye industry. See also **Azo Dyes**.

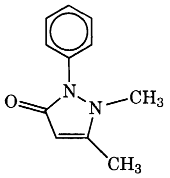
Synthesis

In general, the synthesis of pyrazoles and related compounds can be classified into one of four principal categories, with the first two classes being by far the most important: (*1*) from the reaction of hydrazine or its derivatives with β-bifunctional compounds, or compounds that give rise to such functionality (eq. 1) (*2*) by 1,3-dipolar cycloaddition, usually involving diazo compounds (eq. 2) (*3*) by ring-opening of more complex systems already containing the pyrazole nucleus; and (*4*) by chemical, thermal, or photochemical rearrangement of other monocyclic heterocycles. Examples from each class follow.

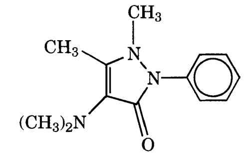


Health Factors

Pyrazole is considered a toxic material because in rats it causes hepatomegaly, anemia, and atrophy of the testis. It also inhibits the enzyme alcohol dehydrogenase, leading to severe hepatotoxic effects and liver necrosis when administered in combination with alcohol. Pyrazolones with a free NH group are easily nitrosated and give rise to nitrosamines, which cause tumors in the liver of test animals. The analgesics antipyrine (**22**) and aminopyrine (two pyrazolones), (**23**), if admixed with nitrites, are mutagenic when tested *in vitro*; however, when tested in the absence of nitrites, negative results are obtained.



(**22**)



(**23**)

Pyrazolone-type drugs, such as phenylbutazone and sulfinpyrazone, are metabolized in the liver by microsomal enzymes, forming glucuronide metabolites that are easily excreted because of enhanced water solubility.

Applications

Pyrazoles, pyrazolines, and pyrazolones have all found wide use in many fields. Their greatest utility resides in pharmaceuticals, agrochemicals, dyes (textile and photography), and to a lesser extent in plastics. The main uses of the pharmaceuticals that incorporate the pyrazole nucleus are as antipyretic, antiinflammatory, and analgesic agents. To a lesser extent, they have shown efficacy as antibacterial/antimicrobial, antipsychotic, antiemetic, and diuretic agents.

Compounds containing the pyrazole nucleus have also found utility in agriculture. The organophosphate and carbamoyl functionalities, which impart insecticidal activity through linkage to many organic molecules. These compounds act by interfering with acetyl-cholinesterase in the cholinergic synapses.

Pyrazole derivatives have also considerable herbicidal activity.

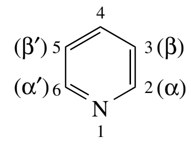
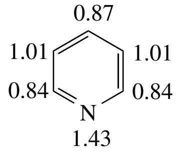
PYRIDINE AND DERIVATIVES. Pyridine, [CAS: 110-86-1], is a slightly yellow or colorless liquid; hygroscopic; bp, 115.5°C; fp, −41.7°C; unpleasant odor; burning taste; slightly alkaline in reaction; soluble in water, alcohol, ether, benzene, and fatty oils; specific gravity, 0.978; flash point (closed cup), 20°C; autoignition temperature, 482°C. Pyridine, a tertiary amine, is a somewhat stronger base than aniline and readily forms quaternary ammonium salts.

Pyridine and derivatives of pyridine occur widely in nature as components of alkaloids, vitamins, and coenzymes. These compounds are of continuing interest to theoretical physical, organic, and biochemistry and to industrial chemistry. Pyridine and derivatives have many uses, e.g., herbicides and pesticides, pharmaceuticals, feed supplements, solvents and reagents, and chemicals for the polymer and textile industries.

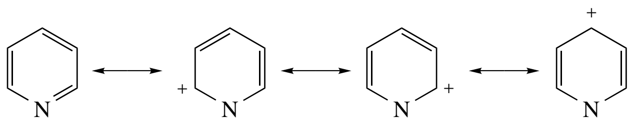
Structure and Nomenclature. The pyridine group consists of a six-membered, heterocyclic, aromatic compound with one nitrogen atom in the ring. The parent compound of this group is pyridine I with ring positions numbered as shown. Alternative denotations of the 1, 2, and 4 positions in the ring are alpha, beta, and gamma, respectively.



I



II



I*a* I*b* I*c* I*d*

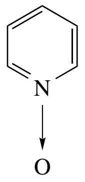
The behavior of pyridine in substitution reactions can be understood on the basis of its resonance structures (Ia–d) and on the basis of the electron-density distribution at the various ring positions as derived from molecular-orbital-theoretical calculations. An example of the published pi-electron density distribution is shown in II. The resonance energy of pyridine is 35 kcal/mole (versus 39 kcal/mole for benzene).

Electrophilic substitution occurs at the 3 and 5 positions, but usually requires drastic conditions because the species actually being attacked is a pyridinium ion. For example, nitration of pyridine with KNO_3 and concentrated H_2SO_4 at 300°C gives a 15% yield of 3-nitropyridine. Electrophilic substitution in the pyridine ring is facilitated by the presence of electron-donating substituents.

Nucleophilic substitution occurs in the 2, 4, and 6 positions of pyridine under relatively mild conditions. As an example, amination of pyridine with sodium amide in *N*, *N*-dimethylaniline at 180°C gives 2-aminopyridine in good yield.

Homolytic (free-radical) substitution may occur in any of the 2 to 6 positions of pyridine. Thus, the reaction of pyridine with benzenediazonium salts gives a mixture of 2-, 3-, and 4-phenylpyridine.

Many pyridine derivatives difficult to make directly from pyridine are readily accessible starting from pyridine *N*-oxide, made by oxidation of pyridine with hydrogen peroxide in acetic acid. As but one example, the nitration of pyridine *N*-oxide gives 4-nitropyridine *N*-oxide in high yield. Reduction of the *D*-oxide to the parent pyridine nucleus is readily effected by hydrogenation or reagents, such as PCl_3 or triphenyl phosphine.



Pyridine *N*-oxide

Trivial names for the methylpyridines are the *picolines*; the dimethylpyridines are the *lutidines*; and the trimethylpyridines (and in older literature the ethyldimethylpyridines) are the *collidines*. The refractive indices for these alkyl pyridines and for pyridine itself fall in the range: $n_D{}^{20} \sim 1.50-1.51$.

Production of Pyridine and Homologues

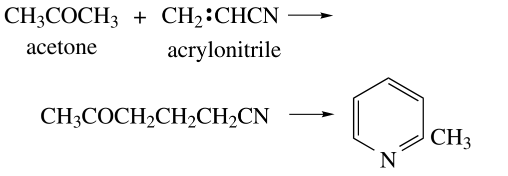
Coke Manufacture By-products. In United States practice, coking of coal is done almost exclusively by the high-temperature (900–1200°C) process. For many years, the major source of the pyridines was the chemical-recovery coke oven. The volatiles produced in the coke oven are only partially condensed. The noncondensed gases are passed through a scrubber (the ammonia saturator) containing sulfuric acid. After removal of crystals (ammonium sulfate), a solution of ammonium sulfate and pyridinium sulfates is obtained and treated with ammonia to liberate and contained pyridine bases (~ 70% is pyridine itself). See also **Coal Tar and Derivatives**. The balance of the pyridine bases is extracted from the crude coal tar, i.e., the condensed, main portion of the volatilization products from coking. The crude tar contains approximately 0.1–0.2% pyridine bases. Further separation of the pyridines involves a rather complex series of extractions, distillations, and crystallizations.

Synthetic Methods of Manufacture. Due to rising demand, production of the pyridine bases by large-scale synthesis passed the volume of tar bases extracted from coal tar in the 1960s. By the early 1970s, capacity in the United States for the synthetic manufacture of pyridine, the picolines, and 2-methyl-5-ethylpyridine (MEP) was in the tens of millions of pounds. All of these products can be made by condensation reactions of aldehydes and ammonia. MEP is no longer made in the United States.

When acetaldehyde and ammonia in a 3:1 mole ratio are fed over dehydration-dehydrogenation catalysts, such as PbO or CuO on alumina, ThO_2, or ZnO or CdO on silica-alumina, or CdF_2 on silicamagnesia at 400–500°C and atmospheric pressure, an equimolar mixture of 2- and 4-picolines can be obtained in 40–60% yields. When a mixture of acetaldehyde, formaldehyde, and ammonia in about 2:1:1 mole ratio is passed over such catalysts, pyridine and 3-picoline are produced; their ratios are usually 1:0.8, but the amounts of pyridine can be increased by changes in the feed.

The lowest-cost synthetic pyridine base, 2-methyl-5-ethylpyridine, is made in a liquid-phase process from paraldehyde (derived from acetaldehyde) and aqueous ammonia in the presence of ammonium acetate at approximately 102–190 atmospheres and 220–280°C in 70–80% yield. Minor byproducts include 2- and 4-picoline.

A new synthetic method for preparing 2-methylpyridine has been commercialized. This process involves the acid/base-catalyzed condensation of acetone with acrylonitrile to make 5-oxo-hexanonitrile. Then the nitrile is converted to a 2-methylpyridine by catalytic cyclization/dehydrogenation:



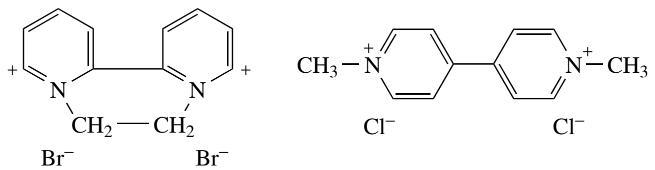
Much recent work has been done on the synthesis of pyridines from alkynes and nitriles over cobalt catalysts. For example, 2-vinylpyridine has been obtained in good yield from acetylene and acrylonitrile using a cyclopentadienyl-cobalt catalyst. Pyridine has also been obtained from cyclopentadiene and ammonia over a silica/alumina catalyst.

In the synthetic processes, mixtures of products are often obtained. Variation in the supply/demand balance of the alkyl pyridine isomers has led to much research on processes which may alleviate such imbalances, including development of the catalytic hydrodealkylation of alkyl pyridines to pyridine as well as the alkylation of pyridine.

Major Uses of Pyridine Derivatives

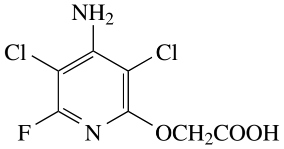
The applications of these compounds are wide-ranging and new uses are proliferating. The following examples are a selection of important commercial products, but hardly a complete listing.

Herbicides. A major outlet for pyridine (20–30 million lb/yr worldwide) is in the manufacture of the desiccant herbicides and aquatic weed killers, such as 1,1′-ethylene-2,2′-dipyridilium dibromide, known as Diquat;® and 1,1′-dimethyl-4,4′-dipyridilium dichloride (or dibromide or dimethylsulfate), known as Paraquat.®

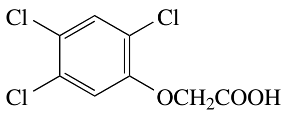


1,1′-ethylene-2,2′-dipyridilium dibromide — 1,1′-dimethyl-4,4′-dipyridilium dichloride

4-Amino-3,5-dichloro-6-fluoro-2-pyridyloxyacetic acid, tradenamed Sta rane,® is a herbicide used to control broadleafed weeds and brush species, and certain deep-rooted perennial weeds. 3,5,6-Trichloro-2-pyridyloxyacetic acid, tradenamed Garlon,® is a herbicide used for vegetation management, such as in rights-of-way.

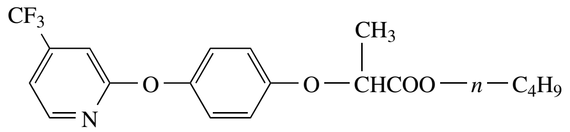


4-amino-3,5-dichloro-6-fluoro-2-pyridyloxyacetic acid



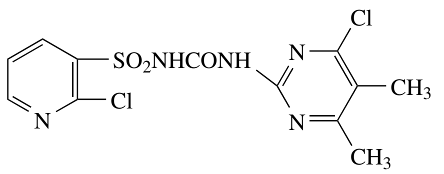
3,5,6-trichloro-2-pyridyloxyacetic acid

A new class of herbicides, the pyridylosy-phenoxyalkanoic acids, is typified by *n*-butyl 2-[4-(5-trifluoromethyl-2-pyridyloxy)phenoxy] propionate, tradenamed Fusillade,® active against annual and perennial grasses:



n-butyl-2-[4-(5-trifluoromethyl-2-pyridyloxy)phenoxy]propionate

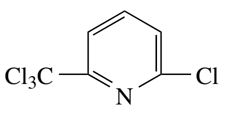
The newest class of pyridine herbicides with pre- and post-emergent activity, the pyridinesulfoneamides, is typified by *N*-(2-chloro-3-pyridinesulfonyl)-*N*′-[2-(4-chloro-5,6-dimethylpyrimidyl] urea.



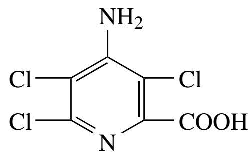
N-(2-chloro-3-pyridinesulfonyl)-*N*′-{2-4-chloro-5,6-dimethylpyrimidyl]urea

2-picoline (2-methyl pyridine) is the source of 2-chloro-6-trichloro methylpyridine, known as N-Serve,® which is useful as a fertilizer additive for reduction of nitrogen losses in the soil due to bacterial

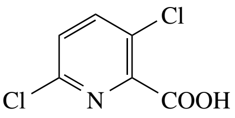
oxidation. 2-Picoline also is the starting material for the production of 4-amino-3,5,6-trichloropicolinic acid, a powerful broad spectrum herbicide for broad-leaved plants, known as Tordon.® 3,6-Dichloropicolinic acid, tradenamed Lontrel® and Format® in different formulations, is used for the postemergence control of broadleafed weeds.



2-chloro-6-trichloromethylpyridine

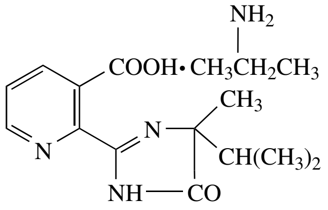


4-amino-3,5,6-trichloropicolinic acid



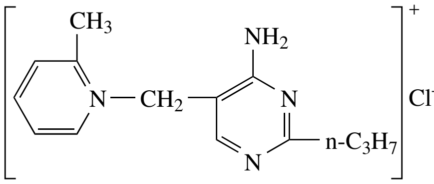
3,6-Dichloropicolinic acid

2,3-Lutidine (2,3-dimethylpyridine) is the starting material for the herbicide 2-[4,5-dihydro-4-methyl-4-(1-methylethyl)-5-oxo-1H-imidazol-2-yl]-3-pyridinecarboxylate (compound with 2-propanamine), tradenamed Arsenal.®

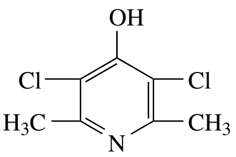


2-[4,5-dihydro-4-methyl-4-(1-methylethyl)-5-oxo-1*H*-imidazol-2-y1]3-pyridinecarboxylate (compound with 2-propanamine)

Pesticides. The compound 2-picoline is a component of 1-[(4′-amino−2′-*n*-propyl-5′-pyrimidinyl)methyl]-2-picolinium chloride hydrochloride, known as Amprolium,® a broad-spectrum coccidiostat. A newer coccidiostat is 3,5-dichloro-4-hydroxy-2,6-lutidine and known as Clopidol.®

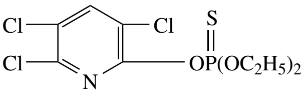


1-[(4′-amino-2′-*n*-propyl-5′-pyrimidinyl)methyl]-2-picolinium chloride hydrochloride

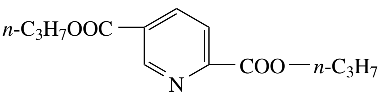


3,5-dichloro-4-hydroxy-2,6-lutidine

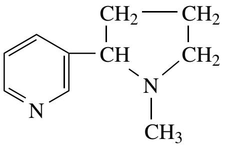
The acaricide *O*,*O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl) thiophosphate, known as Dursban,® is used to control ectoparasites. The similar, *O*,*O*-dimethyl-*O*-3,5,6-trichloro-2-pyridyl) thiophosphate, tradenamed Reldan® and Tumar,® is a nonsystemic insecticide/acaricide. Di(n-propyl)isocinchomerate, known as MGK Repellent 326® is used in fly repellents and is made by oxidation of 2-methyl-5-ethylpyridine and esterification of the isocinchomeronic acid obtained. Nicotine (sulfate) (Black Leaf 40®) is used as an agricultural insecticide, as an external parasiticide, and as an anthelminthic, and is obtained by extraction of tobacco wastes (not by synthesis).



O,*O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl) thiophosphate

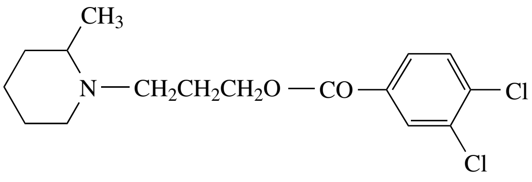


Di (*n*-propyl) isocinchomerate



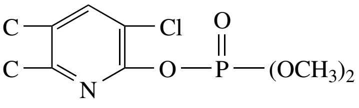
Nicotine

3-(2-Methylpiperidino)propyl-3,4-dichlorobenzoate, tradenamed Pipron,® is a foliar fungicide for the control of powdery mildew:

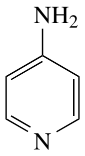


3-(2-methylpiperidino)propyl 3,4-dichlorobenzoate

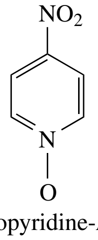
Dimethyl 3,5,6-trichloro-2-pyridyl phosphate, known as Fospirate® or Dowco® 217, is an insecticide useful in antiflea collars for dogs and cats. The compound 4-aminopyridine, known as Avitrol® 100, and 4-nitropyridine-N-oxide, known as Avitrol® 200, are useful as bird repellents.



Dimethyl-3,5,6-trichloro-2-pyridyl phosphate



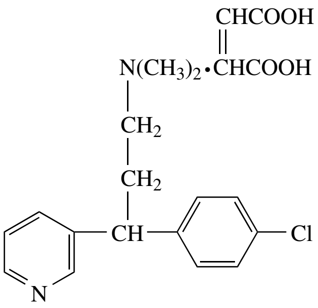
4-aminopyridine



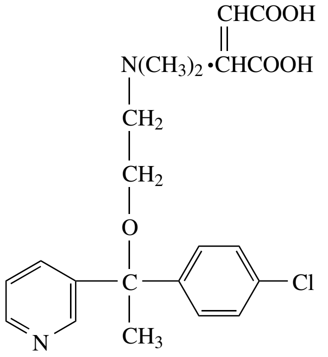
4-nitropyridine-*N*-oxide

Pharmaceuticals. A wide variety of pyridine compounds, with varying, and often multiple, drug action are used commercially. A few examples are given. A number of antihistamines contain the pyridine moiety in their structure, as exemplified by chlorpheniramine maleate (2-[p-chloro-α-(2-dimethylaminoethyl)benzyl] pyridine acid maleate); doxylamine succinate (2-[α-(2-dimethylamino)ethoxy-α-methylbenzyl]-pyridine acid succinate); and pyrilamine maleate (2-(2-dimethyl-aminoethyl-2-p-methoxybenzyl) aminopyridine acid maleate). These products are synthesized, e.g., from

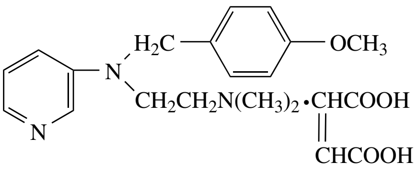
the appropriate benzylpyridines or aminopyridines.



Chlorophenirame maleate

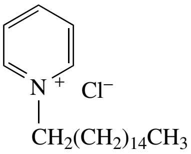


Doxylamine succinate



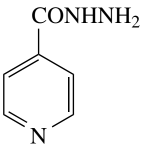
Pyrilamine maleate

Cetylpyridinium chloride is used as a germicide and antiseptic, e.g., in mouthwashes; it is made by quaternization of pyridine with cetyl chloride.



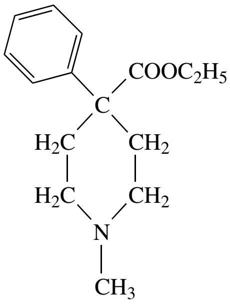
Cetylpyridinium chloride

Isonicotinehydrazide, also known as isoniazid, is an important anti-tubercular drug made by oxidation of 4-alkylpyridine (or 2,4-lutidine) or by hydrolysis of 4-cyanopyridine to isonicotinic acid (pyridine 4-carboxylic acid) and reaction of an ester or the acid chloride of the latter with hydrazine.



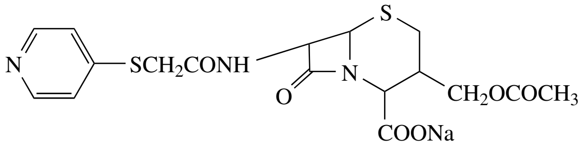
Isonicotinehydrazide

Meperidine hydrochloride (1-methyl-4-carbethoxy-4-phenylpiperidine), also known as Demerol,® is an important narcotic and analgesic. It is not made from piperidine, but rather by ring-closure reactions of appropriate precursors.



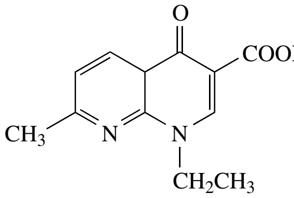
Meperidine hydrochloride

Cephapirin sodium, tradenamed Bristocef,® Cefadyl,® Today® (and others) is a cephalosporin C antibiotic:

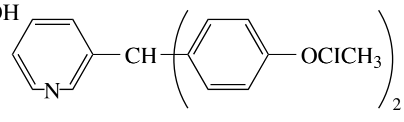


Cephapirin sodium

Nalidixic acid (1-ethyl-7-methyl-1.8-naphthridine-4-one-3-carboxylic acid), many tradenames (e.g., Nalidicron®), is an antibacterial. *Bisacodyl* [4,4′-(2-pyridylmethylene)diphenol diacetate], tradename Dulcolax,® is a laxative.

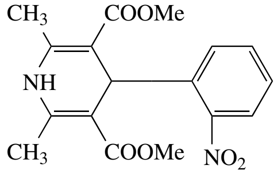


Nalidixic



Bisacodyl

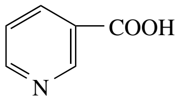
Nifedipine [1,4-dihydro-2,5-dimethyl-3,5-dicarbmethoxy-4-(2-nitroph enyl)pyridine], tradename Procardia,® is used in the treatment of angina.



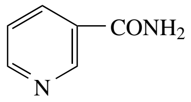
Nifedipine

Nicotinic acid and nicotinamide, members of the vitamin B group and used as additives for flour and bread enrichment, and as animal feed additive among other applications, are made to the extent of 24 million pounds (nearly 11 million kilograms) per year throughout the world. Nicotinic acid (pyridine-3-carboxylic acid), also called *niacin*, has many uses. See also **Niacin**. Nicotinic acid is made by the oxidation of 3-picoline or 2-methyl-5-ethylpyridine (the isocinchomeric acid produced is partially decarboxylated). Alternatively, quinoline (the intermediate quinolinic acid) is partially decarboxylated with sulfuric acid in the presence of selenium dioxide at about 300°C, or with nitric acid, or by electrochemical oxidation. Nicotinic acid also can be made from 3-picoline by catalytic ammoxidation to 3-cyanopyridine, followed by hydrolysis.

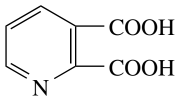
Nicotinamide is prepared by partial hydrolysis of the nitrile, or by amination of nicotinic acid chloride or its esters. Some of the compounds mentioned in the foregoing are shown below.



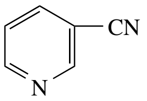
Nicotinic acid



Niacinamide



Quinolinic acid

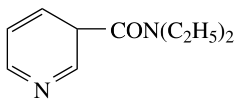


3-cyanopyridine

Several esters of nicotinic acid are used as vasodilators.

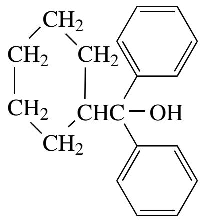
Nikethamide is a respiratory and heart stimulant, used beneficially against overdoses of barbiturates and morphine. Also known as Coramine,® this compound (*N*, *N*-diethylnicotinamide) is made by reaction of nicotinic acid esters or the acid chloride with diethylamine. Its

formula is shown below.



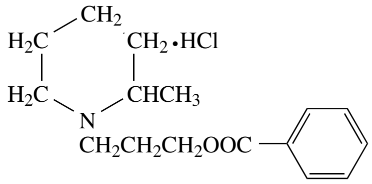
Nikethamide

Pipadrol is a central nervous system stimulant. This compound, α,α-diphenyl-2-piperidinemethanol, is made by condensation of 2-pyridylmagnesium chloride with benzophenone and catalytic hydrogenation of the pyridine ring of the resultant carbinol. Its formula is shown below.



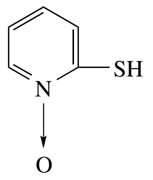
Pipadrol

Piperocaine hydrochloride is used as a local anesthetic. This compound (d,l-(2-methylpiperidino)propyl benzoate hydrochloride) is made by reaction of 2-methylpiperidine with 3-chloropropyl benzoate. Its formula is shown below.



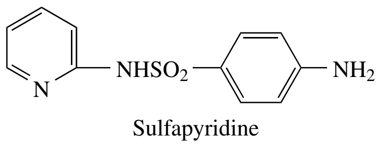
Piperocaine hydrochloride

Pyrithione (zinc salt of) is used as a component of antidandruff shampoos and as a bactericide in soap and detergent formulations. This compound (2-mercaptopyridine N-oxide) exists in equilibrium with N-hydroxy-2-pyridinethione and is a fungicide and bactericide, prepared by reaction of 2-chloropyridine N-oxide with sodium hydrosulfide and sodium sulfide. This compound is also known as Omadine.® Its formula is shown below.



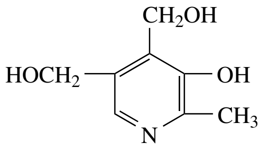
Pyrithione

Sulfapyridine is used to treat dermatitis herpetiformis and also has been used by veterinarians against pneumonia, shipping fever, and foot rot of cattle. This compound (2-sulfanylamidopyridine) is made by condensation of 2-aminopyridine with the appropriate sulfonyl chloride. Its formula is shown below.



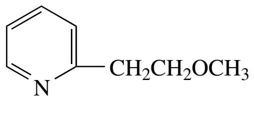
Sulfapyridine

Vitamin B6 is described in detail under **Vitamin B$_6$ (Pyridoxine)**. This is 2-methyl-3-hydroxy-4,5-di(hydroxymethyl)pyridine or pyridoxol. World demand of this compound is estimated at about 5 million pounds (about 2.3 million kilograms) per year. Commercial production is by synthesis, starting, for example, with the base-catalyzed condensation of cyanoacetamide and ethoxyacetylacetone. The formula for pyridoxol is shown below.

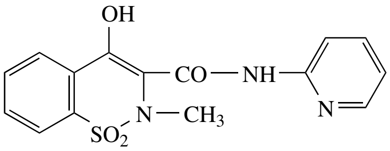


Pyridoxol

Methyridine or 2-(2-methoxyethyl)pyridine, also called Mintic,® is used as an anthelmintic. *Piroxicam*, also known as Feldene,® is a relatively new anti-inflammatory for the treatment and relief of arthritis. See formulas below.

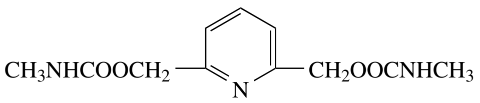


Methyridine



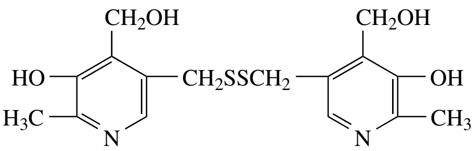
Piroxicam

Pyridinol carbamate has been used as an anti-inflammatory/anti-arteriosclerotic. This compound 2,6-pyridinedimethanol-bis-(N-methyl carbamate) is also known as Anginin.® See the formula below.



Pyridinol carbamate

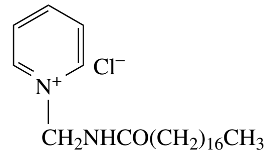
Pyrithioxin is a neurotropic agent that reduces the permeability of the blood-brain barrier to phosphate. This compound, 3,3′-dithio-dimethylene-bis-(5-hydroxy-6-methyl-4-pyridinemethanol), is also known as Life® and Bonifen.® Its formula is shown below.



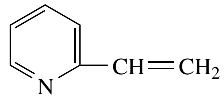
Pyrithioxin

Textile Chemicals. Pyridine derivatives find a number of quite different applications in the textile and related fields.

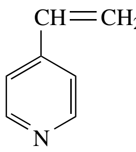
Stearamidomethylpyridinium chloride is used in waterproofing textiles. It is made by reacting pyridine hydrochloride with stearamide and formaldehyde. *Vinylpyridines* are used as components of acrylonitrile copolymers to improve the dyeability of polyacrylonitrile fibers. The commercially important products are 2-vinylpyridine; 4-vinylpyridine; and 2-methyl-5-vinylpyridine. Formulas are shown below.



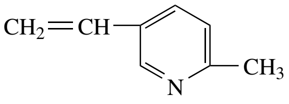
Stearamidomethylpyridinium chloride



2-vinylpyridine



4-vinylpyridine

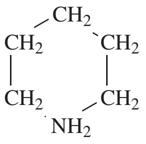


2-methyl-5-vinylpyridine

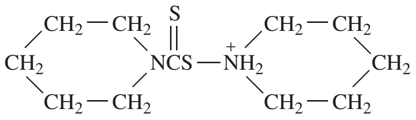
2-Vinylpyridine is used in the terpolymer latex component of tire cord dips to improve the bonding of textile to rubber. Rubber tires built with steel cord, however, do not require vinylpyridine latex-based adhesives for the steel belt. Therefore, the consumption of vinylpyridines may be affected in the future.

Other. The pyridines and methylpyridines and their mixtures are used as chemical processing aids (e.g., acid acceptors, solvents) and as industrial corrosion inhibitors.

Piperidine, the hydrogenation product of pyridine, is used as an intermediate for drugs and for making rubber-vulcanization accelerators, e.g., piperidinium pentamethylenedithiocarbamate (also known as Accelerator 552®). On a commercial scale, piperidine (hexahydropyridine) is prepared by the catalytic hydrogenation of pyridine, e.g., with nickel catalysts at from 68 to 136 atmospheres pressure and at 150–200°C, or under milder conditions with noble-metal catalysts. Pyridine derivatives can be similarly reduced to substitute piperidines. See formulas below.



Piperidine

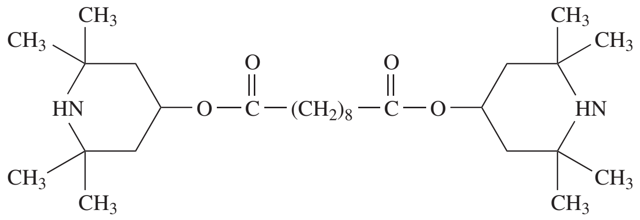


Piperidinium pentamethylendithiocarbamate

4-*N*,*N*-Dialkylaminopyridines have found use as catalysts for acylation reactions.

There are developing applications for linear and crosslinked poly vinylpyridines in photovoltaic cells and batteries, electron beam resists, as catalysts and reagents (e.g., in pollution control).

The hindered-amine light stabilizers for polymers are piperidine derivatives. An example of these products is bis-(2,2,6,6-tetramethyl-4-piperidinyl)sebacate, tradenamed Tinuvin 770,® useful as a light stabilizer for polyolefins and styrenics.



Bis-(2,2,6,6-tetramethyl-4-piperidinyl)sebacate

There is growing evidence of developing high-technology uses of pyridines, particularly as quaternary salts, as components of electrolytic capacitors, photoconductors, rechargeable batteries, complex-coated electrodes for photosensors, electrochromic display elements and photoresist matrix resins.

Health and Safety Factors

Pyridine Acute Toxicology. Pyridine causes gastrointestinal upset and central nervous system (CNS) depression at high levels of exposure. The odor of pyridine can be detected at extremely low concentrations (12 ppb).

Acute Toxicology of Pyridine Derivatives. In general, many pyridines are reasonably safe to handle and do not represent a serious hazard. However, some types of aminopyridines are poisons. Quaternary salts of pyridines can also be toxic. Chloropyridines, especially polychloropyridines, can potentially be mutagenic, teratogenic, and carcinogenic.

Safety Aspects in Handling and Exposure. Pyridine compounds are ubiquitous in the natural environment, and are often found in foods as minor flavor and fragrance components. Some synthetic pyridines are used as food additives. A high proportion of pyridine compounds shows some type of bioactivity, albeit mostly minor, such as herbicidal, insecticidal, or medicinal activity. Therefore, all the normal precautions should be exercised when handling pyridines that would be used when handling other organic products that are potentially bioactive.

Pyridine and alkylpyridines are excellent solvents for many materials, a property that must be taken into account when selecting O-rings, gaskets, and other sealants that are in contact with liquids.

PYRITE. The mineral pyrite or iron pyrites is iron disulfide, FeS_2, its isometric crystals usually appearing as cubes or pyritohedrons. It has a slightly conchoidal to uneven fracture; brittle; hardness, 6–6.5; specific gravity, 5; metallic luster; color, pale to normal brass-yellow; streak, greenish-black; opaque. Arsenic, nickel, cobalt, copper, and gold may be found in small quantities in pyrite, auriferous pyrite being sometimes a very valuable ore. Pyrite is the commonest of the sulfide minerals, and is of worldwide occurrence. It is found associated with other sulfides, or with oxides, in quartz veins, in sedimentary and metamorphic rocks, in coal beds, and as the replacement material in fossils. There are many well-known pyrite localities, among which are the Rio Tinto mines in Spain, where copper-bearing pyrite is obtained from huge deposits. Magnificent crystals and crystal groups occur at Ambasaguas (Logrono) in Spain; Quirivulca, Peru; and from the Island of Elba. In the United Stated pyrite is found in California, New York, and Virginia in workable deposits. The name pyrite is derived from the Greek word meaning fire, because of the sparks that result when pyrite is struck with steel.

PYROGENETIC MINERALS. A term for the primary magmatic minerals of igneous rocks as distinguished from those minerals which are the result of special and later processes such as come under the head of pneumatolytic, hydrothermal, etc.

PYROLUSITE. The mineral pyrolusite, manganese dioxide (MnO_2), crystallizes in the tetragonal system, but may be only pseudomorphous after manganite. It is found massive or in indistinct crystalline aggregates, often acicular, and as dendritic growths on fractured rock surfaces and as inclusions within moss agates and other chalcedony varieties of quartz. Hardness, 6–6.5 (crystals), 2–6 (massive); specific gravity, 5.06; luster, metallic; color, steel gray to black; streak black; opaque. Pyrolusite is found as replacement deposits and as residual and sedimentary masses. Psilomelane is its usual associate. European localities for pyrolusite are in Bohemia, Saxony, the Harz Mountains, England, and elsewhere. Other deposits occur in India and Brazil. In the United States it is found in Arkansas and Michigan. It is an ore of manganese. It is from this latter use that it derives the name pyrolusite, from the Greek words meaning *fire* and *to wash*.

PYROLYSIS. Transformation of a compound into one or more other substances by heat alone, i.e., without oxidation. It is thus similar to destructive distillation. Although the term implies decomposition into smaller fragments, pyrolytic change may also involve isomerization and formation of higher-molecular-weight compounds. Hydrocarbons are subject to pyrolysis, e.g., formation of carbon black and hydrogen from methane at 1300°C and the decomposition of gaseous alkanes at 500–600°C. The latter is the basis of thermal cracking (pyrolysis) in the production of gasoline. An application of pyrolysis is the conversion of acetone into ketone by decomposition at about 700°C; the reaction is $CH_3COCH_3 \rightarrow H_2C{=}C{=}O + CH_4$. Pyrolysis of natural gas or methane at about 2000°C and 100 mm mercury pressure produces a unique form of graphite. Synthetic crude oil can be made by pyrolysis of coal, followed by hydrogenation of the resulting tar. Large-scale pyrolysis of solid wastes has been considered in connection with several synfuel projects.

PYROMETER. An instrument for measuring temperatures of 1800°C or higher, for example, molten steels, hot springs, volcanoes, etc. There are three kinds: (1) thermocouples of the graphite to silicone carbide type; (2) optical, in which the indications depend on the brightness at some one wavelength of the hot body whose temperature is being measures; and (3) radiation, in which the indications depend on the radiance of a source of radiant energy.

See also **Thermocouple**.

PYROMETRIC CONES. Small cones that differ in the temperatures at which they soften on heating. They are made of clay and other ceramic materials and are used in the ceramic industries to show furnace temperatures within ranges. In practice, three or four of the cones which

have softening points at consecutive temperature ranges are used, and the increase in kiln temperature is judged from the progressive deformation of the cones.

PYROMORPHITE. The mineral pyromorphite is lead chlorophosphate with a formula corresponding to $Pb_5(PO_4)_3Cl$. The phosphorus is sometimes replaced by arsenic and the lead by calcium. It occurs in prismatic, sometimes hollow, hexagonal crystals or may appear in massive forms. It is brittle; hardness, 3.5–4; specific gravity, 7.04; luster, resinous; color, green, yellow-green, yellow, brown, and less often gray or white; translucent to opaque.

Pyromorphite is a secondary mineral associated with other lead minerals, but is seldom found in large quantities. It has probably resulted from the action of waters bearing phosphoric acid upon the preexisting lead minerals. Localities for pyromorphite are in the Ural Mountains, Saxony, France, Spain, Cornwall and Cumberland, England; in Scotland, Zaire, and Australia. In the United States pyromorphite has been found in Chester and Montgomery Counties, Pennsylvania; in Davidson County, North Carolina, and in the Coeur d'Alene mining district of Idaho. The name is derived from the Greek words meaning fire and form.

PYROPHORIC MATERIAL. Any liquid or solid that will ignite spontaneously in air at about 130F (54.4C). Titanium dichloride and phosphorus are examples of pyrophoric solids; tributylaluminum and related compounds are pyrophoric liquids. Sodium, butyllithium, and lithium hydride are spontaneously flammable in moist air because they react exothermically with water. Such materials must be stored in an atmosphere of inert gas or under kerosene. Some alloys (barium, misch metal) are called pyrophoric because they spark when slight friction is applied.

PYROPHYLLITE. The mineral pyrophyllite is a hydrous silicate of aluminium corresponding to the formula $Al_2Si_4O_{10}(OH)_2$. Monoclinic with a basal cleavage, it is usually, however, in foliated, radiated lamellar, or fibrous masses, sometimes compact. It is a soft mineral with a greasy feel; hardness, 1–2; specific gravity, 2.65–2.9; luster, pearly to dull; color, white, greenish, grayish, yellowish, and brownish; translucent to opaque. It is found making up schists or in foliated masses in the Ural Mountains, in Switzerland, Sweden, Brazil, and in the United States in Pennsylvania, North Carolina, Georgia, and California. It is used to some extent for the same purpose as is the mineral talc, and also for making slate pencils, hence the name pencil stone sometimes applied to pyrophyllite.

PYROTECHNICS. Pyrotechnics involves the combination of science and art to chemically generate heat, and from that heat create light, color, audible effects, and gas pressure for entertainment, emergency signaling, and military applications. The civilian side of pyrotechnics includes fireworks, highway flares (fusees), air bag inflators, and special effects devices for the entertainment industry. Military and aerospace pyrotechnics include a wide range of devices for illumination, signaling, obscuration, and gas generation. A pyrotechnic mixture typically contains one or more oxygen-rich oxidizers and one or more fuels, which undergo an exothermic reaction when heated to the ignition temperature of the mixture. The heat that is produced then creates the desired pyrotechnic effect. The selection of the chemicals used in a pyrotechnic composition, as well as the particle sizes of the chemicals and the degree of intimacy to which the composition is blended, determine in large part the speed of the pyrotechnic reaction. Safety in all aspects of manufacturing and using pyrotechnic mixtures and devices is important.

The industry is professionally represented by the Pyrotechnic Guild International, Inc. http://www.pgi.org/. The primary ingredients of pyrotechnic products are as follows:

1. *Oxidizers:* potassium nitrate, potassium chlorate, or potassium perchlorate; ammonium perchlorate; barium chlorate and nitrate; strontium nitrate.
2. *Fuels:* aluminum, magnesium, antimony sulfate, dextrin, sulfur, and titanium.
3. *Binders:* dextrin and various polymers.

Colored flames are produced by strontium compounds (red); barium compounds (green); copper carbonate, sulfate, and oxide (blue); sodium oxalate and cryolite (yellow); and magnesium, titanium, or aluminum (white). Black powder is used as the propellant.

PYROXENE. This is the name given to a closely related group of minerals, all of which show a distinct cleavage angle of 87° or 93° parallel to the fundamental prism. Chemically the pyroxenes are metasilicates corresponding to the formula $RSiO_3$, where R may be calcium, magnesium, iron, or less commonly manganese, zinc, sodium, or potassium. Rarely titanium, zirconium, or fluorine may be present. A general formula is $ABSi_2O_6$, where A is Ca, Na, Mg, or Fe^{2+}, and B is Mg, Fe^{3+}, or Al. Sometimes the Si is replaced by Al. The pyroxenes crystallize in the orthorhombic, and monoclinic systems, like the amphiboles, the chief difference between the two groups being the cleavage angles, which for amphibole are 56° and 124°. Pyroxene crystals tend to be short, stout, complex prisms as opposed to the long, slender, and simpler amphiboles.

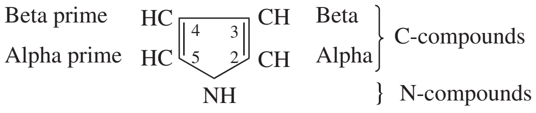
The pyroxenes are common in the more basic igneous rocks, both intrusive and extrusive, and may be developed by the metamorphic processes in gneisses, schists, and marbles.

For descriptions of members of the pyroxene group, see also **Acmite-Aegerine**; **Augite**; **Diallage**; **Diopside**; **Enstatite**; **Hypersthene**; **Jadeite**; and **Spodumene**.

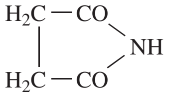
PYRRHOTITE. The mineral pyrrhotite, sometimes called magnetic pyrites, is a sulfide of iron with varying amounts of sulfur. Analyses indicate formulae $Fe_{1-x}S$. Pyrrhotite exists in two modifications: it is monoclinic below, and hexagonal above 138°C (280°F). It is a brittle mineral; hardness, 3.5–4.5; specific gravity, 4.53–4.97; luster, metallic; color, reddish bronze-yellow when fresh, otherwise tarnished; streak, grayish-black; magnetic. It may carry nickel, generally as pentlandite, when it becomes a valuable nickel ore as at Sudbury, Ontario. Pyrrhotite is commonly associated with the basic igneous rocks like gabbro, and norite, and occurs with chalcopyrite, magnetite, and pyrite. Besides being apparently of magmatic origin, it has been found as contact metamorphic and as vein deposits. Austria, Italy, Saxony, Bavaria, Switzerland, Norway, Sweden, and Brazil have deposits of more or less importance, and in the United States it has been found associated with andalusite crystals at Standish, Maine; also at Brewster, New York; Lancaster County, Pennsylvania, and elsewhere. At Ducktown, Tennessee, it is found together with copper and zinc minerals. It is mined for its nickel content, in the form of admixed pentlandite, in Sudbury, Ontario.

Pyrrhotite derives its name from the Greek word *pyrrhos*, meaning reddish, in reference to the color of the fresh ore.

PYRROLE AND RELATED COMPOUNDS. [CAS:109-97-7]. Pyrrole (monoazole, C_4H_5N or C_4H_4NH), contains a ring of 1 nitrogen and 4 carbons, with 1 hydrogen attached to nitrogen and to each carbon:



Pyrrole is a colorless liquid, boiling point 131°C, insoluble in water, soluble in alcohol or ether. Pyrrole dissolves slowly in dilute acids, being itself a very weak base; resinification takes place readily, especially with more concentrated solutions of acids; and on warming with acid a red precipitate is formed. Pyrrole vapor produces a pale red coloration on pine wood moistened with hydrochloric acid, which color rapidly changes to intense carmine red. Pyrrole may be made (1) by reaction of succinimide



with zinc and acetic acid, or with hydrogen in the presence of finely divided platinum heated, (2) by reaction of ammonium saccharate or mucate $COONH_4 \cdot (CHOH)_4 \cdot COONH_4$ with glycerol at 200°C by loss of carbon dioxide, ammonia, and water.

When pyrrole is treated with potassium (but not with sodium) or boiled with solid potassium hydroxide, potassium pyrrole C_4H_4NK is formed, which is the starting point for *N*-derivatives of pyrrole, since reaction of the potassium with halogen of organic compound and with carbon

dioxide, readily occurs. When pyrrole is treated with magnesium metal and ethyl bromide in ether, pyrrole magnesium bromide plus ethane is formed, which may be used as the starting point for C-derivatives of pyrrole, since reaction with sodium alcoholates readily occurs (with separation of magnesium oxybromide).

The pyrrole nucleus has been shown to be present in the complex substances chlorophyll (the green coloring matter of plants), hematin (the red coloring matter of blood), and in the coloring matter of bile.

PYRUVIC ACID. See **Carbohydrates**; **Coenzymes**; **Vitamin**.

Q

QUAD. An energy unit that has come into use in recent years in predicting future energy requirements on a national basis. One quad equals 10^{15} Btus (British thermal units), which is the energy equivalent of 10^{12} cu ft natural gas, or 182 million barrels of oil, or 42 million tons of coal, or 293 billion kilowatt-hours of electricity.

QUADRUPLE POINT. The temperature at which four phases are in equilibrium, such as ice, saturated salt solution, water vapor, and salt.

QUANTUM CHEMISTRY. The use of the principles of quantum mechanics for the resolution of problems in chemistry, notably in connection with the electronic structure of molecules. Some authorities attribute the beginnings of this field to James and Coolidge who, as early as 1933, theorized on the molecular structure of hydrogen and, in these efforts, demonstrated that the Schrödinger equation (primarily proposed for atoms) could be applied to molecules. Over a period of years, studies by other researchers followed. In 1968, for example, Kolos and Wolniewicz carefully investigated the dissociation energy of the hydrogen molecule. But, as early as 1960, some investigators in quantum chemistry turned their attention to methylene (CH_2) as the molecular target of choice. The predictive powers of computational quantum chemistry have since been demonstrated in connection with other molecules. Schaefer (1986) suggests, however, that methylene is the paradigm for computational quantum chemistry. In his paper, three important roles for quantitative theory are outlined: (1) theory precedes experiment, (2) theory overturns experiment, as resolved by later experiments, and (3) theory and experiment work together to gain insight that is afforded independently to neither. See also **Quantum Mechanics**.

QUANTUM EFFICIENCY. A measure of the efficiency of conversion or utilization of light or other energy, being in general the ratio of the number of distinct events produced in a radiation sensitized process to the number of quanta absorbed (the intensity-distribution of the radiation in frequency or wavelength should be specified). In the photoelectric and photoconductive effects, the quantum efficiency is the number of electronic charges released for each photon absorbed. For a phototube, the quantum efficiency is defined as the average number of electrons photometrically emitted from the photocathode per incident photon of a given wavelength. In photochemistry, the quantum efficiency or yield is the ratio of the number of molecules transformed to the number of quanta of radiation absorbed.

QUANTUM ELECTRODYAMICS. A quantized field theory of the interaction between electrons, positrons and radiation based on the quantized form of the Maxwell equations and the Dirac electron theory. The theory is characterized by its remarkably accurate predictions (see also **Positronium**) and its meaningless results. The latter arise from divergent integrals that appear in the development of the theory by perturbation techniques based on expansion in powers of the fine structure constant. These divergences may be pictured in terms of the model of a vacuum as consisting of an infinite sea of negative energy electrons, since the introduction of a charge into this distribution causes infinite currents to be induced.

In 1948, techniques introduced by Schwinger and Feynman enabled these difficulties to be avoided, without being removed. Their relativistically covariant development of the theory allowed such infinite terms to be treated unambiguously, and in particular terms which are to be understood as electrodynamic contributions to the charge and mass of a particle were put in a form which is invariant under Lorentz transformations. The program of charge renormalization and renormalization of mass then enabled such terms to be related to the experimentally observed charge and mass of the particle. See also **Quantum Mechanics**.

QUANTUM MECHANICS. The wave theory of light as originally developed by Maxwell in the 1860s became well established, but it did not accommodate certain phenomena. For example, experiments on thermal radiation uncovered gross disagreement or contradiction with classical theories. The equilibrium distribution of electromagnetic radiation (i.e., emission and absorption of radiation at constant temperature) in a hollow cavity could not be explained on the basis of classical electrodynamics (Maxwell's equations plus the laws of motion of particles). Thermal radiation is a certain function of the temperature (T) of the emitting body. When dispersed by a prism, thermal radiation forms a continuous spectrum. It was found that the energy distribution of the radiation had a regular dependence on its wavelength. Furthermore, the energy E_v as a function of the temperature of the material did not depend upon the structure of the cavity or its shape. On these bases, it was shown that the energy E_v should have a functional dependence upon frequency v, at temperature T, in the form:

$$E_v = v^3 F\left(\frac{cT}{v}\right)$$

All attempts to find the correct form of the function F on the basis of classical theory failed. The classical theory led to the now well-known "ultraviolet catastrophe," since the contribution of high frequencies caused the energy to assume an infinite value. The difficulty was removed by a hypothesis of Planck, according to which the energy of a monochromatic wave with frequency n can only assume those values which are integral multiples of energy hv, i.e., $E_n = nhv$, where n is an integer referring to the number of "photons." Thus the energy of a single photon of frequency v is:

$$E = hv \tag{1}$$

The finiteness of Planck's constant h and its resulting implications laid the foundations of quantum theory. Quantum theory, like the special theory of relativity, was discovered through experiments on electromagnetic phenomena and their theoretical interpretations.

The fundamental equation of quantum mechanics, Eq. (1), implies, on the one hand, that energy of radiation stays concentrated in limited regions

of space in amounts of $h\nu$ and, therefore, behaves like the energy of particles. On the other hand, it establishes a definite relationship between the frequency ν and the energy E of an electromagnetic wave. This dual behavior of light corresponds, in one way, to experimental situations of the interference properties of radiation, for the description of which one uses the wave theory of light. In another way, it corresponds to the properties of exchange of energy and momentum between radiation and matter, which require for their explanation the particle picture of light. Thus, the dual behavior of light has necessitated the quantum description (quantization) of the electromagnetic field. A unified point of view was formulated quantitatively by de Broglie, according to which all forms of energy and momentum related to matter will manifest a dual behavior of belonging to a wave or particle description of the physical system, depending upon the type of experiment performed.

The most interesting example of a quantum mechanical object is the photon itself. By using the relativistic and quantum mechanical definition of the photon energy, we can obtain a quantitative formulation of the concepts just described. The relativistic form of the total energy of a particle with rest mass m and momentum ρ is:

$$E = c(\rho^2 + m^2c^2)^{1/2} \tag{2}$$

We set $m = 0$ and obtain the relativistic definition of the energy of a photon:

$$E = c\rho \tag{3}$$

Hence the first unification of relativity and quantum theory originated from the combination of Eqs. (1) and (3) in the form

$$c\rho = h\nu \tag{4}$$

By using $\nu\lambda = c$ for the plane electromagnetic wave, we obtain the fundamental statement of quantum mechanics:

$$\lambda\rho = h \tag{5}$$

valid for all particles with or without mass, where

$$\lambda = \frac{\lambda}{2\pi}; = \frac{h}{2\pi} \tag{6}$$

These assumptions of quantum theory have laid the foundations of new physical and philosophical concepts for the process of measurement in physics and the definition of physical reality.

It is necessary to develop a dynamic theory to describe the wave character of material particles. In the case of particles with mass, one has the possibility of comparing their kinetic energies with their rest masses. If the kinetic energy is small compared to rest energy, then we can formulate a nonrelativistic theory. However, with the photon there exists no possibility for the formulation of a nonrelativistic theory. There are important advantages in entering quantum mechanics via the photon:

1. The energy of a photon is a quantum mechanical quantity, $E = h\nu$.
2. It has provided a natural basis to postulate the wave-particle relation, $\lambda = h\rho$.
3. The wave aspects of the photon are completely described by charge-free Maxwell equations. Therefore, it is natural to try to reconcile Planck's hypothesis with the wave theory of light.

During 1979, scores of distinguished scientists reviewed the accomplishments of Albert Einstein who was born a century earlier (March 14, 1879). Many papers describing and reviewing the works of Einstein were prepared in honor of the centenary of Einstein's birth. Among Einstein's accomplishments, three were cited by Viktor Weisskopf, one of the speakers at the Pontifical Academy of Science (Vatican City) on November 10, 1979 at a special session devoted to Einstein. The relation between waves and particles was given as one of these, the other two, topically related, were special and general relativity. In commenting on Einstein's interest in wave-particle duality, Weisskopf made the following observations.

> ... Einstein's idea started a truly revolutionary development in physics: quantum mechanics. It opened up wide new horizons and clarified many outstanding problems in our view of the structure of matter. Quantum mechanics is based on the idea of wave-particle duality. Einstein first applied this idea to the nature of light, but it was soon applied to the nature of elementary entities such as electrons and other constituents of matter.

The idea was that all these entities exhibit both wave and particle properties. This double nature taxes our imagination: few things differ as much as a beam of particles and a running wave. In a beam of particles, matter is concentrated in small units, whereas a wave spreads continuously over space. Still, wave and particle properties are observed for electrons and other fundamental entities.

The wave nature of electrons explains so many previously unexplained facts for the following reason. If waves are confined to a finite region of space, they form characteristic shapes and patterns that are specific to the nature of the confinement. [Figure 8 in the entry on **Chemical Elements** shows waves in space confined to the neighborhood of a central point.] Only those and no other patterns can develop in this sort of confinement. But this is just the confinement that electrons suffer when they are confined around the atomic nucleus by electric attraction. The electron waves in atoms must assume some of these patterns. The simple patterns are "lower" than the more complex ones; they are lower in energy. Indeed, the electrons in an atom assume the lowest possible patterns.

This is the explanation of the stability of atoms—it takes energy to change to the next higher pattern. For example, the energy of molecular collisions in air is not sufficient to change the electron patterns in oxygen. Thus oxygen survives unchanged the many millions of collisions in air.

The typical shapes of the electron patterns determine the specific properties of atoms. For example, in the oxygen atom the electrons fill the lowest patterns up to the fourth one. The resulting pattern combination is characteristic for oxygen and is responsible for its properties; it determines how oxygen combines with other atoms (forming water with hydrogen, for example) and how the atoms fall into a symmetrical crystalline order when they form solids, such as ice crystals.

The electron patterns are the primal shapes of nature. Fundamentally, all of nature's shapes can be traced to such patterns. Even the properties of living substances are based on them—in particular, the properties of the molecules that carry the hereditary code. In the final scientific analysis, the stability of electron wave patterns causes the same flowers to bloom every spring and makes children similar to their parents.

Einstein started this great development as early as 1905 by an almost unimaginable act of vision, when he concluded that the concept of such an electromagnetic wave does not suffice to explain important properties of light. He drew the revolutionary conclusion that there must exist light-particles, the photons. The particle-wave duality was born. Einstein recognized the fertility of his idea, but he was never completely satisfied with the conceptual basis of quantum mechanics. The lack of complete causality and the frequent use of probability instead of certainty were always a matter of deep concern for him.

The next great development in physics was again an outgrowth of Einstein's ideas. Dirac was not satisfied with the fact that early quantum mechanics did not fit into the framework of relativity theory. The velocities of electrons in ordinary atoms are so small compared to the speed of light that the neglect of relativity theory did not matter much. But what about wave mechanics of particles that move much faster? Dirac was able in 1927 to unite relativity with quantum mechanics.

In so doing, Dirac discovered a new symmetry in nature, the matter-antimatter symmetry. He discovered it, not by experimenting, but solely by putting together the two great ideas of Einstein: the space-time unity of relativity and the wave-particle duality of quantum mechanics. Dirac saw that for every particle there must be an antiparticle with opposite charge. Although in our own environment we find only negatively charged electrons and protons with positive charge, which is ordinary matter, Dirac concluded that nature must also admit the opposite side. Such anti-matter, he predicted, would not be stable in the presence of ordinary matter; it would annihilate when in touch with it; in a sort of explosion where the masses would be transformed into energy—a direct manifestation of Einstein's equivalence of mass and energy.

A few years later the antielectron was found, and almost 30 years later, the antiproton. Antimatter indeed exists in nature, as Dirac predicted from Einstein's work. This theoretical prediction was one of the greatest intellectual achievements of science. Today, beams of antimatter are produced in many laboratories; they run in carefully evacuated tubes in order not to hit any ordinary matter until they reach their target, where they annihilate with the target substance.

Also, at the aforementioned Pontifical Academy Session on Einstein, P.A.M. Dirac observed:

> By 1905, the wave theory of light based on Maxwell's equations was well established, but certain phenomena would not fit in. It seemed that emission and absorption of light occur discontinuously. This led Einstein to the view that the energy is concentrated in discrete particles. It was a revolutionary idea, very hard to understand, as the successes of the wave theory were undeniable. It seemed that light had to be understood sometimes as waves, sometimes as particles, and physicists had to get used to it. The idea was incorporated into Bohr's theory of the hydrogen atom and forms an essential part of it.
>
> The statistics of an assembly of light particles was studied by Bose, who found that ordinary statistics was not applicable. The laws for the new statistics were formulated jointly by Bose and Einstein. By studying an atom in statistical equilibrium, Einstein saw the necessity for the phenomenon of stimulated emission of radiation. This effect is, in the first place, extremely small, but it can be very much enhanced with a suitable apparatus, because of the new statistics. This led to the laser, a useful tool in present-day technology, which we owe to Einstein.
>
> The appearance of waves connected with particles was shown by de Broglie to be applicable to all particles, not just those having the velocity of light. De Broglie worked out the mathematical relations between waves and particles, using only the requirements of special relativity. He found that the waves move faster than light. However, they cannot be used to transmit signals faster than light, which is an important feature of special relativity.
>
> De Broglie's theory was extended by Schrödinger and led to wave mechanics, which is fundamental for modern atomic theory. Here again, we have a long line of development of physics, originated by Einstein.

In 1926, the Schrödinger equation described the motion of the de Broglie phase waves under the influence of an externally applied potential, and the physical significance of the phase wave ψ was recognized particularly by Born by identifying $\psi^*(q_k)\psi(q_k)d\tau$ with the probability of finding the system in the element of configuration space $d\tau$ between q_1 and $q_1 + dq_1$, etc. Independently in 1925 Heisenberg developed a calculus of observable quantities, representing dynamical variables such as momentum, position, etc., by means of matrices, the time rate of change of a variable X being given by $i\text{X} = XH - HX$ where H is the Hamiltonian of the system. This formulation (matrix mechanics) of quantum theory is equivalent to the Schrödinger formulation (wave mechanics). However, it emphasizes the role played by the observer in the measurement of a physical quantity, and the fact that natural limits imposed on measurements he makes must be incorporated into a theory which purports to describe such measurements. Thus in particular to specify the momentum p and corresponding position x of a particle is strictly speaking not legitimate since the very measurement of the one will lead to an unpredictability of the other given by the Heisenberg indeterminacy relation $\Delta x \Delta p <$. Dynamical variables which cannot be measured simultaneously with arbitrary precision are thus represented by matrices, or, more generally, operators, which may not commute, while a system in the state ψ has a definite value for the dynamical variable A if ψ is an eigenfunction of the operator A, i.e., $A\psi = a\psi$ (a = number). Thus if A and B do not commute ψ cannot be at once an eigenfunction of both A and B. A system in an eigenstate of energy is thus described by the equation $H\psi = E\psi$ where H is the Hamiltonian of the system. In the Schrödinger representation (wave mechanics) ψ is regarded as a function of position and time and the momentum p appearing in the Hamiltonian is represented by the operator—i grad, which automatically yields the commutation relation $p_i x_j - x_j p_i = -i\delta_{ij}$. In the Heisenberg representation (matrix mechanics) the position and momentum are represented by matrices which satisfy this commutation relation, and ψ by a constant vector in Hilbert space, the eigenvalues E being the same in two cases.

The Hamiltonian of a particular system is formally identical with that of the classical theory, the simplest, for one particle of mass m moving in a potential V, being

$$H = \frac{p^2}{2m} + V = E$$

which in the Schrödinger representation gives the Schrödinger equation

$$\left(-\frac{\hbar^2}{2m}\nabla^2 + V\right)\psi = E\psi$$

In the presence of a magnetic field B derived from the vector potential A it is necessary to replace

$$\mathbf{p} = -i\hbar\nabla$$

by

$$\mathbf{p} - \frac{e}{c}\mathbf{A} = -i\hbar\left[\nabla - \frac{ie}{hc}\mathbf{A}\right]$$

and in addition to note the contribution $-\mu B$ to the energy arising from the magnetic moment μ of the particle. The vector μ is itself an operator, being, for an electron, $(e/mc)\mathbf{S}$ where $\mathbf{S}$ is the electron spin, $\mathbf{S} = (h/2)\sigma$ the components of σ being the Pauli spin operators.

The value *e/mc* for the electron gyromagnetic ratio was first postulated by Uhlenbeck and Goudsmit and later shown to be a consequence of the Dirac electron theory.

Nonrelativistic quantum mechanics, extended by the theory of electron spin and by the Pauli exclusion principle, provides a reliable theory for the computation of atomic spectral frequencies and intensities, of cross sections for scattering or capture of electrons by atomic systems, of chemical bonds and many properties of solids, including magnetic properties, although with much more complicated systems it has not always proved possible to develop with adequate accuracy the consequences of the theory. Quantum mechanics has also had a limited success in nuclear theory although in this field it is possible that a more fundamental system of mechanics is required.

Relativistic quantum mechanics is a generalization of nonrelativistic quantum mechanics in which the quantum equations of motion satisfy the principle of relativity. In its simplest form the equation of motion of a particle is the Klein-Gordon equation, but since this neglects the spin properties of the particle, the best verified form of relativistic quantum mechanics is provided by the Dirac electron theory. In general the relativistic quantum theory of a system may always be derived, in accordance with present knowledge, from a Lagrangian, the relativistically covariant properties of the resulting equations of motion being automatically assured if the Lagrangian is invariant under Lorentz transformations.

QUANTUM NUMBER. A number assigned to one of the various quantities that describe a particle or state. Many different characteristics of atomic and nuclear systems, as well as of those entities that are introduced as a part of particle physics, are described by means of quantum numbers. The quantum numbers arise from the mathematics of the eigenvalue problem and may be related to the number of nodes in the eigenfunction. Any state may be described by giving a sufficient set of compatible quantum numbers. In the customary formulations, each quantum number is either an integer (which may be positive, negative, or zero) or an odd half-integer.

Quantum Number (Magnetic). A quantum number that describes the component of the angular momentum vector of an atomic electron or group of electrons in the direction of an externally applied magnetic field. The values of these components are restricted, i.e., quantized. The symbol for the magnetic quantum number is m.

Quantum Number (Orbital). A quantum number characterizing the orbital angular momentum of an electron in an atom or of a nucleon in the shell-model description of the atomic nucleus. The symbol for the orbital quantum number is l.

Quantum Number (Principal). A quantum number that, in the old Bohr model of the atom, determined the energy of an electron in one of the allowed orbits around the nucleus. In the theory of quantum mechanics, the principal quantum number is used most commonly to describe the atomic shell in which the electrons are located. In a somewhat general way, it is related to the energy of the electronic states of an atom. The symbol for the principal quantum number is n. In x-ray spectral terminology, a K-shell is identical to an $n = 1$ shell, and an L-shell to an $n = 2$ shell, etc.

Quantum Number (Spin). A number that describes that part of the total angular momentum of the electron that is due to the rotation of the electron on its own axis. This contribution is quantized, having only a single value $\frac{1}{2}$ in terms of $h/2\pi$ units of angular momentum (h = Planck's constant). The magnetic quantum number associated with the spinning electron can have two values, either $+\frac{1}{2}$ or $-\frac{1}{2}$. The spin angular momentum of the electron can then couple in more than one way with its orbital angular momentum to provide a basis for the occurrence of many multiplet lines in atomic spectra. The symbol for the spin quantum number is s.

See also **Electron**; **Orbitals**; **Proton**; and **Pauli Exclusion Principle**.

QUANTUM THEORY OF SPECTRA. The present theory of spectra, which is based on an idea that there exist in each atom or molecule certain permitted energy levels. An atom or molecule absorbs or radiates energy as it moves from one energy level to another. The frequency (v) of the radiation associated with such change of energy level is given by

$$E_1 - E_2 = hv$$

E_1, E_2 are the energy levels and h is the Planck constant.

QUARKS. Quarks are fundamental matter particles that are constituents of neutrons and protons and other hadrons. There are six different types of quarks, (physicists call them 'flavors'), each of which have a unique mass. The two lightest, unimaginatively called 'up' and 'down' quarks, combine to form protons and neutrons. The heavier quarks aren't found in nature and have so far only been observed in particle accelerators. No one has ever seen a quark. Yet physicists seem to know quite a lot about the properties and behavior of these ubiquitous elementary particles.

History

The quark hypothesis was first proposed independently in 1964 by M. Gell-Mann and G. Zweig, both at the California Institute of Technology. These researchers pointed out that all the known hadrons (i.e., particles that interact via the strong nuclear force) of that time could be constructed out of simple combinations of three particles (and their three antiparticles). These hypothetical particles had to have slightly peculiar properties (the most peculiar being a fractional electric charge). Gell-Mann called them quarks and they were designated p, n, and λ because they somewhat resemble the proton, neutron, and Λ^0 hyperon. The theory supposed that three quarks bind together to form a baryon, while a quark and an antiquark bind together to form a meson. If it is supposed that the binding is such that the internal motion of the quarks is nonrelativistic (which requires that the quarks be massive and sit in a broad potential well), then many quite detailed properties of the hadrons can be explained. One notable exception—the *omega minus particle* discovered in 1964.

A brief review of the complexities to which the quark theory is addressed is in order. Particles which can interact via the strong nuclear force are called hadrons. Hadrons can be divided into two main classes—the mesons (with baryon number zero) and the baryons (with nonzero baryon number). Within each of the classes there are small subclasses. The subclass of baryons which has been known the longest consists of those particles with spin $\frac{1}{2}$ and even parity. The members of this class are the proton, the neutron, the Λ^0 hyperon, the three Σ hyperons and the two Ξ hyperons. There are no baryons with spin $\frac{1}{2}$ and even parity (or, to the usual notation, $J^P = \frac{1}{2}^+$). The next 'family' of baryons has ten members, each with $J^P = \frac{3}{2}^+$. The mesons can be grouped into similar families. One of the first successes of the quark model was to explain just why there should be eight baryons with $J^P = \frac{1}{2}^+$, ten with $\frac{3}{2}^+$, etc., and why the various members of these families have the particular quantum numbers observed.

The chief drawback of the quark model, as voiced soon after the theory was described, has been the failure to produce a beam of individual quarks, much as one can produce a beam of pions, kaons, negative protons, and so on. As of the early 1980s, this objection remains to be satisfied, but because of much theoretical work and new discoveries since 1964, a majority of the community of particle physicists now accept the theory (with modifications and refinements thereof). Explanations offered for the failure to date to isolate quarks is that quarks exist and have already been seen in numerous experiments, but without recognition. Or, that quarks do not exist, but that the hadrons behave as if they did. A somewhat similar belief was once held by some scientists concerning the neutrino. Some theories have yielded quark-like models in which the particles are not fractionally charged, but they were found to have a number of deficiencies. A compelling argument is that the mass of quarks is greater than the energy available and many scientists are looking forward to more powerful accelerators now underway.

The initial quark model was formulated to explain the diversity of the hadrons and not to explicitly describe the internal structure of any particle. It was inevitable, however, that with further research there was a tendency to identify new findings with the hypothetical quarks. A number of properties of the partons, such as their intrinsic spin angular momentum, have been measured and have proved to be consistent with the predictions of the quark model.

During the course of developing several theories concerning the nature of quarks, physicists required a new nomenclature. To persons outside the

field, the words used seem as peculiar as the word quark itself. Some writers have referred to the whimsical character of the names used. The kinds of quarks are called *flavors*.[1] The three kinds of flavors initially proposed are *up, down*, and *strangeness*. It was proposed a bit later that a fourth flavor, *charm*, should be added to describe a new property of matter. Discovery of the *psi* or *J particle* in 1974 provided strong evidence for the charmed quark. More recent research has pointed toward the need for a fifth quark, called *bottom*. Inasmuch as the other four quarks appear to be organized in pairs, it is generally assumed that there is also a sixth flavor, named *top*.

Quarks also possess another distinctive property that governs their binding together to form hadrons. This property, called *color*, is of three varieties (*red, blue*, and *yellow*) and thus numerous combinations are available, but only certain combinations of them seem possible at this juncture. The property of color[2] plays a role in binding the quarks together in a hadron. Some physicists point out that this is analogous to the role of electric charge in binding together the particles that make up an atom, described by a precise and well-tested theory called quantum electrodynamics. It will be recalled that this theory allows the attraction or repulsion between two charged particles to be communicated by exchange of photons (quanta of electromagnetic radiation).

A theory modeled on the quantum electrodynamics theory has been proposed which describes the interactions between colored quarks and it is known as *quantum chromodynamics*. Mediation of these forces is by hypothetical particles called *gluons*, whose role it is to "glue" the quarks together. Eight kinds of gluon are required. Gluons are themselves colored particles. This means that they are subject to the same forces they transmit. This contrasts with the photon, which communicates electromagnetic forces between charged particles, but in itself carries no electric charge, so that a particle can emit or accept a photon without changing its charge. A number of successful predictions have been made by quantum chromodynamics, but as yet they do not compare with quantum electrodynamics in terms of precision.

In the quantum chromodynamics theory, it is suggested that the effective strength of the force between quarks is small when at close range, but much greater when the quarks are separated by a distance comparable to the diameter of a proton. This concept, in itself, is counter to the much better understood forces of electromagnetism and gravitation, where forces become greater as bodies become closer and weaker as bodies recede from one another. It would appear that, within a hadron, the quarks are constrained very little, whereas the energy required to extract them increases at a rapid rate. If it is simply a matter of mounting sufficient energy, then perhaps quarks have not been found in past experiments simply because too little energy was applied. Or, as some physicists have proposed, perhaps the quarks are permanently confined in some manner. For example, K. A. Johnson and a team at the Massachusetts Institute of Technology proposed a *bag model* of quark confinement in 1979. Simply stated, it is hypothesized that quarks are confined in bags analogous to the bubbles in a liquid. This is an interesting concept and is well described by K. A. Johnson in *Sci. Amer.*, **241**, 1, 112–121, 1979. A number of other concepts have been proposed to explain the peculiar behavior of quarks.

Among other experimental objectives in connection with quarks, physicists have been looking for evidence of gluons in the jets of debris which result from particle collisions, notably between electrons and positrons. It is reasoned that some events should produce two oppositely directed jets that become increasingly thin and pencil-like as the collision energy increases. According to some investigators, double-jet events have occurred during the last few years. Some jets have been described as having the shape of a tennis racket. Findings of this kind have been reported by Deutsches Elektronen-Synchrotron (DESY) in Hamburg. In an August 1979 conference held at Fermilab (Fermi National Accelerator Laboratory), researchers from DESY reported events in which three jets form a pattern like the *Mercedes* 3-pronged star. They appeared in early experiments using a new electron-positron colliding beam storage ring called PETRA. For the time being, these results were expressed as "mimicking the expectations of the quantum chromodynamics theory."

[1] One definition of flavor is: "the characteristic quality of something—distinctive nature."

[2] Color, as used here, has nothing to do with visual color. The manner in which different colored quarks combine in quantum mechanics is suggestive of the way in which visual colors combine. Hadrons are "colorless" since they are averages of the three colors.

QUARTZ. [CAS: 14808-60-7]. The mineral quartz, oxide of the nonmetallic element silicon, is the commonest of minerals, and appears in a greater number of forms than any other. Its formula is SiO_2. Quartz commonly occurs in prismatic hexagonal crystals terminated by a pyramid. This pyramid is due to the equal development of two rhombohedrons, and may be observed in cases where one rhombohedron predominates. Cleavage is not observed; the fracture is typically conchoidal; hardness is 7; specific gravity, 2.65; luster, vitreous to greasy or dull; colorless to white, pink, purple, yellow, blue, green, smoky brown to nearly black; transparent to opaque.

There are two distinct modifications of quartz, depending upon the temperature at which they were formed. The low-temperature variety is formed below 573°C and is the more common sort, being found in veins, geodes, etc. It is called low-quartz. The high-temperature modification is formed between 573°C and 870°C, and is found chiefly in granites and granite or rhyolite porphyries. This is called high-quartz. Above 870°C tridymite is the stable form of SiO_2. The differences between high- and low-quartz are entirely crystallographic, low-quartz having a vertical axis of threefold symmetry and three horizontal axes of twofold symmetry, while high-quartz has a vertical axis of six-fold symmetry and six horizontal axes of twofold symmetry. It is usual to separate the many kinds of quartz into (1) crystalline or vitreous varieties, actual crystals or vitreous crystalline masses, and (2) cryptocrystalline varieties, mostly compact nonvitreous sorts, but which may show a crystalline structure under the microscope.

1. Crystalline or Vitreous: Rock crystal, colorless crystals or masses. Amethyst, clear violet or purple, either crystals or masses. Rose quartz, usually massive but rarely in crystals, delicate shades of pink or rose, sometimes red. Citrine or yellow quartz, sometimes called false or Spanish topaz, light to deep yellow. Smoky quartz, smoky brown to almost black, often called cairngorm stone from Cairngorm, Scotland. Milky quartz, often showing delicate opalescence, transparent to nearly opaque, often with a greasy luster. Aventurine quartz incloses glistening scales of mica or hematite. Rutilated quartz incloses needle-like prisms of rutile called "fleches d'amour." Other acicular minerals such as actinolite, tourmaline, and epidote, may also be thus inclosed; Cat's Eye shows a peculiar opalescence, probably due to inclosed masses of some fibrous mineral. Tiger's Eye is a siliceous pseudomorph after crocidolite of a golden yellow brown color.

2. Cryptocrystalline: The following cryptocrystalline varieties of quartz are treated under their own headings: agate, basanite, bloodstone, carnelian, chalcedony, chert, chrysoprase, flint, heliotrope, jasper, moss agate, onyx, plasma, prase, sard, and sardonyx. Quartz readily forms pseudomorphs after various minerals or structures. Silicified wood is a quartz pseudomorph after the organic material of which it originally consisted. Quartz is often pseudomorphic after calcite, barite, and fluorite. Quartz is an essential constituent of many igneous rocks, for example, granites, granite porphyries, and felsites, as well as quartz diorites and their surface equivalents, the dacites. In the metamorphic rocks quartz Figures very largely in the gneisses and schists, and, of course, in quartzite. In the sedimentary rocks most sandstones are composed chiefly of grains of quartz, and quartz forms veins and nodules in limestones.

Of the many places that have yielded fine specimens of quartz, a few include: the Swiss Alps, the Piedmont of Italy, the Island of Elba, Dauphiné in France, Cumberland in England, Banffshire in Scotland, and Madagascar, Uruguay, Mexico and Brazil. Magnificent rose quartz crystals occur at the Arassuahy-Jequitinhonha District, Minas Gerais, Brazil. In the United States the following localities are well known: Paris, Maine, especially for rose quartz; Herkimer County, New York, for small but very brilliant crystals found in the Cambrian dolomites or in the soil. Amethyst County, Virginia, furnishes amethysts, as do Lincoln and Alexander Counties, North Carolina. Other localities for amethyst and smoky quartz are South Dakota, in the Black Hills; the Pikes Peak district, Colorado; Yellowstone National Park, Wyoming; Jefferson County, Montana; and in Canada in the Province of Ontario in the Thunder Bay region. The word *quartz* is believed to have been originally of German origin. Besides the use of the different varieties of quartz for jewelry and other ornamental purposes, this mineral has extensive industrial uses in the ceramic arts, optical and other sorts of scientific instruments, abrasive, scouring, polishing materials, and for refractories.

Certain mineral classes of low symmetry possess no center of symmetry, and their axes, known as polar axes, have different properties at their terminal ends. Quartz belongs to one of those classes. When quartz is exposed to an exerted compressive or mechanical stress along one of these polar axes, electrical charges are developed on that axis; a negative charge is produced at one end, a positive charge at the opposing end. Conversely, when quartz crystals are subjected to an applied electric field along a polar axis, mechanical strains will be developed in those crystals. This phenomenon is known as piezoelectricity. Plates or disks cut perpendicular to such polar axes and properly oriented with established specifications are subject to mechanical vibrations (oscillations) at predetermined frequencies under an applied electric field. Those frequencies are designed to coincide with and stabilize the circuit frequency of radio transmitters and receivers. This property is utilized extensively in the control of frequency oscillations in the field of radio telemetry. Between January 1942 and V-J Day over 70 million such units were manufactured for the United States armed forces, and consumed over 4 million pounds (1.8 million kilograms) of radio grade quartz. The excessive demand for natural quartz of required quality to produce those wafers resulted in the development of a new industry, synthesizing quartz to meet the demand.

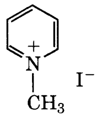
QUARTZITE. A hard, tough, and compact metamorphic rock composed almost wholly of quartz sand grains that have been recrystallized to form a particularly massive siliceous rock. The term is also used for non-metamorphosed quartzose sandstones and grits whose clastic grains have been firmly cemented by silica that has grown in optical continuity around each grain.

QUARTZ PORPHYRY. One of the hypabyssal or effusive rocks chemically related to the granite or alkali family but rich in silica, which occurs as quartz phenocrysts in a crypto- or microcrystalline ground mass.

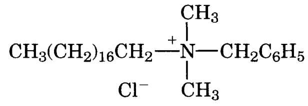
See also **Porphyry**.

QUATERNARY AMMONIUM COMPOUNDS. There are a vast number of quaternary ammonium compounds (quaternaries). Many are naturally occurring and have been found to be crucial in biochemical reactions necessary for sustaining life. Many quaternaries are also produced synthetically and are commercially available.

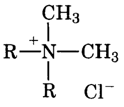
Most quaternary ammonium compounds have the general formula $R_4N^+X^-$ and are a type of cationic organic nitrogen compound. The nitrogen atom, covalently bonded to four organic groups, bears a positive charge that is balanced by a negative counterion. Heterocyclics, in which the nitrogen is bonded to two carbon atoms by single bonds and to one carbon by a double bond, are also considered quaternary ammonium compounds. The R group may either be equivalent or correspond to two to four distinctly different moieties. These groups may be any type of hydrocarbon: saturated, unsaturated, aromatic, aliphatic, branched chain, or normal chain. They may also contain additional functionality and heteroatoms. Examples include methylpyridinium iodide (**1**); benzyldimethyloctadecylammonium chloride (**2**); and di(hydrogenated tallow)alkyldimethylammonium chloride (**3**), where $R = C_{14} - C_{18}$.



(**1**)



(**2**)



(**3**)

Nomenclature

Quaternary ammonium compounds are usually named as the substituted ammonium salt. The anion is listed last. Substituent names can be either common (stearyl) or IUPAC (octadecyl). If the long chain in the compound is from a natural mixture, the chain is named after that mixture, e.g., tallowalkyl. Prefixes such as di- and tri- are used if an alkyl group is repeated. Complex compounds usually have the substituents listed in alphabetical order.

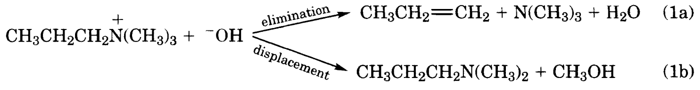
Properties

Physical Properties. Most quaternary compounds are solid materials that have indefinite melting points and decompose on heating. Physical properties are determined by the chemical structure of the quaternary ammonium compound as well as any additives such as solvents. The simplest quaternary ammonium compound, tetramethylammonium chloride, is very soluble in water and insoluble in nonpolar solvents. As the molecular weight of the quaternary compound increases, solubility in polar solvents decreases and solubility in nonpolar solvents increases.

The ability to form aqueous dispersions is a property that gives many quaternary compounds useful applications.

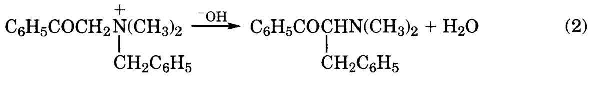
Higher order aliphatic quaternary compounds, where one of the alkyl groups contains ~10 carbon atoms, exhibit surface-active properties. These compounds compose a subclass of a more general class of compounds known as cationic surfactants.

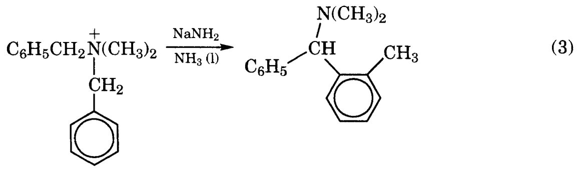
Chemical Properties. Reactions of quaternaries can be categorized into three types: Hoffman eliminations, displacements, and rearrangements. Thermal decomposition of a quaternary ammonium hydroxide to an alkene, tertiary amine, and water is known as the Hoffman elimination (eq. 1a).



Displacement of a tertiary amine from a quaternary (eq. 1b) involves the attack of a nucleophile on the α-carbon of a quaternary and usually competes with the Hoffman elimination.

The Stevens rearrangement (eq. 2) is a base-promoted 1,2-migration of an alkyl group from a quaternary nitrogen to carbon. The Sommelet-Hauser rearrangement (eq. 3) is a base-promoted 1,2-migration of a benzyl group to the *ortho*-position of that benzyl group.

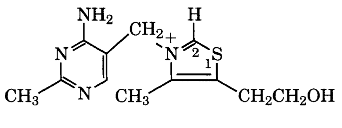




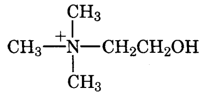
Naturally Occurring Quaternaries

Many types of aliphatic, heterocyclic, and aromatic derived quaternary ammonium compounds are produced both in plants and invertebrates. Examples include thiamine (vitamin B_1) (**4**). See also **Vitamin**; choline

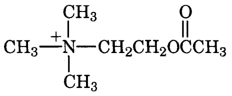
(**5**); and acetylcholine (**6**). These have numerous biochemical functions.



(**4**)



(**5**)



(**6**)

Biochemically, most quaternary ammonium compounds function as receptor-specific mediators; they also function biochemically as messengers.

Analytical Test Methods

There are no universally accepted wet analytical methods for the characterization of quaternary ammonium compounds. The American Oil Chemists' Society (AOCS) has established, however, a number of applicable tests.

The chain length composition of quaternaries can be determined by gas chromatography.

Mass spectral analysis of quaternary ammonium compounds can be achieved by fast-atom bombardment (fab) ms.

Liquid chromatography has been widely applied for analysis of quaternaries. Modified reverse-phase columns can provide chain length information, whereas normal-phase chromatography results in groupings of alkyl distributions.

Nuclear magnetic resonance (nmr) spectroscopy is useful for determining quaternary structure.

Toxicology and Environmental Fate

Some quaternary ammonium compounds are potent germicides, toxic in small (mg/L range) quantities to a wide range of microorganisms. Bactericidal, algicidal, and fungicidal properties are exhibited. Many quaternaries are considered to be moderately to severely irritating to the skin and eyes.

Most uses of quaternary ammonium compounds can be expected to lead to these compounds' eventual release into wastewater treatment systems except for those used in drilling muds. Useful properties of the quaternaries as germicides can make these compounds potentially toxic to sewer treatment systems. It appears, however, that quaternary ammonium compounds are rapidly degraded in the environment and strongly sorbed by a wide variety of materials.

The threat of accidental misuse of quaternary ammonium compounds coupled with potential harmful effects to sensitive species of fish and invertebrates has prompted some concern. Industry has responded with an effort to replace the questionable compounds with those of a more environmentally friendly nature. A newer class of compounds containing an ester linkage has been developed which are more readily biodegraded.

Synthesis and Manufacture of Quaternaries

Quaternary ammonium compounds are usually prepared by reaction of a tertiary amine and an alkylating agent (eq. 4). Some alkylating reagents pose significant health concerns and require special handling techniques.

$$R{-}N(R'){-}R'' + R'''X \longrightarrow R{-}\overset{+}{N}(R')(R'''){-}R'' \quad X^- \qquad (4)$$

Synthesis and Manufacture of Amines. The chemical and business segments of amines and quaternaries are closely linked. The majority of commercially produced amines originate from three amine raw materials: natural fats and oils, α-olefins, and fatty alcohols. The amines are then used to produce a wide array of commercially available quaternary ammonium compounds. Some individual quaternary ammonium compounds can be produced by more than one synthetic route. See also **Amines**.

Uses

Uses of quaternary ammonium compounds range from surfactants to germicides and encompass a number of diverse industries.

Fabric Softening. The single largest market for quaternary ammonium compounds is as fabric softeners. The use of quaternary surfactants as fabric softeners and static control agents can be broken down into three main household product types: rinse cycle softeners; tumble dryer sheets; and detergents containing softeners, also known as softergents.

Hair Care. Quaternary ammonium compounds are the active ingredients in hair conditioners. Quaternaries are highly substantive to human hair because the hair fiber has anionic binding sites at normal pH ranges.

Other Uses. An important market for quaternaries is sanitation. Quaternaries find use as disinfectants and sanitizers in hospitals, building maintenance, and food processing; in secondary oil recovery for drilling fluids; and in cooling water applications. See also **Petroleum**. Additional applications of quaternaries include the manufacture of organo-modified clays and use as phase-transfer catalysts.

Other important classes of quaternaries are the polyamine-based (polyquats) and the perfluorinated quaternaries, both of which have a number of applications.

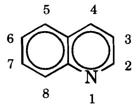
QUELET REACTION. Passage of dry hydrogen chloride through a solution in inligroin of a phenolic ether and an aliphatic aldehyde in the presence or absence of a dehydration catalyst to yield α-chloroalkyl derivatives by substitution in the *para* position to the ether group or in the *ortho* position in *para*-substituted phenolic ethers.

QUENCHING. Immersion of hot metals in liquid baths in order to effect rapid cooling. In steel heat-treating practice quenching oils give slower and brine solutions give faster cooling rates than water. Dilute caustic solutions are sometimes used for rapid cooling rates comparable to brine. These baths are maintained at or near room temperature. For special quenching procedures requiring baths held at moderately elevated temperatures, molten metals, such as lead, and fused salts may be used.

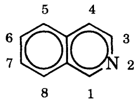
Quenching of ordinary steel is for the purpose of hardening it. Certain non-hardenable steels, for example austenitic stainless steel, and many non-ferrous metals may be cooled rapidly from elevated temperatures for other reasons.

QUICKSILVER. See **Mercury**.

QUINOLINES AND ISOQUINOLINES. The isomeric heterocycles quinoline (**1**) and isoquinoline (**2**) possess structures that occur frequently in alkaloids and pharmaceuticals for example, quinine and morphine. See also **Alkaloids**.



(**1**)



(**2**)

Quinoline and isoquinoline are aromatic, but less intensely than benzene.

Comparative Properties

Physical Properties. Both (**1**) and (**2**) are weak bases, showing pK_a 4.94 and 5.40, respectively. Selected physical data for quinoline and isoquinoline are given in Table 1.

Chemical Properties. The presence of both a carbocyclic and a heterocyclic ring facilitates a broad range of chemical reactions for (**1**) and (**2**). Quaternary alkylation on nitrogen takes place readily, but unlike pyridine both quinoline and isoquinoline show addition by subsequent

TABLE 1. PHYSICAL PROPERTIES OF QUINOLINE AND ISOQUINOLINE

reaction with nucleophiles. Nucleophilic substitution is promoted by the heterocyclic nitrogen. Electrophilic substitution takes place much more easily than in pyridine, and the substituents are generally located in the carbocyclic ring. Their facile formation of crystalline salts with either inorganic or organic acids and complexes with Lewis acids is in each case of considerable interest.

Quinoline

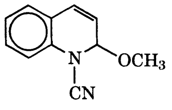
Reactions. Quinoline exhibits the reactivity of benzene and pyridine dine rings, as well as its own unique reactions.

As an aromatic system, (**1**), shows important synthetic and mechanistic nistic nitro group chemistry. See also **Nitration**. The experimental conditions employed usually determine the product structure.

The main sulfonation product of quinoline at 220°C quinolinesulfonic acid; at 300°C it rearranges to 6-quinolinesul acid.

Unlike pyridine, quinoline undergoes facile addition to the nitrogen-containing ring. Allylmagnesium chloride reacts with quinoline in deoxygenated tetrahydrofuran to produce 80% 2-allyl-1,2-dihydroquinoline. Similar results are observed with vinyl Grignard reagents and with alkyllithium reagents.

Treatment of quinoline with cyanogen bromide, the von Braun reaction, in methanol with sodium bicarbonate produces a high yield of 1-cyano-2-methoxy-1,2-dihydroquinoline (**3**).



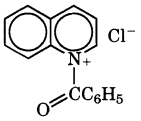
(**3**)

2-Aminoquinoline is obtained from quinoline in 80% yield by treatment with barium amide in liquid ammonia.

As with nitration, halogenation under acidic conditions favors reaction in the benzenoid ring, whereas reaction at the 3-position takes place in the neutral molecule.

The synthesis of quinolinic acid and its subsequent decarboxylation to nicotinic acid has been accomplished directly in 79% yield using a nitric−sulfuric acid mixture above 220°C. A wide variety of oxidants have been used in the preparation of quinoline *N*-oxide.

The ring nitrogen of quinoline reacts with a wide variety of alkylating and acylating agents to produce useful intermediates, for example, *N*-benzoylquinolinium chloride (**4**).



(**4**)

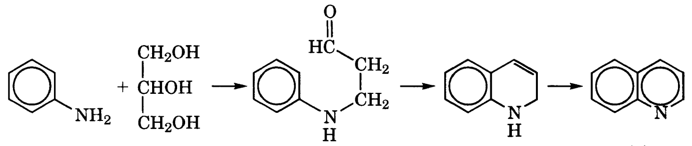
The direct introduction of carbon−carbon bonds in quinoline rings takes place in low yield and with little selectivity.

Quinoline may be reduced rather selectively, depending on the reaction conditions. Catalytic reduction with platinum oxide in strongly acidic solution at ambient temperature and moderate pressure gives a 70% yield of 5,6,7,8-tetrahydroquinoline. Further reduction of this material with sodium−ethanol produces 90% of *trans*-decahydroquinoline.

Manufacture From Coal Tar. Commercially, quinoline is isolated from coaltar distillates. Tar acids are removed by caustic extraction, and the oil is distilled to produce the methylnaphthalene fraction (230−280°C).

Syntheses of Quinolines

Skraup Synthesis. This general method, used for many quinolines, consists of heating a primary aniline with glycerol, concentrated sulfuric acid, and an oxidizing agent. Often the nitrobenzene corresponding to the aniline employed is used as the oxidant, and iron(II) sulfate is added to moderate the often violently exothermic process. The use of compounds related to acrolein, such as crotonaldehyde and methyl vinyl ketone, allow substituents to be placed in the heterocyclic ring. With ortho- and para-substituted anilines, a single product is usually found; meta-derivatives produce mixtures.



(**1**)

Döbner-von Miller Synthesis. A much less violent synthetic pathway, the Döbner-von, Miller, uses hydrochloric acid or zinc chloride as the catalyst. α, β-Unsaturated aldehydes and ketones make the dehydration of glycerol unnecessary, and allow a wider variety of substitution patterns. No added oxidant is required.

Combes Synthesis. When aniline reacts with a 1,3-diketone under acidic conditions a 2,4-disubstituted quinoline results, e.g., 2,4-dimethylquinoline from 2,4-pentadione.

Conrad-Limpach-Knorr Synthesis. When a β-keto ester is the carbonyl component of these pathways, two products are possible. Aniline reacts with ethyl acetoacetate below 100°C to form 3-anilinocrotonate, which is converted to 4-hydroxy-2-methylquinoline by placing it in a preheated environment at 250°C. If the initial reaction takes place at 160°C, acetoacetanilide forms and can be cyclized with concentrated sulfuric acid to 2-hydroxy-4-methylquinoline. This example of kinetic vs thermodynamic control has been employed in the synthesis of many quinoline derivatives. They are useful as intermediates for the synthesis of chemotherapeutic agents.

Pfitzinger Reaction. Quinoline-4-carboxylic acids are easily prepared by the condensation of isatin with carbonyl compounds. The products may be decarboxylated to the corresponding quinolines.

Frieländer Synthesis. The methods cited thus far all suffer from the mixtures which usually result with meta-substituted anilines. The use of an ortho-disubstituted benzene for the subsequent construction of the quinoline avoids the problem. In the Frieländer synthesis a starting material like 2-aminobenzaldehyde reacts with an α-methyleneketone in the presence of base. The difficulty of preparing the required anilines is a limitation in this approach.

New Synthetic Approaches. There have been a number of efforts to prepare quinolines by routes quite different from the traditional methods. In one, the cyclization of 3-amino-3-phenyl-2-alkenimines using alkali metals leads to modest yields of various 4-arylaminoquinolines. Because this structure is found in many natural products and few syntheses of it exist, the method merits further investigation.

The importance of quinolinium salts to dye chemistry accounts for the long, productive history of their synthesis. The reaction of *N*-methylformanilide with ketones, aldehydes, ketone enamines, or enol acetates in phosphoryl chloride leads to high yields of *N*-methylquinolinium salts.

Toxicology. Quinoline is a poison when it enters the body by any of the normal routes, i.e., ingestion, or subcutaneous or intraperitoneal injection. Even contact with the skin produces a moderate toxic reaction, and can result in severe irritation. There is evidence that quinoline is mutagenic, and long exposure can produce lung problems.

Uses

Antioxidants. The 1,2-dihydroquinolines have been used in a variety of ways as antioxidants. These compounds react with aldehydes, and the products are useful as food antioxidants.

Corrosion Inhibitors. Steel-reinforcing wire and rods embedded in concrete containing quinoline or quinoline chromate are less susceptible to

corrosion. Treating the surface of metals with 8-hydroxyquinoline makes them resistant to tarnishing and corrosion. Ethylene glycol-type antifreeze may contain quinoline or its derivative to prevent corrosion.

Agricultural Chemicals. A herbicide possessing activity comparable to 2,4-D is found in compounds like quinolyl esters of N-substituted dithiocarbamic acids. A wide variety of compounds containing the quinoline system are herbicides. Derivatives and salts of 8-quinolinecarboxylic acid as well as quinolyl carbamates are each useful insecticides. The copper salt of 8-hydroxyquinoline is an effective fungicide.

Polymers. Quinoline and its derivatives may be added to or incorporated in polymers to introduce ion-exchange properties.

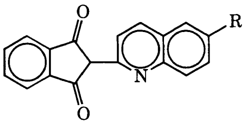
Platinum-group metals form complexes with chelating polymers with various 8-mercaptoquinoline derivatives.

Metallurgy. The extraction and separation of metals and plating baths have involved quinoline and certain derivatives see also **Electroplating**. The extraction of metal ions depends on the chelating ability of 8-hydroxyquinoline. Dilute solutions of heavy metals such as mercury, cadmium, copper, lead, and zinc can be purified using quinoline-8-carboxylic acid adsorbed on various substrates.

Catalysts. Acrolein and methacrolein 1,4-addition polymerization is catalyzed by lithium complexes of quinoline. The peracetic acid epoxidation of a wide range of alkenes is catalyzed by 8-hydroxyquinoline.

Medicine. In addition to the naturally occurring compounds, a large number of synthetic quinolines have been prepared and studied for use in medicine.

Quinoline Dyes. The reaction of 2-methylquinoline with phthalic anhydride produces a 2:1 mixture of 2-(2-quinolinyl)-1,3-indandione ((**5**), R=H) and 2-(6-methyl-2-quinolinyl)-1,3-indandione ((**5**), R = CH_3).



(**5**)

This mixture is known as Quinoline Yellow A and is most widely used with polyester fibers. Several other quinoline dyes are commercially available and find applications as pigments, biological stains, and analytical reagents.

Isoquinoline

The widespread occurrence of the isoquinoline (**2**) structure in such important alkaloids as those found in cactus, opium, and curare has created a long-standing interest in its synthesis and properties.

Reactions. In general, isoquinoline undergoes electrophilic substitution reactions at the 5-position and nucleophilic reactions at the 1-position. Nitration with mixed acids produces a 9:1 mixture of 5-nitroisoquinoline and 8-nitroisoquinoline. Sulfonation of isoquinoline gives a mixture with 5-isoquinolinesulfonic acid as the principal product.

Amination of isoquinoline with sodamide in neutral solvents gives 1-aminoisoquinoline.

Direct bromination of isoquinoline hydrochloride in a solvent like nitrobenzene gives an 81% yield of 4-bromoisoquinoline.

The oxidation of isoquinoline has also been examined using ruthenium tetroxide. In this instance, the observation that phthalic acid is the only significant product (58%) was made; this fact is both important and difficult to explain. Isoquinoline is also oxidized to its N-oxide by peracids. The N-oxides of isoquinolines have proved to be excellent intermediates for the preparation of many compounds.

Isoquinoline can be reduced quantitatively over platinum in acidic media to a mixture of *cis*-decahydroisoquinoline and *trans*-decahydroisoquinoline.

Synthesis of Isoquinoline and Isoquinoline Derivatives.

Bischler–Napieralski Reaction. This synthetic method involves the cyclodehydration of *N*-acyl derivatives of β-phenethylamines to 3,4-dihydroisoquinolines, such as 1-methyl-3,4-dihydroisoquinoline.

Pictet-Spengler Synthesis. An acidic catalyst results in the condensation of β-phenethylamines with carbonyl compounds to give 1,2,3,4-tetrahydroisoquinolines.

Pomeranz-Fritsch Synthesis. Isoquinolines are available from the cyclization of benzalaminoacetals under acidic conditions.

Miscellaneous Synthetic Reactions. A number of *o*-disubstituted benzenes have been used to prepare isoquinolines. For example, the Radziszewski method and subsequent dehydration converts *o*-cyanomethylbenzoic acid to homophthalimide in 90% yield.

Toxicology. Isoquinoline is a poison when ingested or injected intraperitoneally. Even in cases of skin contact it is moderately toxic. Its vapors are irritating to the eyes, nose, and throat.

Uses. Isoquinoline and isoquinoline derivatives are useful as corrosion inhibitors, antioxidants, pesticides, and catalysts. They are used in plating baths and miscellaneous applications, such as in photography, polymers, and azo dyes. Numerous derivatives have been prepared and evaluated as pharmaceuticals. Isoquinoline is a main component in quinoline still residue bases, which are sold as corrosion inhibitors and acid inhibitors for pickling iron and steel.

4-Aminoisoquinoline is a component of an ethylene glycol-based corrosion inhibiting antifreeze agent.

A great many alkaloids and synthetic medicinal compounds are isoquinoline derivatives.

Coppola and H. F. Schuster, Part III, 1995, in A. Weissberger and E. C. Taylor, eds., *The Chemistry of Heterocyclic Compounds*, Vols. 32 and 38, Wiley-Interscience, New York.

QUINONES. These useful compounds have played a central role in both theoretical and practical organic chemistry since the 1840s. The compound 1,4-benzoquinone (**1**)

(**1**)

provides the generic name quinone. This simple, descriptive nomenclature has been abandoned by *Chemical Abstracts*, but remains widely used. The systematic name for (**1**) is 2,5-cyclohexadiene-1,4-dione. Several examples of quinone synonyms are given in Table 1. Common names are used in this article.

Simple quinones have two notable physical properties: odor and color. The 1,4-benzo- and 1,4-naphthoquinones and many of their derivatives have high vapor pressures and pungent, irritating odors. The single-ring compounds are often found as constituents of insects chemical defense against predators. In general, the 1,2-quinones are vibrant in color, ranging from orange to red, whereas the 1,4-quinones are usually lighter, i.e., yellow to orange.

The quinones have excellent redox properties and are thus important oxidants in laboratory and biological synthons. The presence of an extensive array of conjugated systems, especially the α, β-unsaturated ketone arrangement, allows the quinones to participate in a variety of reactions. Characteristics of quinone reactions include nucleophilic substitution; electrophilic, radical, and cycloaddition reactions; photochemistry; and normal and unusual carbonyl chemistry.

Physical Properties

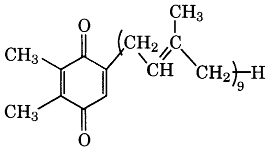
Selected physical data for various quinones are given in Table 2.

Chemical Properties

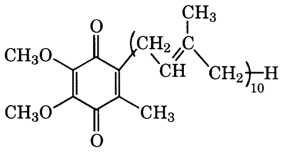
Biochemical Reactions. The quinones in biological systems play varied and important roles. In insects they are used for defense purposes, and the vitamin K family members, which are based on 2-methyl-1,4-naphthoquinone, are blood-clotting agents. See also **Vitamin**; and **Vitamin K**.

Two groups of substituted 1,4-benzoquinones are associated with photosynthetic and respiratory pathways; the plastoquinone, e.g., plastoquinone

(**2**), and the ubiquinones, e.g., ubiquinone (**3**), are involved in these processes. Although they are found in all living tissue and are central to life itself, a vast amount remains to be learned about their biological roles.



(**2**)

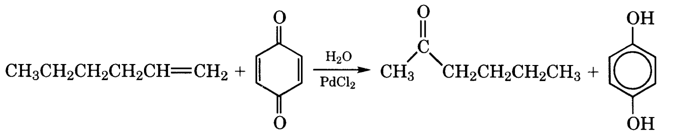


(**3**)

Quinones of various degrees of complexity have antibiotic, antimicrobial, and anticancer activities.

Dehydrogenation. The oldest and still important synthetic use of quinones is in the removal of hydrogen, especially for aromatization. This method has often been applied to the preparation of polycyclic aromatic compounds. Quinones are used extensively in the dehydrogenation of steroidal ketones. Such reactions are marked by high yield and selectivity. Generally, the results when using nonsteroidal ketones are disappointing.

Oxidation. The use of 1,4-benzoquinone (**1**) in combination with palladium(II) chloride converts terminal alkenes such as 1-hexene to alkyl methyl ketones in high yield (81%). The quinone appears to reoxidize the palladium.



(**1**)

Photochemical Reactions. Increased knowledge of the centrality of quinone chemistry in photosynthesis has stimulated renewed interest in their photochemical behavior. Synthetically interesting work has centered on the 1,4-quinones and the two reaction types most frequently observed, ie [2 + 2] cycloaddition and hydrogen abstraction.

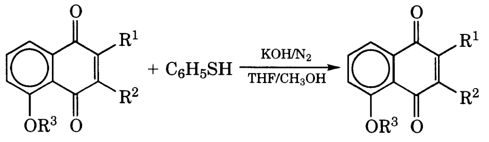
TABLE 1. QUINONE NOMENCLATURE

Common name	Synonym
1,4-benzoquinone	*p*-benzoquinone
1,2-benzoquinone	*o*-benzoquinone
1,4-napthoquinone	α-naphthoquinone
4,4′-diphenoquinone[a]	diphenoquinone
o-chloranil[b]	tetrachloro-*o*-quinone
p-chloranil[c]	tetrachloro-*p*-quinone
2,3-dichloro-5,6-dicyano-1,4-benzoquinone[d]	DDQ

[a] Bis-2,5-cyclohexadien-1-ylidene,4,4′-dione; 4-(4-oxo-2,5-cyclohexadiene-1-ylidene)-2,5-cyclohexadien-1-one is also used.
[b] 3,4,5,6-Tetrachloro-3,5-cyclohexadiene-1,2-dione.
[c] 2,3,5,6-Tetrachloro-2,5-cyclohexadiene-1,4-dione.
[d] 4,5-Dichloro-3,6-dioxo-1,4-cyclohexadiene-1,2-dicarbonitrile.

Addition Reactions. The addition of nucleophiles to quinones is often an acid-catalyzed, Michael-type reductive process. The addition of benzenethiol to 1,4-benzoquinone (**1**) was studied by A. Michael for a better understanding of valence in organic chemistry. The presence of the reduced product thiophenylhydroquinone, the cross-oxidation product 2-thiophenyl-1,4-benzoquinone, and multiple-addition products such as 2,5-bis(thiophenyl)-1,4-benzoquinone and 2,6-bis(thiophenyl)-1,4-benzoquinone, is typical of many such transformations.

Nucleophilic Substitution Reactions. Many of the transformations realized through Michael additions to quinones can also be achieved using nucleophilic substitution chemistry. In some instances the stereoselectivity can be markedly improved in this fashion, e.g., in the reaction of benzenethiol with esters ($R^3 = CH_3C{=}O$) and ethers ($R^3 = CH_3$) of 1,4-naphthoquinones. 2-Bromo-5-acetyloxy-1,4-naphthoquinone, $R^1 = Br$, yields 75% of 2-thiophenyl-5-acetyloxy-1,4-naphthoquinone, $R^1 = SC_6H_5$. 3-Bromo-5-methoxy-1,4-naphthoquinone, $R^2 = Br$, yields 82% of 3-thiophenyl-5-methoxy-1,4-naphthoquinone $R^2 = SC_6H_5$.

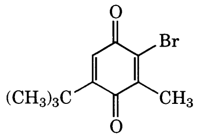


Syntheses

Syntheses of quinones often involve oxidation, because this is the only completely general method. Thus, in several instances, quinones are the reagents of choice for the preparation of other quinones. Oxidation has been especially useful with catechols and hydroquinones as starting materials. The preparative utility of these reactions depends largely on the relative oxidation potentials of the quinones.

For the preparation of $\leq$10 g of a quinone, the oxidation of a phenol with Fremy's salt in the Teuber reaction is the method of choice. A wide range of phenols has been used, including some having 4-substituents.

In small-scale syntheses, a wide variety of oxidants has been employed in the preparation of quinones from phenols. Of these reagents, chromic acid, ferric ion, and silver oxide show outstanding usefulness in the oxidation of hydroquinones. Thallium(III) trifluoroacetate converts 4-halo- or 4-*tert*-butylphenols to 1,4-benzoquinones in high yield. For example, 2-bromo-3-methyl-5-*t*-butyl-1,4−benzoquinone (**4**) has been made by this route.

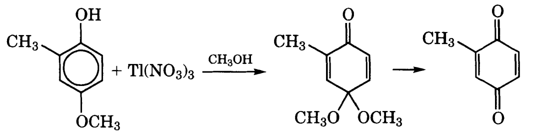


(**4**)

Thallium trinitrate oxidizes naphthols and hydroquinone monoethers, respectively, to quinones and 4,4-dialkoxycyclohexa-2,5-dienones, e.g., 4,4-dimethoxy-2-methyl-2,5-cyclohexadienone (**5**). The yield of (**5**) is 89%.

TABLE 2. PHYSICAL PROPERTIES OF SELECTED QUINONES

Name	Color	Mp, °C	Crystalline form	Solubility: Soluble	Solubility: Insoluble
1,4-benzoquinone	yellow	113, 116	monoclinic prisms	alcohol, ether	water, pentane
1,2-benzoquinone	red	60–70 dec	plates or prisms	ether, benzene	pentane
1,2-naphthoquinone	yellow-red orange	145–147	needles	water, alcohol	ligroin
1,4-naphthoquinone	bright yellow	125, 128.5	needles	alcohol, benzene	water, ligroin
3,4,5,6-tetrachloro-1,2-benzoquinone	orange-red	133, 122–127			
2,3,5,6-tetrachloro-1,4-benzoquinone	yellow	290, 294	monolinic prisms	ether	water, ligroin
2,3-dichloro-5,6-dicyano-1,4-benzoquinone	bright yellow	201–202 dec	plates		
2-chloro-1,4-benzoquinone	yellow-red	57	rhombic-hexagonal	water, alcohol	
2,5-dichloro-1,4-benzoquinone	pale yellow	161–162	monoclinic prisms	ether, chloroform	water, alcohol
2,5-dimethyl-1,4-benzoquinone	yellow	125		ether, alcohol	water, alcohol
2-methyl-1,4-benzoquinone	yellow	69	plates or needles	ether, alcohol	water
3-chloro-1,2-naphthoquinone	red	172 dec	needles	alcohol, benzene	water
2,3-dichloro-1,4-naphthoquinone	yellow	193, 195	needles	benzene, chloroform	water, alcohol
2-methyl-1,4-naphthoquinone	yellow	105–107	needles	ether, benzene	water, alcohol



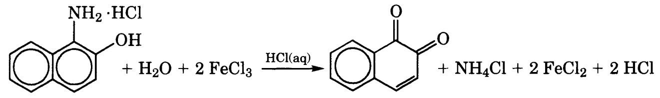
(**5**)

The oxidation of 4-bromophenols to quinones can also be accomplished using periodic acid.

The anodic oxidation of hydroquinone ethers to quinone ketals yields synthetically useful intermediates that can be hydrolyzed to quinones at the desired stage of a sequence.

Manufacture

With the exceptions of 1,4-benzoquinone and 9,10-anthraquinone, quinones are not produced on a large scale, but a few of these are commercially available. See also **Anthraquinone**. The few large-scale preparations involve oxidation-of aniline, phenol, or aminonaphthols, e.g., (**6**), from which 1,2-napthoquinone (**7**) is obtained in 93% yield.



(**6**) (**7**)

In the case of 1,4-benzoquinone (**1**), the product is steam-distilled, chilled, and obtained in high yield and purity. Direct oxidation of the appropriate unoxygenated hydrocarbon has been described for a large number of ring systems, but is generally utilized only for the polynuclear quinones without side chains. A representative sample of quinone uses is given in Table 3.

TABLE 3. USES OF SELECTED QUINONES

Quinone	Use
1,4-benzoquinone	oxidant, amino acid determination
2-chloro-, 2,5-dichloro-, and 2,6-dichloro-1,4-benzoquinone	bactericides
2,3-dichloro-5,6-dicyano-1,4-benzoquinone	oxidation and dehydrogenation agent
2-methyl-and 2,3-dimethyl-1,4-naphthoquinone	vitamin K substitutes, antihemorrhagic agents

Health and Safety Factors

Because of the high vapor pressure of the simple quinones and their penetrating odor, adequate ventilation must be provided in areas where these quinones are handled or stored. Quinone vapor can harm the eyes. In either solid or solution form quinone can cause severe local damage to the skin and mucous membranes. Swallowing benzoquinones may be fatal. The higher quinones are less of a problem because of their decreased volatility.

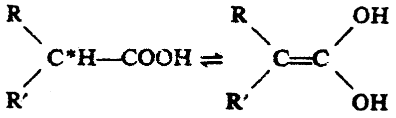
RACEMIZATION. The conversion of an optically active compound i.e., one that rotates the plane of polarized light, into its racemic or optically inactive form is known as *racemization*. In this process half of the optically active compound is converted into its mirror image. The resultant mixture of equal quantities of the dextro- and levo-rotatory isomers is without effect on plane-polarized light due to external compensation (meso forms are internally compensated). Racemization of compounds possessing more than one asymmetric atom may yield products with residual optical activity due to the presence of unchanged centers of asymmetry. An example of this is found in the mutarotation of either α- or β-D-glucose in which only 1 of the 5 asymmetric centers is affected by the opening and closing of the hemiacetal ring.

Racemization may occur in molecules in which structural changes, such as those due to resonance, enolization, substitution or elimination of groups, temporarily destroy the asymmetry needed to maintain the optical activity. Also, Walden inversion of half of an optically active isomer can yield a racemate without the destruction of the center of asymmetry; this phenomenon is observed in the reaction of D-butanol-2 with $HClO_4$.

In the case of the optically active acids, racemization is postulated as the result of the enolization mechanism:



In this case it is seen that the hydrogen attached to the alpha carbon migrates to the oxygen of the carbonyl group forming a carbon-to-carbon double bond and thereby destroying the asymmetry previously found at the alpha carbon atom. Reversion of the enol to the acid reforms the center of asymmetry on a random basis (i.e., giving the same quantities of dextro and levo forms of the acid). Variations of pH, temperature, solvents and catalysts are likely to change the rates of racemization. The progress of the reaction is conveniently followed by examination of the reaction mixture with plane-polarized light in a polarimeter. A similar racemization of disodium L-cysteine in liquid ammonia in the presence of $NaNH_2$ is reported to occur through abstraction of the α-proton to form a carbanion followed by random recombination of the proton.

Although most racemization reactions have been observed to occur in solution, L-leucine on the surface of silicates has been completely racemized by heating to 200°C for 6 hours. Racemization has also been observed in optically active compounds which possess no asymmetric atom but owe their activity to hindered rotation around a single C−C bond. For example, 8′-methyl-1,1′binaphthyl-8-carboxylic acid has been resolved into its optically active forms and racemized by heating in dimethylformamide.

One of the earliest known examples of racemization was described by Pasteur in his studies of tartaric acid. By heating D-tartaric acid to 165°C in water he partially converted it into a mixture of D-, L- and *meso*-tartaric acids. The occurrence of some DL-tartaric acid along with the natural D-tartaric acid in the wine industry is explained on the basis of partial racemization.

The process of racemization has a number of practical application in the laboratory and in industry. Thus, in the synthesis of an optical isomer it is frequently possible to racemize the unwanted isomer and to separate additional quantities of the desired isomer. By repeating this process a number of times it is theoretically possible to approach a 100% yield of synthetic product consisting of only one optical isomer. An example of the utilization of such a process is found in the production of pantothenic acid and its salts. In this process the mixture of D- and L-2-hydroxy-3,3-butyrolactones are separated. The D-lactone is condensed with the salt of beta-alanine to give the biologically active salt of pantothenic acid. The remaining L-lactone is racemized and recycled.

The process of racemization is important in the survival and growth of living cells and is catalyzed by a group of enzymes called racemases. Alanine racemase, for example, is able to convert D-alanine to DL-alanine if a suitable alpha keto acid is also present. In this reaction the asymmetry of the alpha-carbon atom of alanine is lost as the amino acid is converted to the keto acid and back. This process is analogous to the well-known process of transamination in which racemization seldom occurs.

RACKING. Experimental cold-stretching of unvulcanized rubber, whose behavior under stress is unique among natural materials. A thin narrow strip stretched at, for example, 500–600% at 0°C will retain that extension indefinitely after release of stress as long as the low temperature persists. In this state it loses its elasticity and has virtually 100% permanent set. It also displays a crystalline X-ray pattern similar to that of a fiber, in contrast to the amorphous structure of the unstretched state. On exposure to room temperature it slowly retracts to its original length; higher temperature it slowly retracts its rate of recovery. Tests made on racked rubber have shown that crude rubber can be exposed to any degree of low temperature, for any length of time without impairment of its properties.

RADIATION. 1. The emission and propagation of energy through space or through a material medium in the form of waves; for instance, the emission and propagation of electromagnetic waves, or of sound and elastic waves.

2. The energy propagated through space or through a material medium as waves; for example, energy in the form of electromagnetic waves or of elastic waves. The term radiation, or radiant energy, when unqualified, usually refers to electromagnetic radiation; such radiation commonly is classified, according to frequency, as radio-frequency, microwave, infrared, visible (light), ultraviolet, x-rays, and γ-rays. Radiation may also be designated as monochromatic, when it has, ideally, one wavelength, or actually a narrow band of wavelengths; or as heterogeneous, when it has two or more narrow bands of wavelengths (or particles of two or more narrow energy ranges); or as homogeneous, when it has only one narrow band of wavelengths (or consists of essentially monoenergetic particles).

3. Corpuscular emissions, such as alpha- and beta-radiation or rays of mixed or unknown type.

4. In a looser sense the term *radiation* also includes energy emitted in the form of particles that possess mass and may or may not be electrically charger, (i.e., α [positive] and β [negative] and also neutrons. Beams of such particles may be considered as "rays". The charged particles may all be accelerated and the high energy imparted to "beams" in particle accelerators such as cyclotrons, betatrons, synchrotrons, and linear accelerators.

Radiation is used in medicine in the form of X-rays and radioactive isotopes. It is used in industry in many ways, e.g., as vitamin activator, sterilizing agents, and polymerization initiator; it is also the basis of all types of spectroscopic analysis.)

RADIATION (Biochemistry). The study of substances having the ability to protect cells and body tissue against the deleterious effects of ionizing radiation. See also **Radiation (Ionizing)**. Because one of these effects is to deprive proteins of sulfhydryl ($^{-}$SH) groups necessary for cell division, the injection of compounds rich in this radical (notably cysteine) has been successfully tried with laboratory animals. Thiourea has been found to protect DNA from depolymerization by X-rays; enzymes containing $^{-}$SH groups inactivated by radiation are reactivated by addition of glutathione.

Some of the other radiochemically induced reactions that adversely affect biochemical activity are:

1. Formation of hydrogen peroxide (a biological poison) by free radical mechanism.
2. Denaturation of proteins.
3. Change in substituent groups of amino acids.
4. Oxidation of hemoglobin.
5. Depolymerization of DNA.

RADIATION (Industrial). Chemical or physiochemical changes induced by exposure to various types and intensities of radiation are as follows:

1. Synthesis of ethyl bromide from hydrogen bromide and ethylene, using α-radiation from cobalt-60.
2. Cross-linking of such polymers as polystyrene and polyethylene with either β- or γ-radiation.
3. Vulcanization of rubber with ionizing radiation.
4. Polymerization of methyl methacrylate monomer with cobalt-60 as source of γ-rays. Free radical formation is involved in both cross-linking and polymerization reactions. This technique is also being applied in the textile finishing field for grafting and cross-linking fibers with chemical agents for durable-press fabrics.
5. Processing of various foods (cooking, drying, pasteurizing, etc.) by electromagnetic energy in the microwave region of the spectrum; preservation and sterilization of food products by ionizing radiation (γ- and X-rays). The dosage of radiation is strictly controlled, and FDA approval is required. Irradiation is also effective in inhibiting sprouting and preventing insect infestation of stored grains.
6. Curing or hardening of organic protective coatings (paints, inks) by exposure to infrared, UV, or electron-beam radiation. Required are a monomer or oligomer and a photoninitiator, which induces polymerization by free radical formation.

See also **Radioactivity**.

RADIATION (Ionizing). Extremely short-wave-length, highly energetic, penetrating rays of the following types:

1. γ-rays emitted by radioactive elements and isotopes (decay of atomic nuclei).
2. X-rays generated by sudden stoppage of fast-moving electrons.
3. Subatomic charged particles (electrons, protons, deuterons) when accelerated in acyclotron or betatron.

The term is restricted to electromagnetic radiation at least as energetic as X-rays, and to charged particles of similar energies. Neutrons also may induce ionization.

Such radiation is strong enough to remove electrons from any atoms in its path, leading to the formation of free radicals. These short-lived but highly reactive particles initiate decomposition of many organic compounds. Thus ionizing radiation can cause mutations in DNA and in cell nuclei; adversely affect protein and amino acid mechanisms; impair of destroy body tissue; and attack bone marrow, the source of red blood cells. Exposure to ionizing radiation for even a short period is highly dangerous, and for an extended period may be lethal. The study of the chemical effects of such radiation is called radiation chemistry or (in the case of body reactions) radiation biochemistry.

See also **Radiation (Industrial)**; and **Radioactivity**.

RADIOACTIVE WASTE. Disposal of waste containing radioisotopes and of spent nuclear reactor fuel presents a serious problem for which there is as yet no completely satisfactory solution. Such wastes may remain radioactive for thousands of years and can constitute a long-term hazard that is restraining the development of nuclear-generated electric power. Safe disposal techniques are being intensively studied. Ocean dumping, practiced some years ago, is no longer permissible. Small amounts of low-level wastes containing radioisotopes can be diluted sufficiently with an inert material to reduce its activity to an acceptable point. High-level reactor waster, for example, at Hanford are stored in concrete tanks lined with steel and buried under a foot of concrete and 5 or 6 ft of soil. Containers of compressed alumina (corundum) have been recommended, as this material remains impervious to water indefinitely. Storage in the form of calcine (granular solid) and in borosilicate glass is a promising possibility under active investigation. The DOE has recommended disposal in deep geologic formations, although the heat generated by the radioactivity could cause fracturing of the surrounding rock structures; this would admit water that would eventually rise to the surface after being contaminated. A test program involving storage in basalt is being conducted by the DOE. Storage is salt formations is under serious consideration because they are self-sealing and free from water.

See also **Nuclear Power Technology**.

RADIOACTIVITY. The spontaneous disintegration of the nucleus of an atom with the emission of radiation. This phenomenon was discovered by Becquerel in 1896 by the exposure-producing effect on a photographic plate by pitchblende (uranium-containing mineral) while wrapped in black paper in the dark. Soon after this, it was found that uranium minerals and uranium chemicals showed more radioactivity than could be accounted for by the uranium content. About the same time, radioactivity of thorium minerals and thorium chemicals was also discovered.

The excess radioactivity of mineral over chemical uranium led Pierre and Marie Curie to experiment with the mineral. To detect the presence of radioactivity the discharge of a charged gold-leaf electroscope was used. A quantitative estimation of the amount of radioactivity was made by observing the rate of drop of the gold leaf. By chemically separating the uranium mineral into fractions and examining each fraction by the electroscope, they found in the bismuth element fraction the first new radioactive element to be discovered. It was named polonium (1898). They found that polonium disappeared rapidly, half of its radioactivity vanishing in about six months. The fraction containing barium element was also found by them to be radioactive. Repeated fractional crystallizations of the chloride and bromide solutions made possible the recovery by them of practically pure salt of the second new radioactive element. It was named radium (1898).

Radium is chemically similar to barium; it displays a characteristic optical spectrum; its salts exhibit phosphorescence in the dark, a continual evolution of heat taking place sufficient in amount to raise the temperature of 100 times its own weight of water 1°C every hour; and many remarkable physical and physiological changes have been produced. Radium shows radioactivity a million times greater than an equal weight of uranium and, unlike polonium, suffers no measurable loss of radioactivity over a short period of time (its half life is 1620 years). From solutions of radium salts, there is separable a radioactive gas; radium emanation, radon, which is a chemically inert gas similar to xenon and disintegrates with a half life of 3.82 days, with the simultaneous formation of another radioactive element, Radium A (polonium-218).

Definitions[1]

Decay. The diminution of a radioactive substance due to nuclear emission of alpha or beta particles, gamma rays or positrons.

Decay Constant. A constant λ that relates the instant rate of radioactive decay of a radioactive species to the number of atoms N present at a *given time* t:

$$-(\partial N/\partial) = \lambda N$$

Where N is the number of atoms present at time *zero*:

$$N = N_o e^{-\lambda t}$$

Decay Product. A *nuclide* that results from the radioactive disintegration of a radionuclide that is formed either directly or as the result of progressive transformations in a radioactive series. The nuclide thus produced is sometimes called the daughter or *daughter* element.

Half-Life (Radioactive Element). The average time required for one-half of the atoms in a sample of radioactive element to decay. The half-life $t\frac{1}{2}$ is given by

$$t_{\frac{1}{2}} = (\ln 2)/\lambda$$

Types of Radioactivity

Beginning in 1899 and continuing through the next two decades, E. Rutherford and his associates conducted a rather thorough study of

[1] Data pertaining to radioisotopes is provided in quantitative detail in the "Handbook of Chemistry and Physics," 80th Edition, CRC Press, LLC., Boca Raton, FL. 2000.

the radiations emitted by radioactive substances. During this study the radiations were found to be of three types, called alpha, beta, and gamma radiations. In kind, they resemble anode rays, cathode rays, and x-rays, respectively. In this behavior toward electrical and magnetic fields, the resemblance is qualitatively complete: (1) Alpha rays are positively charged particles of mass number 4 and slightly deflected by electrical and magnetic fields. (2) Beta rays are negatively charged electrons, and strongly deflected by electrical and magnetic fields. (3) Gamma rays are undeflected by electrical and magnetic fields, and of wavelength of the order of 10^{-8} to 10^{-9} centimeters.

Alpha Ray Emission. Alpha rays have a definite velocity and a definite range for each radioactive nuclide. The velocity is from 5–7% that of light. *Range* is defined as the distance traversed in a homogeneous medium before absorption. The penetrating power of alpha rays is the smallest of the three kinds of rays, the beta rays being of the order of 100 times, and the gamma rays 10,000 more penetrating. The alpha rays are twice-ionized nuclei of helium (He^{2+}). Ramsay and Royds (1909) experimentally demonstrated that accumulated alpha particles, quite independently of the matter from which they have been expelled, consist of helium. They sealed radon in a glass tube with a wall so thin that the alpha particles passed through the wall into a surrounding vessel and after six days the optical spectrum of helium was observed. Helium itself does not diffuse through such a wall. Therefore, alpha particles on losing their positive charge become ordinary helium. This is the first instance of the production of a known element during radioactive transformation. The loss of a single alpha particle by an atom leaves the residual atom four units less in mass number, and two units less in atomic number. The shooting of alpha particles was visibly registered by Crooke's spinthariscope in which the tip of a wire, coated by a tiny amount of radium salts, was placed near a screen coated with zinc blende. Viewed in the dark with a magnifying eyepiece, each alpha particle striking the zinc blende target was observed to produce a visible scintillation. The detection and counting of single alpha particles was accomplished by Rutherford and Geiger (1908), by the deflection of an electrometer needle upon the arrival of each alpha particle in a gas at low pressure in an electric field somewhat below the sparking point.

Beta Radiation. Beta rays are electrons. They have varying velocities almost up to that of light. The loss of a single negatron by an atom leaves the residual atomic nucleus the same in mass number and one unit greater in atomic number, while the loss of a positron or an orbital electron capture leaves the residual atomic nucleus the same in mass number, and one unit less in atomic number.

Double-Beta Decay. In a scholarly paper, M. Moe (University of California, Irvine) and S. Rosen (Los Alamos National Laboratory) describe what is considered to be a very rare radioactive event, namely that of double-beta decay. Searching since 1971, Moe and colleagues observed a double-beta event directly in 1987. In an event of this type, using a selenium atom, which contains 48 neutrons and 34 protons, as an example, two of the neutrons decay simultaneously into two protons. During the process, two beta rays and two antineutrinos are generated. Application of an external magnetic field will cause the paths of the ejected electrons to spiral, but in different directions. A double spiral of this type, when observed, is indicative of a double-beta event. The atom remaining has gained two additional protons and lost two neutrons, as compared with its original state (i.e., prior to the double-beta decay event). The selenium has been transformed to krypton.

The neutrino problem is described in the article on **Particles (Subatomic)**. The double-beta decay event may contribute to the solution of that problem. In their introductory to the aforementioned article, the authors observe, "The future of fundamental theories that account for everything from the building blocks of the atom to the architecture of the cosmos hinges on studies of this rarest of all observed radioactive events."

Gamma Radiation. Gamma rays are photons of electromagnetic radiation. This radiation is much more penetrating than alpha or beta particles. The presence of gamma rays from 30 milligrams of radium can be observed in an electroscope after passing through 30 centimeters of iron (Rutherford). For the protection of the operator, radium is kept in lead outer containers or screened by lead sheets.

The naturally occurring radioactive elements at the upper end of the periodic table of elements form a number of series, the elements of each series existing in radioactive equilibrium, unless individual elements are separated chemically away from the series. These series include the Uranium Series, the Thorium Series, and the Actinium Series. See Tables 1, 2, and 3. These arrangements are useful in showing the decay chain (i.e., the parent-daughter) relationships of radioactive elements, including such concepts as radioactive equilibrium. Other naturally occurring radioactive elements also exist, including, for example, ^{40}K, ^{87}Rb, and ^{148}Sm.

TABLE 1. THE URANIUM SERIES

Radioelement	Corresponding element (2)	Symbol	Radiation	Half-life
Uranium I	Uranium (92)	^{238}U	α	4.51×10^9 yr
↓				
Uranium X_1	Thorium (90)	^{234}Th	β	24.1 days
↓				
Uranium X_2^*	Protactinium (91)	^{234}Pa	β and I.T.	1.17 min
99.87% | 0.13%				
Uranium II	Uranium (92)	^{234}U	α	2.48×10^5 yr
Uranium Z	Protactinium (91)	^{234}Pa	β	6.66 hr
Ionium	Thorium (90)	^{230}Th	α	7.5×10^4 yr
↓				
Radium	Radium (88)	^{226}Ra	α	$1.62^3 10^3$ yr
↓				
Ra Emanation	Radon (86)	^{222}Rn	α	3.82 days
↓				
Radium A	Polonium (84)	^{218}Po	α and β	3.05 min
99.96% | 0.04%				
Radium B	Lead (82)	^{214}Pb	β	26.8 min
Astatine-218	Astatine (85)	^{218}At	α	2 sec
↓				
Radium C	Bismuth (83)	^{214}Bi	β and α	19.7 min
99.96% | 0.04%				
Radium C	Polonium (84)	^{214}Po	α	1.5×10^{-4} sec
Radium C″	Thallium (81)	^{210}Tl	β	1.32 min
↓

↓				
Radium E	Bismuth (83)	^{210}Bi	β and α	2.6×10^6 yr
~100% | ~10^{-5}%				
Radium F	Polonium (84)	^{210}Po	α	138.4 days
Thallium-206	Thallium (81)	^{206}Tl	β	4.23 min
↓				
Radium G (end product)	lead (82)	^{206}Pb	None	Stable

* Undergoes ismeric transition (I.T.) to form uranium Z(^{234}Pa); the latter has a half life of 6.66 hr, emitting β radiation and forming Uranium II ^{234}U.

Ionizing Radiation. This type of radiation is of major importance because it represents a biological and environmental hazard. Radioactive isotopes contribute to this potential danger. The extent of damage varies immensely with the dose (exposure over a long or short period of time) and with the source material. The principal ionizing radiations are summarized in Table 4.

Artificially Induced Radioactivity

In addition to the radionuclides already discussed, there are also the great numbers of artificially produced radioactive elements. They are represented

TABLE 2. THE THORIUM SERIES

Radioelement	Corresponding element	Symbol	Radiation	Half-life
Thorium ↓	Thorium	^{232}Th	α	1.39×10^{10} yr
Mesothorium I ↓	Radium	^{228}Ra	β	6.7 yr
Mesothorium II ↓	Actinium	^{228}Ac	β	6.13 hr
Radiothorium ↓	Thorium	^{228}Th	α	1.90 yr
Thorium X ↓	Radium	^{224}Ra	α	3.64 days
Th Emanation ↓	Radon	^{220}Rn	α	54.5 sec
Thorium A	Polonium	^{216}Po	α	0.16 sec
~100% | 0.014%				
Thorium B	Lead	^{212}Pb	β and α	10.6 hr

↓ Actinium D (end product)	Lead	^{207}Pb	None	Stable

in the Neptunium Series and in various collateral series, because, in addition to the three main natural, and the one artificial, disintegration series of radioelements, each has been found to have at least one parallel or collateral series. The main series and the collateral series have different parents, but they become identical when, in the course of disintegration, they have a member in common. Collateral with the natural uranium series is an artificial series discovered in the United States by M.H. Studier and E.K. Hyde. Its parent is ^{230}Pa formed by the bombardment of thorium with alpha particles or deuterons of high energy. The decay scheme of the series has been found to be

$$^{230}\text{Pa} \xrightarrow{\beta-} {}^{230}\text{U} \xrightarrow{\alpha} {}^{226}\text{Th} \xrightarrow{\alpha} {}^{222}\text{Ra} \xrightarrow{\alpha} {}^{218}\text{Rn} \xrightarrow{\alpha} {}^{214}\text{Po} \longrightarrow \text{Uranium Series}$$

The loss of the alpha particle by the emanation, ^{218}Rn, leads to the formation of ^{214}Po, which is identical with radium C′ of the Uranium Series; the subsequent decay of the collateral series thus becomes identical with that of the main Uranium Series at this point.

Another collateral Uranium Series has for its progenitor ^{226}Pa which is found among the products of bombardment of thorium with 150-MeV deuterons. The decay scheme is represented by:

$$^{226}\text{Pa} \xrightarrow{\alpha} {}^{222}\text{U} \xrightarrow{\alpha} {}^{218}\text{Th} \xrightarrow{\alpha} {}^{214}\text{Ra} \xrightarrow{\alpha} {}^{210}\text{Bi} \longrightarrow \text{Uranium Series}$$

Still other collateral series are the following:

$$^{228}\text{Pa} \xrightarrow{\alpha} {}^{224}\text{Ac} \xrightarrow{\alpha} {}^{220}\text{Fr} \xrightarrow{\alpha} {}^{216}\text{At} \xrightarrow{\alpha} {}^{212}\text{Bi} \longrightarrow \text{Thorium Series}$$

$$^{232}\text{Pa} \xrightarrow{\alpha} {}^{228}\text{U} \xrightarrow{\alpha} {}^{224}\text{Th} \xrightarrow{\alpha} {}^{220}\text{Ra} \xrightarrow{\alpha} {}^{216}\text{Rn} \xrightarrow{\alpha} {}^{212}\text{Po} \longrightarrow \text{Thorium Series}$$

$$^{227}\text{Pa} \xrightarrow{\alpha} {}^{223}\text{Ac} \xrightarrow{\alpha} {}^{219}\text{Fr} \xrightarrow{\alpha} {}^{215}\text{At} \xrightarrow{\alpha} {}^{211}\text{Bi} \longrightarrow \text{Actinium Series}$$

$$^{239}\text{U} \xrightarrow{\beta} {}^{239}\text{Np} \xrightarrow{\beta} {}^{239}\text{Pu} \xrightarrow{\alpha} {}^{235}\text{U} \longrightarrow \text{Actinium Series}$$

$$^{239}\text{U} \xrightarrow{\alpha} {}^{225}\text{Th} \xrightarrow{\alpha} {}^{221}\text{Ra} \xrightarrow{\alpha} {}^{217}\text{Rn} \xrightarrow{\alpha} {}^{213}\text{Po} \longrightarrow \text{Neptunium Series}$$

See Table 5.

Frederic and Irene Joliot-Curie found in 1933 that boron, magnesium, or aluminum, when bombarded with α-particles from polonium, emit neutrons, proton, and positrons, and that when the source of bombarding particles was removed, the emission of protons and neutrons ceased, but that of positrons continued. The targets remained radioactive, and the emission of radiation fell off exponentially just as it would for a naturally occurring radioelement. The results of this work may be stated in two equations as follows:

$$^{4}\text{He} + {}^{27}\text{Al} \longrightarrow {}^{30}\text{P} + n$$

$$^{30}\text{P} \xrightarrow{\beta+} {}^{30}\text{Si}$$

The first of these equations shows that the result of the nuclear reaction in which aluminum is bombarded with α-particles is the emission of a neutron and the production of a radioactive isotope of phosphorus. The second equation shows the radioactive disintegrations of the latter to yield a stable silicon atom and a positron. Continuation of this line of investigation by several research groups confirmed that radioactive nuclides are formed in many nuclear reactions.

Generally, if any two isobars differ in charge by $\pm e$, one had a higher ground-state energy than the other and is beta radioactive. Any nuclide that

TABLE 4. PRINCIPAL TYPES OF IONIZING RADIATION

Name	Symbol	Location in aton	Relative rest mass	Charge
Proton $(H^1)^+$	p	Nucleus	1	+1
Neutron	n	Nucleus	1	0
Electron	e	Outer shells	0.00055	−1
Beta⁻ (electron)	β	Emitted during decay processes	0.00055	−1
Beta⁺ (positron)	β^+		0.00055	+1
Alpha $(He^4)^{++}$	α		4	+2
Gamma[a] (photon)	γ	Emitted during decay processes	0.0	0

[a] X-rays of equal energy are identical, but of extranuclear origin. Although only the gamma or x-rays are electromagnetic in character and thus “radiations” in the classical sense, the distinction between radiations and ionizing (particles) is often not made. X-rays are distinguished from gamma rays only with respect to their origins. Gamma rays result from nuclear interactions or decays. X-rays result from transitions of atomic or free electrons, produced artificially by bombarding metallic targets with energetic electrons. As pointed out by Mel and Todd (see references), it is sometimes difficult to make a clear distinction between ionizing and nonionizing electromagnetic radiations, particularly in condensed phases. The ionization potential of gaseous elements, that is, the energy required for removal of the first, electron, ranges from 3.9 eV (cesium) to 24.6 eV (helium). Although ultraviolet and even visible light in special cases can ionization, the general assumption is that the more energetic x- or gamma radiation is needed to insure ionization. Neutrons also lead to ionization, but for other reasons. Ionization, of course, is not the only interaction of high-energy particles and radiations with matter. The excitation of atomic electrons into higher-energy states always accompanies ionization as well.

can be formed from a nuclear reaction and is not one of the known stable nuclides is radioactive. Nuclides having higher atomic number (Z) than the nearest stable isobar decay to it through positron emission (β^+ decay) or orbital electron capture. Nuclides with lower Z than the nearest stable isobar decay to it through negatron emission (β^- decay). Occasionally, as for ^{64}Cu, a radioactive nuclide is located between two stable isobars and can decay to either of them, in this case either ^{64}Ni or ^{64}Zn. The simplest radioactive nuclide is the neutron, which has a half life of 12 minutes, and decays into a proton, a negatron, and a neutrino.

Energy-level diagrams for nuclear transformations are usually drawn to show the relative energies of levels of an entire neutrally charged atomic system. Since the nuclear charge increases in magnitude by e if a beta radioactive nucleus emits a negatron, one additional external electron must be added to maintain a neutral atom. On the other hand, the nuclear charge changes by $-e$ during positron emission; therefore, in order to maintain a neutral atom, an electron must also be lost by one of the atomic shells. Thus, for negatron decay the total energy difference between initial and final energy states is only the sum of the negatron kinetic energy and the neutrino energy. For positron emission, however, the atom loses a minimum energy equal to twice the rest energy of an electron, $2m_0c^2$. These energy relationships are shown schematically in Fig. 1. During orbital electron capture the nucleus loses a single positive charge merely by taking an electron from one of its own atomic shells. The only energy loss is that energy emitted as X radiation during rearrangement of the atomic shells following electron capture and the energy carried away by the neutrino. See Fig. 1 on p. 2925.

A table of nuclides showing mass number and isotopic abundance is given in the entry on **Chemical Elements**.

Exotic Nuclei and Their Decay. As reported by J.C. Hardy (Chalk River Nuclear Laboratories, Atomic Energy of Canada, Ltd.), recent advances in nuclear accelerators and experimental techniques have led to an increasing ability to synthesize new isotopes. As isotopes are produced with more and more extreme combinations of neutrons and protons in their nuclei, new phenomena are observed, and the versatility of the nucleus is increased as a laboratory for studying fundamental forces. Hardy reports that, among the newly discovered decay modes are: (1) proton radioactivity, (2) triton, two-proton, two-neutron, and three-neutron decays that are beta-delayed, and (3) ^{14}C emission in radioactive decay. Precise tests of the properties of the weak force have also been achieved.

The fundamental usefulness of exotic nuclei and their decay assures a continuing interest in the field. New heavy-ion accelerators will ensure that

TABLE 5. THE NEPTUNIUM SERIES

Element (2)	Symbol	Radiation	Half-life
Curium (96) ↓	^{245}Cm	α	9300 yr
Plutonium (94) ↓	^{241}Pu	β	13.2 yr
Americium (95) ↓	^{241}Am	α	458 yr

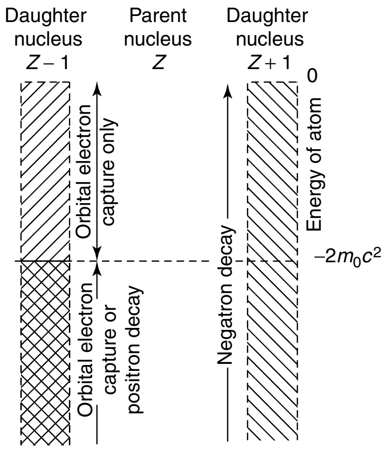

Fig. 1. The energy regions for which negatron emission, positron emission, and orbital electron capture are energetically possible

this interest is matched by an ever-increasing capability to synthesize new isotopes and provide the nuclear laboratory with renewed flexibility. Hardy further emphasizes that applications uniquely suited to the decay modes of exotic nuclei, are starting to appear and indeed are sophisticated. Many of the new forms provide greater detail than can be obtained with stable nuclei. As an example, beta-delayed proton decay has been used to time

the life of excited nuclear states. The technique is sensitive to lifetimes in the range of 10^{-16} second, a span in which it has few competitors, and has been applied to a number of different nuclei.

Useful Applications for Isotopes

Although care must always be exercised to avoid undue exposure to various radioisotopes, these materials have found wide acceptance in analytical chemistry, medicine, radiocarbon and other radioelement dating (geology, archaeology, etc.), and other special situations—for example, as a fuel source in spacecraft.

The radionuclides commercially available and most commonly used for a number of the foregoing applications include: antimony-125; barium-133, 207; bismuth-207; bromine-82; cadmium-109, 115 m; calcium-45; carbon-14; cerium-141; cesium-134, 137; chlorine-36; chromium-51; cobalt-57, 58, 60; copper-64; gadolinium-153; germanium-68; gold-195, 198; hydrogen-3 (tritium); indium-111, 114 m; iodine-125, 129, 131; iron-55, 59; krypton-85; manganese-54; mercury-203; molybdenum-99; nickel-63; phosphorus-32, 33; potassium-42; promethium-147; rubidium-86; ruthenium-103; samarium-151; scandium-46; selenium-75; silver-110 m; sodium-22, strontium-85; sulfur-35; technetium-99; thallium-204; thulium-171; tin-113, 119 m, 121 m; titanium-44; ytterbium-169; and zinc-65.

Radioisotopes in Chemical Analysis

There is a wide range of applications for methods of analysis that are based upon the energies and intensities of the radiations emitted by radioactive nuclides. These techniques sometimes are termed *radiometric methods of analysis*. The methods are not restricted to the determination of substances initially radioactive, since there is wide use of methods involving the irradiation of stable nuclides to produce radioactive ones, followed by measurement of their radiations, from which the composition of the original stable substance can be inferred. This method is *radioactivation analysis*. Another method for the use of measurements of radioactivity in the analysis of stable substances is that of *tracer techniques*, that is, by the addition to them of radioactive nuclides, which can then be used to follow the course of various reactions or processes. There are various ways of introducing the radioactive nuclides, which are discussed later in this entry.

All methods of radiometric analysis involve, of course, the use of various radiation detection devices. The devices available for measuring radioactivity will vary with the types of radiations emitted by the radioisotope and the kinds of radioactive material. Ionization chambers are used for gases; Geiger-Müller and proportional counters for solids; liquid scintillation counters for liquids and solutions; and solid crystal or semi-conductor detector scintillation counters for liquids and solids emitting high-energy radiations. Each device can be adopted to detect and measure radioactive material in another state, e.g., solids can be assayed in an ionization chamber. The radiations interact with the detector to produce a signal.

Since many radionuclides decay with gamma rays, many measurements are being made by gamma-ray scintillation spectrometry. Usually, a crystal detector, such as a sodium iodide crystal, is connected to a spectrometer. As described above, the gamma-rays interact with the crystal to produce light pulses which are converted to electrical pulses by a multiplier phototube. The pulse height analyzer of the spectrometer sorts out the gamma-rays of various energies. From this operation, a spectrum of the radionuclide's gamma-rays can be obtained to the *photopeaks* of full-energy pulses and the continuum of lower-energy pulses associated with the decay of the radionuclide. The photopeak, or photopeaks, in the gamma-ray spectrum can be used to identify and quantitatively measure the radionuclide.

Radioactivation Analysis. The principle of this technique is that a stable isotope when irradiated by neutrons, by charged particles such as protons or deuterons or by gamma rays, can undergo a nuclear reaction to produce a radioactive nuclide. After the radionuclide is formed, and its radiations have been characterized by radiation detection devices, calculations can be made of the elements contained in the sample before irradiation.

An important reaction used quite widely for this purpose is irradiation by neutrons and measurement of the energies of radiations emitted. The source of the neutrons may be a nuclear reactor, a particle accelerator, or an isotopic source, that is, a sealed container in which neutrons are produced by alpha rays emitted by a source such as radium, sodium-24(^{24}Na), yttrium-88(^{88}Y), etc., and arranged so that the alpha rays react-with a substance such as beryllium which in turn emits neutrons. The neutrons react with stable nuclides in the sample to produce radioactive ones. Thus ordinary sodium undergoes a nuclear reaction with neutrons as follows:

$$\mathrm{Na}^{23} + n \longrightarrow \mathrm{Na}^{24} + \gamma$$

The ^{24}Na decays with a half-life of 15 hours to yield gamma rays and β-particles

$$\mathrm{Na}^{24} \longrightarrow \mathrm{Mg}^{24} + e^{-} + \gamma$$

Moreover the energies of these β-particles (electrons) are known to be 1.39 MeV and that of the gamma-rays 1.38 MeV so that the measured values of these magnitudes are characteristic of substances containing sodium. (Measurement of the γ-radiation is the usual procedure.) At least 70 of the elements can be activated in this way, by the capture of thermal neutrons, i.e., by *neutron activation analysis*. An activation analysis follows a procedure similar to that shown in Fig. 2. In almost all analyses, the sample materials are not treated before the bombardment, but are placed directly into the bombardment capsule or container. The length of the bombardment interval is usually determined by the half-life of the radionuclide used for the element of interest and the flux of nuclear particles.

The post-bombardment processing of the activated sample may follow either a nondestructive assay of the radioactivity in the sample (gamma-ray scintillation spectrometry is used most often for this) or a chemical processing of the sample prior to the radioactivity assay. Techniques involving either precipitation, electrodeposition, solvent extraction, and ion exchange or some combination of these form the basis of the radio-chemical separation techniques used in activation analysis.

Neutron activation has been successfully applied to a great variety of determinations of small concentrations of elements present in alloys, for example, vanadium and manganese in iron. Other metallurgical applications include the determination of some 70 elements: including the metals, aluminum, antimony, arsenic, barium, bismuth, cadmium, calcium, cerium, cesium, and so on alphabetically down the list. Minerals and soils have also been extensively analyzed by the method. However, it is not restricted to trace quantities or to inorganic substances, one interesting application being the determination of phosphorus, oxygen and nitrogen in organic phosphorus compounds. Sodium has been determined in blood plasma, and numerous other biochemical determinations have been made accurately. See also **Neutron**.

Tracer Analysis. This method is readily performed with radioactive isotopes because their ease of detection by measurement of their

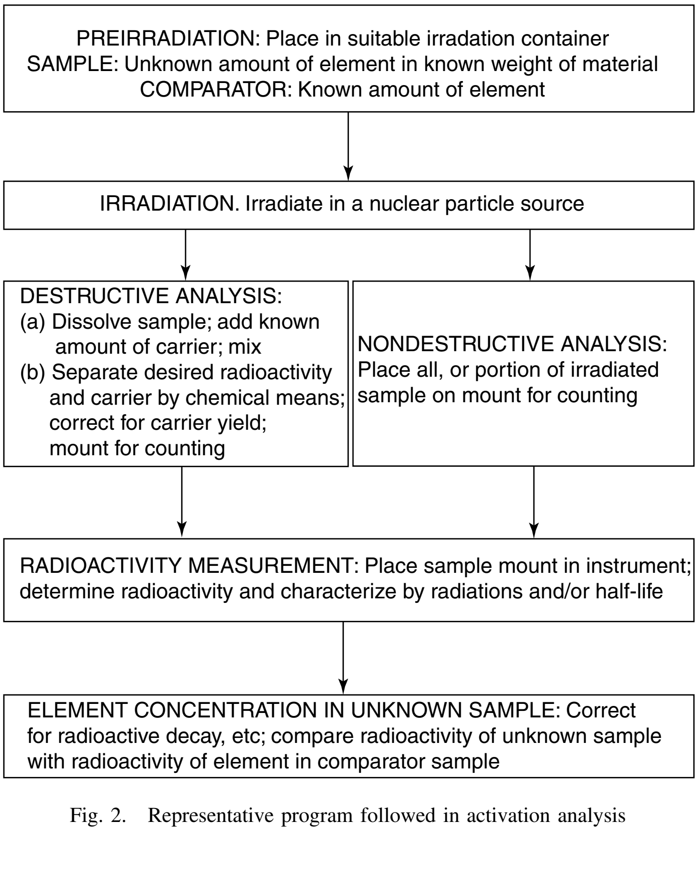

Fig. 2. Representative program followed in activation analysis

radioactivity makes them effective means of "tagging" their stable isotope counterparts (e.g., ^{24}Na(sodium-24) to tag ordinary sodium). Since compounds are usually involved, rather than elements, one merely synthesizes enough of the radioactive compound to tag the compound under analysis. The tagged compound may be followed through any analytical scheme, industrial system, or biological process. It is essential that a compound be tagged with an atom, however, which is not readily exchangeable with similar atoms in other compounds under normal conditions. For example, tritium could not be used to trace an acid if it were inserted on the carboxyl group where it is readily exchanged by ionization with the solvent.

Radiometric methods employing reagent solutions or solids tagged with a radionuclide have been used to determine the solubility of numerous organic and inorganic precipitates, or as a radioreagent for titrations involving the formation of a precipitate. In this type of application it is necessary to establish the ratio between radioactivity and weight of radionuclide plus carrier present. This may be established by evaporating an aliquot to dryness, weighing the residue, and measuring the radioactivity.

Closely related to tracer analysis is the method of *isotopic dilution analysis*. Here, instead of checking the effectiveness of a method from known amounts of an element in the sample, and of its radioactive isotope, one knows only the amount of radioactive isotope added, and by precipitating or otherwise separating the total amount of that element present, and then measuring its radioactivity, one determines its amount, and hence the amount present in the original sample.

Radioactive tracer methods lend themselves well to research applications in studying entire processes in science and industry, and in the biological as well as the physical sciences.

Industrial Applications for Radioisotopes

Radioisotopes are widely used in the measurement of process variables, including the level of liquids and solids in tanks, silos, and other vessels, the density and specific gravity of fluids and solids, the thickness of sheets and coatings, the moisture content of soils and other solids, the mass flow of materials in pipelines or on belts, and the determination of chemical composition of raw materials, in-process materials, and end-products. Representative examples of these applications are given in Table 6.

Density, level, and thickness measurements all depend upon the determination of the number of radiations per unit time penetrating the sample and producing a measurable signal in the radiation detector. When the amount of matter between the source and the detector increases, there usually is a decrease in the signal. The following relationship demonstrates the exponential nature of the attenuation of beta or gamma radiation:

$$\frac{I}{I_0} = Be^{-\mu\rho t}$$

TABLE 6. REPRESENTATIVE RADIOISOTOPE PROCESS INSTRUMENTATION APPLICATIONS

Variable measured	Representative applications	Radioisotope frequently used
Mass flow in pipes	Slurries and viscous or corrosive materials	^{60}Co, ^{124}Sb
Mass flow on belts	Conveyance of solids, such as coal, woodchips, gravel, etc.	varies with material
Level	Slurries, viscous materials, solids, crushed rock, aircraft and rocket fuels, etc.	^{137}Cs, ^{60}Co, ^{226}Ra and daughter
Density—fluids	Coal slurries, sewage sludges, granular materials, black and green liquor (paper pulp processing), chemicals	^{137}Cs, ^{60}Co, ^{226}Ra and daughter
Density—solids	Compacted soil density for roads, footings, dams, asphaltic concrete	^{137}Cs, ^{60}Co, ^{226}Ra and daughter
Thickness	Thin plastic sheets, films	^{14}C
	Light paper and plastics	^{85}Kr
	Heavy paper, thin metal, rubber	^{90}Sr-^{90}Y
Moisture	Soils and solids	Neutron sources: ^{226}Ra-Be, ^{210}Po-Be, ^{124}Sb-Be, ^{239} Pu-Be, ^{252}Cf, ^{241}Am-Be

where I_0 = initial radiation intensity
I = radiation intensity through absorbing material
B = a buildup factor dependent on the energy and collimation of the source, and on ρ and t. B accounts for radiation which has been "scattered" or changed in direction by interactions that do not stop the radiation.
μ = absorption coefficient, dependent on composition of absorbing material, energy of radiation, and source detector geometry
ρ = specific gravity of absorbing material
t = thickness of absorbing material

Beta radiation has a finite range, whereas in theory x- and gamma rays are exponentially attenuated. It should be noted that x-radiation of each energy exhibits sharp changes in absorption coefficients for certain absorbers.

Where density and specific gravity measurements are made of liquids and slurries, major signal generation changes can result from temperature changes. Thus, compensation for temperature changes should be built into the instrumentation. Major errors also may result from the presence of air bubbles, grease deposits, and pipewall corrosion.

In a typical level-measuring gage, a gamma-emitting radioactive source is mounted in a shielded holder on one side of the vessel and a suitable detector is mounted on the other side. Several radiation receivers, mounted at vertical increments, are required to provide a range of levels. Greater accuracy and flexibility can be obtained with a motor-driven level gage. Here the radiation source and detector cell move up and down in unison as controlled by a motor-driven drum. Potentiometers provide output voltages; one indicates full range in feet; a second potentiometers indicates inches within range. A digital readout also may be provided.

Moisture measurements can be made by using a source of fast neutrons. If such a source (Sb-Be, Pu-Be, ^{252}Cf) is located on or in a medium containing hydrogen, some of the neutrons will be slowed (moderated or thermalized) by collisions with the hydrogen atoms. The number of slow neutrons per unit area per unit time can be determined with a detector selectively sensitive only to slow neutrons. A representative detector of this type is a ^{3}He or BF_3-filled proportional or Geiger-Mueller detector. The relative response of the detector will provide a measure or the hydrogen content of the medium surrounding or adjacent to the source. Thus, if water is the only or principal hydrogen-containing variable constituent of the medium, the technique can be used to measure moisture content.

Pressure measurements involve the interaction of alpha radiations with a gas, which results in the formation of positive and negative ions. The latter can be collected and measured as electric current. The number of ions produced in a gas by alpha particles depends upon the density and composition of the gas. Where either of these factors is known the other can be inferred from these measurements. Several vacuum gages employ this principle.

For the measurement of thickness and coverage (coatings) of very thin materials, the absorption of alpha radiation may be used as a measure of weight/unit area. For moderately thick materials, the beta radiation emitted by ^{90}Sr (strontium-90), ^{85}Kr (krypton-85), or ^{14}C (carbon-14) is used. For greater thicknesses, bremsstrahlung or gamma sources are used.

The uniformity of mixing may be determined by mixing radioactive ^{24}Na in sodium chloride as the tagged compound and, after mixing, determining the uniformity of the presence of the isotope in the samplings. The mixing patterns in fluid catalytic cracking units have been ascertained by tagging catalysts with ^{51}Cr (chromium-51), ^{46}Sc (scandium-46), and ^{144}Ce (cerium-144).

Radioisotope techniques also find application in determining diffusion rates in the study of metals, porous bodies, liquids, and gases. Tritiated water is used in studies of the permeability of thin, flexible plastic sheets. The thin sample sheets are placed over a dish containing tritiated water (^{3}H, heavy hydrogen in the water) solidified by gelatin. Then methane is passed over the upper surface of the septum and into a counter. Pulses of the counter resulting from the tritium diffused in the methane are measured. Similar techniques have been used for studying flow patterns of underground water supplies of for tracing cross flow between oil wells. In one application, water tagged with ^{131}I (iodine-131) is used in the study of the subsurface flow of water in secondary oil recovery—to determine the path, velocity, and carrying strata of the water.

Three main techniques are used for applying radioisotopes to the measurement of flow rate: (1) peak timing, (2) dilution, and (3) total count. In peak timing, a gamma emitter (^{60}Co or ^{124}Sb) is injected quickly at a point close to the section of the pipe in which the velocity is to be determined. The time of passage of the peak of the tracer wave is determined by two detectors located at a known distance apart and external to the pipe. The dilution technique is based on the fact that the concentration of mixed tracer in a line resulting from the continuous bleeding of a tracer at a known rate into the line will be inversely proportional to the relative flow rates of the line and the bleeder, assuming that the tracer will uniformly mix with the flowing liquid. In the total-count method, flow rate is based upon measurement of the total counts from a radioactive tracer that has been added to the flowing stream. The total count bears a simple inverse relation to the flow rate.

Radioisotopes also are used for detection of interfaces in pipelines. Since some pipelines handle many different stocks, ranging from crude oil to finished petroleum products to chemicals, etc., effective control requires a knowledge of the precise instant when the interface between two materials passes the control point. This is obtained by adding to the interface a radioactive nuclide, which emits a strong beam of radiation, such as ^{124}Sb. The half-life of the radioisotope used must be quite short to insure that the activity will have decayed to a safe level before it reaches the ultimate user of the transported material.

Metallurgical Applications. Some of the outstanding industrial applications of radioactivity have been in metallurgy. The wear of piston rings in internal combustion engines is important in the selection of alloys for this service. Since the rate of wear is relatively slow, a long period of test would be required to give effects measurable by ordinary methods. However, if the piston ring is made radioactive by irradiation, and the lubricating oil is then tested for the radioactivity of particles of metal abraded from the ring, the more sensitive radiation counters will show measurable and comparable results after relatively short test periods.

Another metallurgical application of radioactivity is in determining the distribution of metals in alloys. A case in point is the molybdenum alloys, where the distribution of the molybdenum between the various solid phases is important to the properties of the alloy. Such studies can be made by polishing a sample of the alloy, etching its surface with properly chosen reagents, and examining its grain structure under the microscope. This process can often be shortened by enriching the molybdenum with one of its radioactive isotopes before adding this metal to the melting furnace. Alloys containing such radioactive elements can be photographed directly through the microscope, whereupon the radioactive areas of the metal show dark on the film.

A related metallurgical application is the use of radioactive nuclides, which emit high energy gamma rays and have a reasonably long half-life, such as ^{60}Co, 113-day ^{182}Ta or 100-day ^{88}Y, to take radiographs of metallic articles. This replaces the x-ray technique for the detection of holes, inclusions and other internal defects in castings and other parts. A similar technique is employed in the beta-ray gauges used in checking the uniformity of the thickness of sheets of material and various articles, such as paper, plastics, steel, textiles, rubber, glass, roofing, flooring, and cigarettes. Here the highly penetrating gamma rays would not be appreciably absorbed by the thin, nonmetallic material; therefore, radioactive nuclides emitting beta rays are used instead. This type of application constitutes an extensive use of radioactive radiations for testing purposes.

Radioisotopes in Medicine

Radiopharmaceuticals are almost ideal diagnostic tools because radioisotope tracers do not alter body physiology, and they permit external monitoring with minimal instrumentation. Presently, there are three major areas of nuclear medicine: (1) physiological function studies, (2) radionuclide imaging procedures, and (3) therapeutic techniques.

Physiologic Function Testing. An example of this application is the assay of thyroid hormone levels in the blood which, in turn, can aid in the assessment of thyroid function. The radioactive iodine uptake test, which involves the administration of a dose of ^{131}**I** (iodine-131) to the patient, is also a valuable procedure in assessing thyroid function. At present, the technique is best reserved for problem cases rather than used as a primary screening test. The main disadvantage of this test is the effect of the dietary intake of iodine, which reacts in various ways in different individuals.

The gamma camera, with computer-assisted data analysis, is used together with ^{131}I-hippuran to measure renal function. The renogram is of most clinical value in the assessment of ureter impairment in pre-and postoperative patients with carcinoma of the cervix and other pelvic and gynecological tumors.

Radionuclides also are useful in assessment of hematological status to detect anemia and iron deficiency, and in studying radioactivity in feces in order to detect significant blood loss through the gastrointestinal tract. Although considerable development remains, radioisotopes show promise of facilitating differentiation between well-vascularized and ischemic tumors and organs.

Radionuclide Imaging Procedures. Brain tumors can be detected by external counting of radionuclides, a procedure introduced into general clinical use in the late 1950s. A significant advance in brain tumor imaging was the introduction of the gamma camera, which permitted more rapid studies with multiple views, as well as dynamic cerebral blood flow assessment.

The ^{85}Sr (strontium-85) scanning of metastatic bone disease is another important tumor localization technique. Since metastatic lesions of bone are frequently associated with new bone formation, there is usually a significant localization of several radioisotopes in the general vicinity of the metastasis. Early metastatic lesions often go undetected on roentgenographic examination because a 30–50% change in bone density is required to produce visible changes on X-ray examination. Bone scans, however, are generally positive quite early in the development of metastasis. Patients with prostatic carcinoma and carcinoma of the breast are most often candidates for study with this technique.

The liver scan, using radioactive colloids, utilizes a slightly different approach to tumor detection. In this scan, the radioisotope concentrates in the normal tissue, and the tumor appears as a nonradioactive, or "cold" area. This procedure is often an indicated procedure in the cancer patient because of the frequency of liver metastases, and because the liver is not easily visualized using routine radiographic techniques. There are limitations to the approach. Lesions that are smaller than two centimeters in diameter generally go undetected because of limitations of resolution of scanning devices. A number of other disease conditions also may interfere with localization of radiocolloids, producing defects on the liver scan that are indistinguishable from neoplastic disease.

Lung scans also are useful in checking for changes before and after radiation treatment of carcinoma of the lung. Although not widely used at present, a technique for detecting bronchial obstruction has been developed using inhalation of radioactive aerosols. A liver-pancreas scan also can be performed, although interpretation of pancreatic scans is often difficult because of normal variation in size and shape and in trace concentration. When the scan appears to be within normal limit range, however, the presence of disease is unlikely.

Thyroid scans with ^{131}I are useful in determining the activity of thyroid nodules in the intact thyroid gland. A nonradioactive, "cold" nodule indicates a higher risk of thyroid carcinoma, but the scan alone is not recommended as a technique of selecting patients for surgery. After removal of a thyroid carcinoma, a scan of the neck may demonstrate areas of increased activity in the cervical lymph nodes and other organs, indicating metastatic disease.

Scintigram techniques of the kidney can be helpful in distinguishing between cysts and neoplasms, and salivary gland scanning can be useful in confirming abnormality in the salivary gland where tumor is suspected. Lymph node scans with the radiocolloid injected subcutaneously on the dorsum of the feet can be used as screening procedures for lymph flow.

The search continues for a general tumor-scanning agent. Although several radionuclides have been found to localize tumors of widely different types and regions of the body, current interest is in the use of ^{67} Ga-citrate, which is undergoing a wide clinical trial and may prove to be useful in the localization of lymphomas as well as some adenocarcinomas. Medical imaging techniques are discussed in several articles of this encyclopedia. Consult alphabetical index.

Therapeutic Techniques. Probably the most prominent therapeutic use of radiopharmaceuticals is radioactive iodine in the treatment of metastatic thyroid cancer. ^{131}I has a half-life of about 8 days and emits gamma and beta rays. When iodine salts are taken into the body, most of the dose is concentrated in the thyroid gland. A dose of radioactive iodine salt similarly concentrates in the thyroid gland. When there is a cancer in the thyroid gland, or the gland is overactive (hyperthyroidism), the excessive

tissue may be destroyed by the radiation from the radioactive iodine that has been administered. Although removal of metastatic thyroid cancer is not always achieved with ^{131}I therapy, significant palliation can occur. In some instances of lung metastasis and lymph node metastasis in the neck, patients may show no evidence of recurrence, even many years after treatment.

Radiophosphorus is used in the treatment of patients with a number of diseases. This element has a half-life of about 14 days and emits beta rays. It is taken up by the body in the greatest quantity by those tissues which manufacture blood cells. In polycythemia vera, a condition in which too many red blood cells are formed, the radiation from this isotope often brings about a sufficient suppression of the blood cell-making tissues to alleviate some of the symptoms of the disease. Leukemia patients, in whom there is an excessive production of white cells, are offered added comfort and, in some instances, prolongation of life by the use of radiophosphorus. This element also may be used in treatment of metastatic cancer to the bone and, although the treatment is not used in an attempt to eradicate cancer, it can result in significant palliation of pain in some patients.

^{198}Au (gold-198), in the form of a suspension in water, has found increasing use in the treatment of certain types of cancer. Isotopes of gallium, sodium, arsenic, and other elements have been tested for possible uses in medicine and show some promise. Other methods for using nonsealed sources include arterial therapy of liver cancer, endolymphatic therapy of lymph node cancer, and intracavitary therapy of pleural and peritoneal cancer. The basic principle back of the internal use of all radioactive isotopes depends upon the concentration of the isotope in some particular tissue. The search for elements that are concentrated in each of the organs by the selective abilities of the tissues, or elements that concentrate in tumor tissue as contrasted with normal tissues, is the key to all techniques in radiodiagnosis.

^{60}Co (cobalt-60), a gamma and beta ray emitter with a half-life of about 5.3 years, is used in cancer therapy. Small pieces of radioactive metallic cobalt, made radioactive in a nuclear reactor, are placed into a proper shielding device and the radiation from them used in place of a high-powered x-ray machine or radium implantations in treating patients with localized cancer. Thousands of ^{60}Co irradiators are in use. Among the most significant advances in radiotherapy since 1925 has been the development of supervoltage equipment and the ^{60}Co megavoltage units. The latter are the most suitable, since they are compact, have high activity source in a small volume, are flexible and adapt to many geometric patterns for therapeutic use, and are easy and economical to maintain. With the ^{60}Co isotope, supervoltage is now made available throughout the world, and at a very low cost when compared with the cost of radium per se, or of x-ray generators. ^{137}Cs (cesium-137) units also are in use, but do not have the same therapeutic usefulness as the ^{60}Co, and the activity cannot be concentrated as easily as with cobalt.

See also **X-Ray Scan and Other Medical Imagery**.

Relative Biological Effectiveness (RBE). The roentgen is a measure of the intensity of ionizing radiation in air. One roentgen corresponds to the creation of 1 esu of charge in 1 ml of standard air. The roentgen can be considered as a measure of energy dissipation in air, and its definition has been extended to cover ionization or energy dissipation in other media. One roentgen corresponds to a radiation field dissipating 83.8 ergs/g of air, which dissipates approximately 93.8 ergs/g of body tissue. Ionization in tissue is a measure of physical damage. Thus, allowable radiation exposures for human tissue are expressed in roentgens. Since the same number of roentgens from various types of radiation produce different amounts of body damage, a term called roentgen equivalent man (rem) is used in stating allowable radiation exposure values. The rem $= R\times$ rbe, where rbe, known as *relative biological effectiveness*, has the values given in Table 7.

TABLE 7. VALUES OF RELATIVE BIOLOGICAL EFFECTIVENESS

Type of radiation	rbe
X- and gamma radiation	1
Beta rays	1
Alpha rays	20
Fast neutrons[a]	10
Thermal or slow neutrons	5

[a] Having energies in the range 0.1 to 10 MeV. Above 10 MeV, the rbe increases rapidly.

Radioactive Dating Techniques

Age determinations using radioactive nuclides may be looked upon as processes that are the inverse of half-life measurements. If a radionuclide of known half life exists within an object, the age of that object can be determined either by measuring the number of radionuclides that remain or the number of product nuclides of the radioactive decay. In these determinations it is assumed that, if we know the half life of the radionuclide, an elapsed time t, or age, for the object can be found by using the formula $t = (\ln N_1/N_2)/\lambda$, where λ is the decay constant of the radionuclide and N_1 and N_2 are the amounts of the radionuclide present at the beginning and the end of the interval spanning the time t.

In any use of radioactive dating or age determining processes, a basic assumption is, in general, that the concentration of the radioactive element is changed during the life of the sample only by its natural decay process, and that the accuracy of the determination depends primarily, therefore, upon the accuracy with which the half-life of that radionuclide is known.

Ages of specimens may sometimes be determined by other methods that the measurement of radioactivity, as by combination of radioactive measurements with mass spectroscopic determinations.

D.Q. Bowen (The University College of Wales, Aberystwyth) stresses that, in studies of paleoclimatology (global warming periods, etc.), "The last 130,000 years is especially important because it includes geological analogues which may be useful for predicting future changes in climate, and against which the predicted trace-gas induced global warming may be evaluated."[2]

Preliminary climate modeling suggests that natural trends will eventually overcome the predicted global warming, but better dating of past changes is required to refine such models. Two such dating methods are: (1) *thermoluminescence dating* of sediments, and (2) *amino acid geochronology* of fossil mollusks. All physical and biological sciences involved in research into the Quaternary Period[3] of the last 2.4 million years were revolutionized by the reinterpretation of Emoiliani's (1955) classic work on oxygen isotope variability in marine microfossils. For the reader with a scholarly interest in this topic, the Bowen reference listed contains a depth of understanding of radioactive decay dating in this area.

Age of Rocks. In the table of nuclides given under **Chemical Elements**, there are listed a number of naturally occurring radionuclides with long half-lives. From these known half-lives, the geological age of a rock may be calculated. One method of making this estimate is based upon the amount of radionuclide and its daughter nuclide contained in the rock. This method is based upon various assumptions, which may be stated as follows:

1. Since the rock was formed, the parent nuclidic content of the mineral has been changed only by radioactive decay.
2. All the decay products produced by the parent nuclide have been retained since the mineral was formed.
3. The geological separation of the parent and daughter elements at the time of formation of the mineral was sufficient to make the determination of the decay products unambiguous. For example, if a uranium mineral does not exclude all lead at the time it is formed, the isotopic abundance of the lead at the time of formation cannot be calculated with certainty.
4. The radioactive decay scheme of the parent nuclide is well known.

Another method uses the decay of cosmogenic isotopes that are produced in the atmosphere and then incorporated into terrestrial reservoirs. Examples of this approach include standard ^{14}C and ^{10}Be dating.

The contributions of modern chemistry, including the availability of separated isotopes, the extension of the range of mass spectrometers, and the developments of new chemical methods, which make possible the determination of microgram quantities, have extended the range of application of radioactive age measurements. This extension has been either

[2] The most appropriate past analogue for predicated global warming is from the mid-12. Global temperatures at that time simulate the predicted warming at high latitudes, whereas analogues based on the warmest interglaciations of the past 2 to 4 million years only give appropriate warming in middle latitudes.

[3] The Quaternary Period is subdivided into the Pleistocene Epoch and, commencing at 10,000 years ago, the Holocene Epoch. The Holocene is synonymous with the "Post-glacial or present interglaciation."

to minerals that contain relatively little of the parent element, but maintain a good separation of the parent and daughter elements when they are formed; or to minerals containing radioactive elements that have a very low natural abundance, such as ^{40}K, or a very long half-life, such as ^{87}Rb. Although these extensions have in turn introduced certain new problems and forced some compromises, they have made possible certain conclusions about geological questions and have opened new avenues for research.

A number of possible radioactive dating methods exist, but each method is practical, of course, only if the appropriate radionuclide exists in the mineral. One series of possible dating methods is based on the decay of natural uranium and natural thorium. If the rock has retained the helium produced by the decay of ^{238}U, for example, 8 helium atoms should exist for each nuclide of ^{238}U that has decayed through its complete chain to ^{206}Pb, since 8 alpha particles result from this chain. From a measure of the ratio of the amount of helium to the amount of ^{238}U in the rock, a calculation may then be possible of the age of the rock. In this method, corrections must be made for the decay of ^{235}U and of ^{232}Th, both of which are the initiating nuclides for a natural chain of radioactive nuclides. Because the half lives of ^{232}Th and ^{238}U are different, another method for determining the age of a rock containing both these nuclides is the measurement of the ratio of the amount of ^{206}Pb to the amount of ^{208}Pb, which are the ultimate decay products of the ^{238}U and ^{232}Th chains, provided neither of these isotopes of lead existed in appreciable quantity prior to formation of the rock. A related measurement is the ratio of radiogenic lead (either ^{206}Pb or ^{208}Pb) to nonradiogenic lead (^{204}Pb), which can be assumed to have been of primordial origin. Another correction that may be necessary, especially if the rock comes from a high altitude, is a determination of the amount of helium that has been produced as a result of spallation reactions caused by very high-energy cosmic radiation. Other radioactive age-dating systems are those of potassium-argon (which consists of the decay of ^{40}K to ^{40}Ar, by electron capture, a process with a half-life of 1.27×10^{10} years) and rubidium-strontium which consists of the decay of ^{87}Rb to ^{87}Sr, by electron emission, a process having a half-life of 4.7×10^{10} years.

One conclusion drawn from radioactive measurements is that the pre-Cambrian history of the earth's crust extends beyond 2,700 million years. The pegmatites that have been found to be this old are located in North America and Australia, and they probably exist on all the continents. The oldest rocks in the United States that have been measured are on the south rim of the Bridger Mountains near the Wind River Canyon in Wyoming. These ancient pegmatites intrude geologic formations of sedimentary and volcanic rocks that, themselves, are the result of even more ancient processes than those in which they were formed. Thus, a period of the order of 3,000 million years or more is available for geologic processes that have formed the crust seen today.

Next, the facility to measure the absolute age of micas in igneous intrusives of pre-Cambrian sediments provides a method of correlating these sediments wherever they occur in much the same fashion that fossil correlation of more recent sedimentary formations is possible. A method that is independent of the lithologic characteristics and the general structure of the sediments will provide a crucial test of the validity of these criteria, which have been all that was available to the geologist. Further, any attempts to look for more subtle evidence of such things as changes in the composition of the atmosphere or origins of life itself must be fitted into a time scale of the pre-Cambrian.

Radiocarbon Dating. This is a method of estimating the age of carbon-containing materials by measuring the radioactivity of the carbon in them. The validity of this method rests upon certain observations and assumptions, of which the following statement is a brief summary. The cosmic rays entering the atmosphere undergo various transformations, one of which results in the formation of neutrons, which in turn, induce nuclear reactions in the nuclei of individual atoms of the atmosphere. The dominant reaction is

$$n + {}^{14}\text{N} \longrightarrow {}^{14}\text{C} + p$$

in which the neutrons react with the nuclei of nitrogen atoms of mass number 14 (which make up the nitrogen molecules that constitute nearly $\frac{4}{5}$ of the atmosphere) to form carbon atoms of mass number 14 and protons (p). The ^{14}C atoms are radioactive, having a half life of about 5730 years. The largest rate of formation of ^{14}C atoms from cosmic rays is at 30,000–50,000 feet (9,144–15,240 meters) above sea level and at higher geomagnetic latitudes, although formation occurs at varying rates throughout the entire atmosphere. The ^{14}C atoms react with oxygen in the atmosphere to form carbon dioxide, which is mixed with the nonradioactive carbon dioxide in the atmosphere, and with it gains worldwide distribution by various processes. The radioactive $^{14}CO_2$ enters the carbon cycle in which plants take up carbon dioxide from the atmosphere to form carbohydrates, which enter through plant foods into the composition of animals. In another world-wide process, also of exchange nature, carbon dioxide is dissolved in seawater and then, under changing conditions of acidity and temperature, is partially evolved from the seawater again. As a result of these and other processes, the ^{14}C formed in the atmosphere by cosmic rays tends to become distributed throughout all the nonradioactive carbon, not only in the atmosphere, but in the biosphere, the hydrosphere, and even the upper levels of the lithosphere (there are many carbonate-containing minerals).

Obviously this wide distribution of the ^{14}C formed in the atmosphere takes time; it is believed to require a period of 500–1000 years. This time is not, however, a deterrent to radiocarbon dating because of two factors; the long half-life of ^{14}C and the relatively constant rate of cosmic-ray formation of ^{14}C in the earth's atmosphere over the most recent several thousands of years. These considerations lead to the conclusion that the proportion of ^{14}C in the carbon reservoir of the earth is constant, and that the addition by cosmic ray production is in balance with the loss by radioactive decay. If this conclusion is warranted, then the carbon dioxide on earth many centuries ago had the same content of radioactive carbon as the carbon dioxide on earth today. Thus, radioactive carbon in the wood of a tree growing centuries ago had the same content as that in carbon on earth today. Therefore, if we wish to determine how long ago a tree was cut down to build an ancient fire, all we need to do is to determine the relative ^{14}C content of the carbon in the charcoal remaining, using the value we have determined for the half life of ^{14}C. If the carbon from the charcoal in an ancient cave has only $\frac{1}{2}$ as much ^{14}C radioactivity as does carbon on earth today, then we can conclude that the tree which furnished the firewood grew 5730 ± 30 years ago.

As pointed out by Muller (1978), there are well-documented differences between the ages of materials determined by dating with radioisotopes and the ages determined by other means, such as tree-ring counting. In addition to systematic effects, there are statistical errors due to the limited number of atoms observed. Both types of errors can be considered to be fluctuations in n, the number of atoms observed. A relationship can be derived between the magnitude of these fluctuations and the resulting error in the estimation of age of the sample:

$$n = ke^{-t/\tau} \text{ or } t = \tau \ln(\text{k}/n)$$

where τ is the mean life of the isotope, t is the age of the sample, and k is the initial number of radioactive atoms in the sample multiplied by the efficiency for detecting them. If n has errors associated with it of $+\delta n_1$ and $-\delta n_2$, then the corresponding values of t will be:

$$t = \tau \ln \frac{k}{n^{\delta n_1}_{\delta n_2}} = \tau \ln(k/n) \begin{matrix} + \\ - \end{matrix} \begin{vmatrix} \ln(1 - \delta n_2/n \\ \ln(1 + \delta n_1/n \end{vmatrix}$$

Muller has shown that for $n = 1$, inverse Poisson statistics gives $n_1 = 1.36$ and $n_2 = 0.62$ and thus the foregoing equation becomes:

$$t = \tau \ln(k)^{+0.96\tau}_{-0.86\tau}$$

Further details of this method can be found in aforementioned reference.

Determination of the ratio of two oxygen isotopes has been effective in fixing the age of fossil sediments and can provide information about ice formation and, possibly, water temperatures. The lighter isotope ^{16}O evaporates preferentially and thus precipitation and hence ice in glaciers and polar caps should be enriched with ^{16}O relative to seawater. Thus, fluctuations in the amount of water locked up as ice can be determined from variations in the oxygen isotope ratio of fossils locked up in deep-sea sediments. And, because this ratio also varies with water temperature, thermal information also can be gleaned. Kennett (University of Rhode Island) has employed this technique in determining when significant amounts of ice first formed at the poles. This research has indicated that the Antarctic ice cap formed only about 16 million years ago, after Australia had split off and moved away from Antarctica, leaving the latter continent isolated at the pole and surrounded by the fast-moving circumpolar current.

In 1986, J.I. Hedges and colleagues (see reference) reported on how dissolved and particulate organic material transported by rivers can provide

a continuous record of physical and biological processes at work within the drainage basin. Rivers also contribute a potentially important quantity of organic matter to the ocean, where the dissolved component may exhibit an appreciable residence time. Although the magnitude of the global river contribution is known, the dynamics of organic materials within terrestrial ecosystems and their effects on the composition of the corresponding marine reservoirs are poorly understood. This is particularly true for rivers draining topical rain forests, which account for about 40% of the total riverine organic carbon discharged into the ocean. Hedges and a team studied the Amazon River System using organic carbon-14 dating methods. They found that coarse and fine suspended particulate organic materials and dissolved humic and fulvic acids transported by the Amazon River all contain bomb-produced carbon-14, indicating relatively rapid turnover of the parent carbon pools. However, the carbon-14 contents of these coexisting carbon forms are measurably different and may reflect varying degrees of retention of soils in the drainage basin.

Dating by Accelerator Mass Spectrometry. The cyclotron is mainly used as a source of energetic particles. The cyclotron also can be used as a very sensitive mass spectrometer. Alvarez and Cornog (1939) were the first researchers to use a cyclotron in this manner. This was in connection with their discovery of the true nuclear properties of ^{3}He and tritium. Within the last few years, Muller and associates at the Lawrence Berkeley Laboratory have used this method in a search for integrally charged quarks in terrestrial material. For radioisotope dating, the cyclotron is tuned to accelerate the isotope of interest and the sample is introduced into the ion source, preferably as a gas. For radioisotope dating, the greatest gains over radioactive counting techniques apply to the longer-lived species, which have lower decay rates. It has been estimated that the cyclotron can be used to detect atoms or simple molecules that are present at the 10^{-16} level or greater. For ^{14}C dating, the Berkeley investigators indicate that one should be able to go back 40,000 to 100,000 years with 1-to-100 microgram carbon samples; for ^{10}Be dating, 10–30 million years with from 1 cubic millimeter to 10 cubic centimeter rock samples; and for tritium dating, 160 years with a 1-liter water sample. Over 50 cyclotrons are in operation today that could perform radioisotope dating and, although the instruments are costly, the cost for a dating determination experiment may not be much higher than for decay dating technology.

Other isotopes with which an accelerator mass spectrometer may be effective include ^{26}Al, ^{36}Cl, ^{53}Mn, ^{81}K, and ^{129}I. Chlorine-36 has a half-life of 300,000 years and may be used for dating water in underground reservoirs. ^{10}Be is produced in the atmosphere at the rate of 1.5×10^{-2} atom cm^{-2} sec^{-1} by cosmic rays that break up oxygen and nitrogen nuclei. ^{10}Be has been used in studies of both seafloor spreading and manganese nodule formation. Although tritium (^{3}H) has a short mean life of 17.8 years, tritium dating has been important in cosmic-ray physics, hydrology, meteorology, and oceanography. For example, if one desires to know how long an underground water reservoir may require for refilling, the age of the water can be determined by tritium dating methods.

In 1986, researchers at the Research Laboratory for Archaeology and the History of Art, University of Oxford, reported on how the radioactive carbon-14 isotope can be separated from other atoms in a sample by use of accelerator mass spectrometry, thus making it possible to derive more accurate chronologies from much smaller archaeological or anthropological specimens. For details, consult Hedges/Gowlett reference listed.

In 1992, K.R. Ludwig and colleagues of the U.S. Geological Survey reported on their use of mass-spectrometric ^{230}Th-^{234}U-^{238}U dating of the Devil's Hole calcite vein (Derbyshire, England), which contains a long-term climatic record, but requires accurate chronological control for its interpretation. Mass-spectrometric U-series ages for samples from core DH = 11 yielded ^{230}Th ages, with precisions ranging from less than 1000 years to less than 50,000 years for the oldest samples. The ^{234}U/^{238}U ages could be determined to a precision of approximately 20,000 years for all ages. Tentatively, the researchers have concluded, "Overall, the U-series ages form a remarkably self-consistent suite of age determinations. Because this consistency is both internal (from replicate samples) and external (from the stability of the overall age-distance trend), it seems highly unlikely that the dates have been significantly corrupted by open-system processes, such as uranium gain or loss or alpha-recoil phenomena. The apparent ideality of the U-Th system in the vein material is probably the result of continuous submergence in water that showed limited secular variations of its physical and chemical properties."

Non-Radioactivity Dating Techniques

Several methods in addition to those involving radioactivity have been used to estimate the ages of various materials and objects.

Obsidian Hydration Rate. Obsidian (rhyolitic volcanic glass) can be used as a key to age determinations for both archeological and geological purposes. As pointed out by Friedman and Long (1976), the method depends upon the fact that obsidian absorbs water from the atmosphere to form a hydrated layer, which thickens with time as the water slowly diffuses into the glass. The hydrated layer can be observed and measured under a microscope on thin sections cut normal to the surface. To convert the measured hydration thickness to an age, the equation relating thickness to time must be known. This requires not only the form of the equation (functional dependence), but also the constants in it. Prior to the early 1960s, age could be related to hydration thickness only if combined with known history of a region or through the use of carbon-14 techniques. In the mid-1960s, Friedman and associates conducted actual experimental hydration experiments on obsidian, exposing the materials (taken from the Valles Mountains in New Mexico) to a temperature of 100°C and steam at a pressure of 1 atmosphere over a 4-year period. An equation of the form, $T = kt^{1/2}$ was developed, where T = thickness of hydration layer, t = time, and k is a constant. Investigators have developed a procedure for calculating hydration rate of a sample from its silica content, refractive index, or chemical index and a knowledge of the effective temperature at which the hydration occurred. The effective hydration temperature (EHT) can either be measured or approximated from weather records. The investigators concluded that if the EHT can be determined and measured for the hydration of a particular obsidian, it should be possible to carry out absolute dating to ±10% of the true age over periods as short as several years and as long as millions of years.

Manufactured Glass Objects. Other investigators (Lanford, 1977) have extended the principles applying to obsidian to manufactured glass, which extends back for thousands of years and thus can be useful to archeologists. However, as observed by Lanford, one cannot use the same optical method for measuring the thickness of hydration layers as used with obsidian. The hydration of the two materials differs. Also, glass that is less than a few hundred years old would generally have hydration layers thinner than the wavelength of visible light. The optical method is destructive in that it requires removal of a slice of glass from an object, something much discouraged by art historians and dealers. The Lanford method involves a resonant nuclear reaction between ^{15}N and ^{1}H for measuring the distribution of hydrogen in solids. With this technique, complete depth profiles of the surface hydration layer can be obtained in a fully nondestructive manner. Lanford summarizes by observing that this method of hydration dating need not be limited to glass. Since most silicates are unstable against slow reactions with atmospheric water, many may develop surface hydration layers suitable for dating and authenticating. The glazes on pottery are chemically similar to glass, and it may be possible that a dating method for glazed pottery based upon these procedures can be developed.

Amino Acid Racemization. This dating method is based upon the incorporation of L-amino acids, exclusively, into proteins by living organisms. As pointed out by the researchers Masters and Zimmerman (1978), given sufficient periods of time over which proteins are preserved after synthesis, a number of spontaneous chemical reactions take place. Among these is racemization, which converts L-amino acids into their enantiomers, the D-amino acids. The different amino acids racemize at various rates, and these rates (as with all chemical reactions) are proportional to temperature. One of the fastest racemization rates known is that of aspartic acid, with a half-life of 15,000 years at 20°C. It follows, then, that the older a fossilized material may be, the higher will be its D-aspartic acid content or D/L Asp ratio. Once the k_{asp} is known for a given fossil locality, the age of a specimen can be calculated from the D/L ratio.

This method was used in the examination of an Eskimo who died 1600 years ago. The body was discovered in a frozen state on St. Lawrence Island, Alaska in 1972 and remained frozen until it was brought to Fairbanks in 1973. Examination of the female individual revealed that she had a skull fracture, probably resulting from instant burial caused by a landslide. Aspartic acid racemization analysis of a tooth from the mummy yielded an age at death of 53 ± 5 years, which correlated well with earlier estimates based upon morphological features. This method is an example of the need to preserve mummies (Alaskan, Egyptian, and Peruvian, among others) for application of new dating techniques as they develop.

The racemization dating technique fell out of favor with many paleoanthropologists in the 1980s, but staged a comeback of acceptance in the early 1990s. This resurgence was the result of analyzing samples of African ostrich egg fragments collected from the Border Cave located on the east coast of South Africa. These or close-by sites also contain reputedly human bones. If the age of these bones is determined to be in the range of 100,000 years, this would provide an additional bit of independent evidence for the theory that modern humans came from Africa. In the Border Cave determination, researchers found that amino acid racemization (AAR) time dating compared relatively closely with electron-spin resonance dating carried out at Cambridge University. AAR techniques revealed an age of 80,000 to 100,000 years for the egg-shells, whereas electron-spin resonance dating of human bones shows 60,000 years. See also **Racemization**.

Geochemical Methods. These methods usually involve a combination of chemical analysis of materials coupled with the curiosity of a detective. This is not a singular methodology, but incorporates numerous disciplines and a lot of past experience with the materials in question. The authentication of ancient marble sculptures prior to their procurement by the J. Paul Getty Museum is an example. In this case, an expert geochemist with past experience with dolomite marble studied a phenomenon known as *dedolomitization*, wherein after many centuries the exposed surface of the marble changes into calcite, or calcium carbonate. Thus, this provides a key to age as well as to source of the original material. See Margolis reference listed.

After using numerous dating techniques over a span of several years, by the late 1980s, the much publicized "Shroud of Turin" was finally explained to the satisfaction of most investigators. The answer was put forth by W.C. McCrone, a microscopist who specializes in authenticating art objects. McCrone examined fibers and other materials lifted from the surface of the cloth with adhesive tape. He determined that light-colored portions of the figure were comprised of a gelatin-based medium speckled with particles of red ocher and that fibers from the dark areas (representing blood) contained stains not of blood, but rather were made up of particles of vermilion. The vermilion was found to be of the type developed for artists in the Middle Ages. Also, the practice of painting linen with gelatin-based temperas was common during the late 13th and the 14th century. Final conclusion: The "shroud" had been forged by some unknown 14th century artist.

The use of thermoluminescence (i.e., heating small particles to a high temperature and then analyzing the emanations spectroscopically) can be a key to an object's age. In a paper by P. Lang presented at the 1988 Pittsburgh Conference and Exposition on Analytical Chemistry and Applied Spectroscopy, modern methods involving Fourier transform spectrometry or Raman spectrometry are described. As early as 1818, Sir Humphrey Davey presented a paper along these lines to the Royal Society on the colors used by the ancients in painting.

Tree-ring counting as a measure of age is described under Pine Trees. However, it is of note to mention an August 1990 report on how tree rings were used to reveal the age of the "oldest road," which was found in a peat bog in 1970. The road is located in southwestern England. It dates back 4000 years.

RADIOACTIVITY (Mineral). See **Mineralogy**.

RADIOCHEMISTRY. The subdivision of chemistry that deals with the properties and uses of radioactive materials in industry; biology, and medicine, including tracer research and radioactive waste disposal.

RADIOISOTOPES. See **Radioactivity**.

RADIUM. [CAS: 7440-14-4]. Chemical element symbol Ra, at. no. 88, at. wt. 226.025, periodic table group 2 (alkaline earths), mp 700°C, bp 1,140°C, density 5 g/cm^3 (20°C). Radium metal is white, rapidly oxidized in air, decomposes H_2O, and evolves heat continuously at the rate of approximately 0.132 calorie per hour per mg when the decomposition products are retained, and the temperature of radium salts remains about 1.5°C above the surrounding environment. Radium is formed by radioactive transformation of uranium, about 3 million parts of uranium being accompanied in nature by 1 part radium. Radium spontaneously generates radon gas at approximately the rate of 100 mm^3 per day per gram of radium, at standard conditions. Radium usually is handled as the chloride or bromide, either as solid or in solution. The radioactivity of the material

decreases at a rate of about 1% each 25 years. All isotopes of radium are radioactive. See also **Radioactivity**. The first ionization potential of radium is 5.227 eV; second, 10.099 eV. Other important physical properties of radium are given under **Chemical Elements**.

One year after the discovery of X-rays by Röntgen (1895), Henri Becquerel investigated the relationship between the phosphorescence of various salts after their exposure to sunlight and the fluorescence in an operating x-ray tube. One of the salts under investigation was potassium-uranium sulfate. After exposure to sunlight, Becquerel noted that the salt not only emitted visible light, but also rays similar to x-rays that were able to penetrate the heavy black paper and thin metal foils within which his photographic plates were wrapped. During a period of cloudy weather, Becquerel stored the salt and photographic plates in a closet, awaiting further sunny days. Later, when he inspected the package, he noted that a very intense image had been developed on the photographic plate even though it had not received much prior exposure to sunlight. By further experiments, Becquerel confirmed that the intense image was derived directly from the presence of the salt, regardless of any exposure to sunlight. This constituted the first demonstration of radioactivity. Through further investigations, Ernest Rutherford demonstrated that both alpha and beta radiations were emitted by the salt. Rutherford learned that the alpha rays were easily absorbed by thin sheets of paper, whereas the beta rays acted in the same manner as observed by Becquerel. Later Mme. Marie Curie found that thorium produced about the same intensity of radioactivity as uranium. Further tests disclosed that the uranium ore with which she was working (pitchblende) exhibited more radioactivity than could be accounted for by its uranium content alone. Subsequently, Mme. Curie and her husband, Pierre Curie, successfully separated two previously unknown elements, radium and polonium. Thus, both radium and polonium were identified as chemical elements in 1898. It was found that each of these elements was over a million times more radioactive than uranium.

Radium gained prominence not only from its scientific interest, heralding a whole new area of physics and chemistry, but from its wide use in therapeutic medicine, as an ingredient (very dangerous) of luminous paints, and in various instruments for inspecting structures, such as metal castings. Commercially, radium generally is marketed as the bromide or sulfate and is extremely radioactive in these forms. Use of radium in medical technology has largely been replaced by other sources of radioactivity.

Radium occurs in pitchblende, and in carnotite along with uranium. Radium was first obtained from the uranium residues of pitchblende of Joachimsthal, the Czech Republic and Slovakia, later from carnotite of southwestern Colorado and eastern Utah. Richer ores have been found in Republic of Congo and in the Great Bear region of northwestern Canada.

In an interesting narrative, Landa (1979) describes and depicts what the author calls the “first nuclear industry,” one that flourished during the first third of the 20th century. At that time, the prized element was *not* uranium, but rather it was radium. Radium initiated the concept of radiotherapy for the treatment of cancerous tumors. Even at the peak of radium production no more than a few hundred grams per year were purified. At one time the price approached $180,000 per gram (in early 1900s dollars). In one large extraction plant located in Denver, Colorado (National Radium Institute), carnotite ore was processed by a direct-dissolution method. During the three years (1914–1916) this plant was in operation, only 8.5 grams of Ra had been purified at an average cost of about $38,000 per gram. Pitchblende deposits from the Haut Katanga district of the Belgian Congo were discovered, but because of World War I, were not commercially exploited until 1921. Whereas it previously had required between 300 and 400 tons of a typical American carnotite ore to produce one gram of Ra, less than ten tons of the Kantanga ore were required. In 1931, an extraction plant at Port Hope, Ontario, designed to process uranium found in outcrops along the shores of Great Bear Lake in northwestern Canada, was commissioned. The hazards of radium production and handling were slow to surface and were not seriously recognized until the 1920s after a report had been prepared which implicated the ingestion of Ra in jaw necrosis in radium dial painters and lung cancer in uranium miners. Several workers, possibly including Marie Curie, died of conditions that were probably the result of long-term radiation exposure. By the 1930s, numerous precautions were initiated, including the design of tunnels at the Great Bear Lake mines to minimize radon hazards to miners.

The radium isotope of mass number 226 occurs in the uranium ($2n + 2$) alpha-decay series. Its half-life is 1,620 years, and it yields radon-222 by α-disintegration. Other naturally occurring isotopes of radium are ^{228}Ra in the thorium series, half-life 6.7 years, producing actinium-228 by β-decay, which yields by β-decay thorium-228, which in turn yields ^{224}Ra, half-life 3.64 days, giving radon-220 by α-decay. Another naturally, occurring isotope of radium is found in the actinium series; it is ^{223}Ra, half-life 11.7 days, giving radon-219 by α-decay. In the neptunium series there is ^{225}Ra, half-life 14.8 days, undergoing β-decay to actinium-225. Other isotopes of radium include those of mass numbers 219, 221, 225, 227, 229, and 230.

Chemically related to barium, radium is recovered from its ores by addition of barium salt, followed by treatment as for recovery of barium, usually as the sulfate. The sulfates of barium and of radium are insoluble in most chemicals, so they are transformed into carbonate or sulfide, both of which are readily soluble in HCl. Separation from barium is accomplished by fractional crystallization of the chlorides (or bromides, or hydroxides). Dry, concentrated radium salts are preserved in sealed glass tubes, which are periodically opened by experienced workers to relieve the pressure. The glass tubes are kept in lead shields.

In many of its chemical properties, radium is like the elements magnesium, calcium, strontium and barium, and it is placed in group 2, as is consistent with its $6s^2 6p^6 7s^2$ electron configuration. Its sulfate ($K_{sp} = 4.2 \times 10^{-15}$) is even more insoluble in water than barium sulfate, with which it is conveniently coprecipitated. Like barium and other alkaline earth metals, it forms a soluble chloride ($K_{sp} = 0.4$) and bromide, which can also be obtained as dihydrates. Radium also resembles the other group 2 elements in forming an insoluble carbonate and a very slightly soluble iodate ($K_{sp} = 8.8 \times 10^{-10}$).

RADON. [CAS: 10043-92-2]. Chemical element symbol Rn, at. no. 86, at. wt. 222 (mass number of the most stable isotope), periodic table group 18 (inert gases), mp −71°C, bp −61.8°C. First ionization potential, 10.745 eV. Density 9.72 g/1(0°C, 760 torr), 7.5× more dense than air. The gas has been liquefied at −65°C and solidified at −110°C. Radon was first isolated by Ramsay and Gray in 1908. Prior to acceptance of the present designation, radon was called niton or radium emanation. See also **Radioactivity**.

^{222}Rn is formed by the alpha disintegration of ^{226}Ra. Actinon, its isotope of mass number 219, is produced by alpha disintegration of ^{223}Ra (AcX) and is a member of the Actinium Series. Similarly, thoron, its isotope of mass number 220, is a member of the thorium series. Since the name “radon” may be considered to be specific for the isotope of mass number 222 (from the radium series), the term “emanation” is sometimes used for element number 86 in general. Other isotopes of radon include those of mass numbers 209–218 and 221.

A fluorine compound of radon has been formed by reaction of the elements under higher temperature and pressure, similar to the conditions for forming xenon fluorides. Radon forms a hydrate of atmospheric pressure at 0°C. It forms a compound with phenol, $Rn \cdot 2C_6H_5OH$ that is stable enough to give a sharply defined melting point at 50°C. At low temperatures and pressures, HCl, hydrobromic acid, H_2S, SO_2, and CO_2 all add considerable percentages of radon; the HCl product, although possibly not a compound in the classical sense, being stable enough for its use as a method for separating radon from other gases.

Ionizing Radiation from a Natural Source

Since the mid-1980s, there has been a growing concern among some pollution experts with the topic of *indoor air pollution*, and as a major part of this problem, the presence in homes and other structures of ionizing radiation in the form of radon gas. It is beginning to appear that radon's earlier designation as radium emanation was not inappropriate. Most health

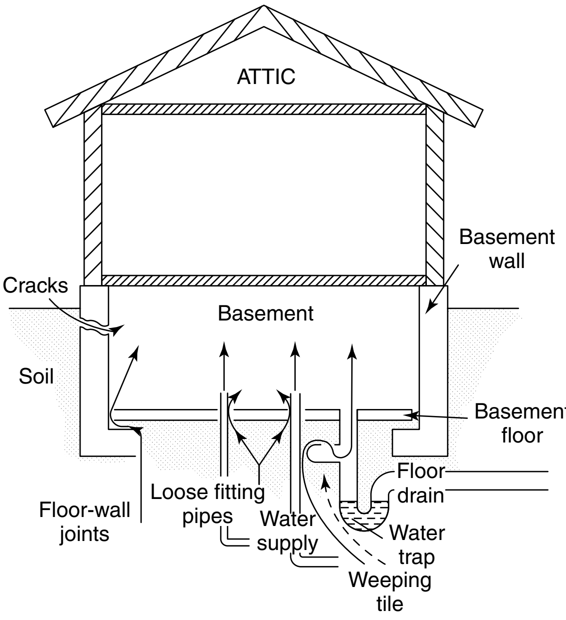

Fig. 1. Ports of entry for radon gas into average residence. (*National Indoor Environmental Institute, Plymouth Meeting, Pennsylvania*)

hazards faced by the citizens of industrialized nations are anthropogenic. Not so in the case of radon. Numerous experts have concluded that the largest dose of ionizing radiation an average person may receive during a lifetime is the radioactive radon gas that emanates from rock formations as the uranium they contain decays. Some epidemiologists and environmental scientists believe that the gas can cause lung cancer in people who have done nothing more hazardous than to live in houses built over such rock formations. Others do not agree and caution has been exercised to avoid the tremendous costs that could be involved in taking remedial actions.

Radon issues continuously from the ground since uranium is present in virtually all rocks and soils. Radon dissipates quickly in open air, but when trapped inside a building, the gas can accumulate in concentrations tens, hundreds, and even thousands of times higher than out of doors.

It is important to note that radon per se is not the direct radiation hazard, but rather it is certain daughters (radioactive-decay products of the radon—mainly isotopes of polonium) that contribute the major radiation dose to lung tissue. These isotopes are chemically reactive. They can stick, either in elemental form or adsorbed onto minute airborne particles, to the lining of the bronchial passageways, whence they eradicate the surrounding tissue.

Dangerous radon concentrations were first noted in Sweden. Radiation measurements were made in well-insulated houses and immediately from that experience it was postulated that energy-efficient houses, designed to minimize the ventilation rate and thus conserve heating or cooling losses, were in effect "radon traps." Later investigations have discounted the importance of ventilation. Attention was shifted from "tight" houses to ways in which radon may enter a building—in an effort to explain the wide disparity of data collected from thousands of structures. In these studies, building materials per se were rarely implicated as major sources of radon. Pathways for radon to enter buildings from underneath are illustrated in Fig. 1.

Because there are so many unanswered questions, most experts are attempting to quell any alarm complex that might arise among the public and to continue to collect data before drawing tentative conclusions. The U.S. Environmental Protection Agency is conducting a comprehensive survey of domestic radon levels. Radon concentrations are being measured in a random nationwide sampling of residential buildings, during which survey consistent instrumentation techniques will be used.

RAMAN SPECTROMETRY. This form of spectrometry is based upon the Raman effect which may be described as the scattering of light from a gas, liquid, or solid with a shift in wavelength from that of the usually monochromatic incident radiation. Discovered by the Indian physicist, C.V. Raman in 1928, it has also been called the Smekal-Raman effect, the former investigator having made some earlier theoretical predictions about it. If the polarizability of a molecule changes as it rotates or vibrates, incident radiation of frequency v, according to classical theory, should produce scattered radiation, the most intense part of which has unchanged frequency. This is Rayleigh scattering. In addition, there should be Stokes and anti-Stokes lines of much lesser intensity and of frequencies $\nu \pm \nu_k$, respectively, where ν_k is a molecular frequency of rotation or vibration. The anti-Stokes line is always many times less intense than the Stokes line and this fact is satisfactorily explained by the quantum mechanical theory of the effect. The vibrational Raman effect is especially useful in studying the structure of the polyatomic molecule. If such a molecule contains N atoms it can be shown that there will be $3N-6$ fundamental vibrational modes of motion only ($3N-5$ if the molecule is a linear one). Those accompanied by a change in electric moment can be observed experimentally in the infrared. The remaining ones, if occurring with a change in polarizability, will be observable in the Raman effect. Thus both kinds of spectroscopic measurements are usually required in a complete study of a given molecule.

Like infrared spectrometry, Raman spectrometry is a method of determining modes of molecular motion, especially the vibrations, and their use in analysis is based on the specificity of these vibrations. The methods are predominantly applicable to the qualitative and quantitative analysis of covalently bonded molecules rather than to ionic structures. Nevertheless, they can give information about the lattice structure of ionic molecules in the crystalline state and about the internal covalent structure of complex ions and the ligand structure of coordination compounds both in the solid state and in solution.

Both the Raman and the infrared spectrum yield a partial description of the internal vibrational motion of the molecule in terms of the normal vibrations of the constituent atoms. Neither type of spectrum alone gives a complete description of the pattern of molecular vibration, and, by analysis of the difference between the Raman and the infrared spectrum, additional information about the molecular structure can sometimes be inferred. Physical chemists have made extremely effective use of such comparisons in the elucidation of the finer structural details of small symmetrical molecules, such as methane and benzene. But the mathematical techniques of vibrational analysis are not yet sufficiently developed to permit the extension of these differential studies to the Raman and infrared spectra of the more complex molecules that constitute the main body of both organic and inorganic chemistry.

The analytical chemist can use Raman and infrared spectra in two ways. At the purely empirical level, they provide "fingerprints" of the molecular structure and, as such, permit the qualitative analysis of individual compounds, either by direct comparison of the spectra of the known and unknown materials run consecutively, or by comparison of the spectrum of the unknown compound with catalogs of reference spectra.

By comparisons among the spectra of large numbers of compounds of known structure, it has been possible to recognize, at specific positions in the spectrum, bands which can be identified as "characteristic group frequencies" associated with the presence of localized units of molecular structure in the molecule, such as methyl, carbonyl, or hydroxyl groups. Many of these group frequencies differ in the Raman and infrared spectra.

When a transparent medium was irradiated with an intense source of monochromatic light, and the scattered radiation was examined spectroscopically, not only is light of the exciting frequency, υ, observed (Rayleigh scattering), but also some weaker bands of shifted frequency are detected. Moreover, while most of the shifted bands are of lower frequency, $\nu - \Delta\nu_1$, there are some at higher frequency, $\nu + \Delta\nu_1$. By analogy to fluorescence spectrometry (see below), the former are called *Stokes bands* and the latter *anti-Stokes bands*. The Stokes and anti-Stokes

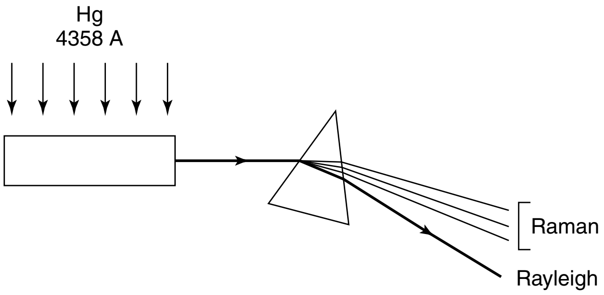

Fig. 1. Optical system to observe a Raman spectrum. The Rayleigh scattering is at the wavelength of the exciting line

bands are equally displaced about the Rayleigh band; however, the intensity of the anti-Stokes bands is much weaker than the Stokes bands and they are seldom observed. This article deals only with the more intense Stokes bands. The geometric arrangement for observing the Raman effect is shown diagrammatically in Fig. 1.

RAMSAY, SIR WILLIAM (1852–1916). A British chemist born in Scotland who received the Nobel prize for chemistry in 1904. He participated in the discovery of helium, argon, neon, xenon, and krypton. Much of his work concerned investigations of inert gases. He was also known for studies in organic, physical, and inorganic chemistry. Ramsay was educated at the Universities of Glasgow, Heidelberg, and Tubingen, and was a Professor at the Universities of Bristol and London.

RANKINE. A scale of absolute temperature based on Fahrenheit degrees. Temperatures on the Rankine scale are 9/5 (or 1.8) times those on the Kelvin scale.

See also **Absolute Temperature**.

RAOULT'S LAW. The vapor pressure of a substance in equilibrium with a solution containing the substance is equal to the product of the mole fraction of the substance in the solution and the vapor pressure of the pure substance at the temperature of the solution. The law is not applicable to most solutions, but is often approximately applicable to a mixture of closely similar substances, particularly the substance present in high concentration.

RARE-EARTH ELEMENTS AND METALS. Sometimes referred to as the "fraternal fifteen," because of similarities in physical and chemical properties, the rare-earth elements actually are not so rare. This is attested by Fig. 1, which shows a dry lake bed in California that alone contains well in excess of one million pounds of two of the elements, neodymium and praseodymium. The world's largest rare earth body and mine near Baotou, Inner Mongolia, China is shown in Fig. 2. It contains 25 million tons of rare earth oxides (about one quarter of the world's human reserves. The term *rare* arises from the fact that these elements were discovered in scarce materials. The term *earth* stems from the fact that the elements were first isolated from their ores in the chemical form of oxides and that the old chemical terminology for oxide is earth. The rare-earth elements, also termed Lanthanides, are similar in that they share a valence of 3 and are treated as a separate side branch of the periodic table, much like the Actinides. See also **Actinide Contraction**; **Chemical Elements**; **Lanthanide Series**; and **Periodic Table of the Elements**.

The properties of the Rare-earth elements are given in Tables 1 and 2. Pronunciation of the elements is as follows: Cerium (*sear' ium*),

Fig. 1. Dry lake mineral bed near Mountain Pass, California contains over one million pounds of neodymium and nearly one-half million pounds of praseodymium, both elements once regarded as "rare earths" and of limited scientific curiosity. During recent years, the rare earths have become significant materials in the electronic, chemical, metallurgical, glass, cryogenic, nuclear, and ceramic refractory industries. Lanthanum, another rare-earth element, is more abundant than lead

Fig. 2. Open-pit operation at Baiyunebo mine. (*The Chinese Society of Rare Earth*)

dysprosium (*dis pröz' ium*), erbium (*ur' bium*), europium (*yoo rö pium*), gadolinium (*gado lin' ium*), holmium (*hol' mium*), lanthanum (*Ian' tha num*), lutetium (*loo tee' shium*), neodymium (*neo dim' ium*), praseodymium (*pra zee o dim' ium*), promethium (*pro mee' thium*), samarium (*sa mar' ium*), scandium (*scan de'ium*) terbium (*tur' bium*), thulium (*thoo' lium*), ytterbium (*i tur' bium*), and yttrium (*it' rium*). The lanthanides are further described by individual alphabetical entries for each element.

C.A. Arrhenius, in 1787, noted an unusual black mineral in a quarry near Ytterby, Sweden. This was identified later as containing yttrium and rare-earth oxides. With the exception of promethium, all members of the Lanthanide Series had been discovered by 1907, when lutetium was isolated. In 1947, scientists at the Atomic Energy Commission at Oak Ridge National Laboratory (Tennessee) produced atomic number 61 from uranium fission products and named it promethium. No stable isotopes of promethium have been found in the earth's crust.

Natural mixtures of these elements have been used commercially since the early 1900s. Mischmetal is the source of the hot spark in cigarette lighter flints. The mixed rare-earth fluorides are burned in the cores of carbon electrodes to create the intense sunlike illumination required by motion-picture projectors and searchlights. The mixed rare-earth oxides, which contain primarily cerium dioxide, are used to grind and polish almost all optical lenses and television faceplates. In the late-1940s, it was discovered that the rare-earth metals effectively control the shape of carbon in normally brittle cast iron, resulting in ductile or nodular iron. During the 1950s, interest in several of the pure elements (europium, gadolinium, dysprosium, samarium, and erbium) was stimulated because these elements have the highest thermal-neutron-absorption properties among the elements. These elements have found application in control rods and as burnable poisons. Yttrium metal was fabricated into tubing and mill products because it is almost transparent to thermal neutrons and has a unique stability at high temperature in contact with liquid uranium, potassium, and sodium. Nuclear aircraft and submarine propulsion programs were the main impetus for these efforts. Radioactive promethium has been used as a power source for pacemakers.

Early in the 1960s, mixtures of the rare-earth elements were incorporated with synthetic molecular-sieve catalysts, resulting in increased petroleum refining efficiency. Various rare-earth compounds have been found to act as catalysts in several chemical processes, such as hydrogenation. Rare-earth mixed oxides and especially CeO_2 are being used in auto exhaust catalysts. In 1964, a new red phosphor for color television was discovered. Relatively large quantities of highly purified europium and yttrium oxides were needed as commercial color television production started. Rare-earth phosphors are also being used in color monitors for computers, X-ray screens, fluorescent lamps, UV-conversion phosphors, dental and surgical lasers, electro- and thermoluminescent devices, and fiber optics.

Permanent magnets having properties several times superior to any other known materials were developed in 1967. Praseodymium, yttrium, samarium, lanthanum, and cerium are alloyed with cobalt in the range RCo_5 to R_2Co_{17}, where $R = a$ rare-earth element. The new family of permanent-magnet materials is bringing about improvements in power generation and electronic communications. Conventional applications now include watches, electric motors, computer printers, automotive devices, frictionless bearings, and loudspeakers. Novel applications for the powerful magnets include magnetic earrings and use in medical treatments.

About 15 years later a new family of iron-neodymium-based permanent magnets were discovered. In 1983 several research groups in the United States and Japan announced the discovery of a new compound with the probable composition, $R_2Fe_{14}B$ ($R = a$ light rare earth lanthanide, predominantly neodymium). These materials exhibit extremely powerful magnetic qualities as compared with traditional magnet materials and about 10–20% stronger than the Sm-Co magnets. One shortcoming, is the loss of desirable magnetic qualities at elevated temperatures above about 200°F. Applications for the new magnetic materials span a wide range from the very sophisticated applications, such as found in nuclear magnetic resonance imaging systems, down to the inexpensive magnets used in toys and around the home. The $Nd_2Fe_{14}B$ materials are made either by rapid solidification or by powder metallurgy techniques. Some investigators have found that the addition of 6% cobalt increases the Curie temperature 100 K while others found that small additions of Dy (less than a 10% substitution of the Nd) are added to raise the Curie temperature. The crystal structure of $Nd_2Fe_{14}B_1$ is tetragonal, an anisotropic structure that contributes to the high coercivity. The relatively low concentrations of light lanthanides and boron, and the fact that the magnetic moments in iron and the lanthanides align parallel (ferromagnetically) to each other, allow the magnetization to remain high. See also **Magnetism**.

Metallurgical Uses

During the 1960s, the rare-earth metals were established as reactive and refining metals in the iron and steel industry. As alloying elements, lanthanum and yttrium improve the high-temperature oxidation and corrosion properties of superalloys. Other metallurgical applications of the rareearths include welding solders, brazing alloys, nonferrous alloys (such as magnesium and aluminum), and dispersion hardening of complex alloys (eg. Y_2O_3 dispersed in nickel based alloys). In the 1990s complex $LaNi_5$-based alloys were developed for use in rechargeable metal hydride batteries, which are slowly replacing NiCd batteries in many applications because of their superior performance and because the $LaNi_5$-based materials are more environmentally friendly. Another fairly recent development is the use of mixed rare earths as fertilizers in agriculture. The Chinese have been quite successful in improving various crop yields, but this application has seen only limited use in other countries.

Miscellaneous applications of rare-earth compounds, complexes and alloys include: MRI (magnetic resonance imaging) contrasting agents in the medical field; high temperature oxide superconductors; magnetic recording alloys and magnetic bubble devices; electronic components, capacitors and semiconductors; optical glasses and fiber optics; magnetic cooling and refrigeration; corrosion inhibitors; dying and printing textiles; cosmetics; oxidizer in self-cleaning ovens; fuel cell cathodes; and Y_2O_3 (and other R_2O_3)-stabilized ZrO_2 as oxygen sensors, electrolytes, structural ceramics, and synthetic jewelry.

The Institute for Physical Research and Technology sponsors a Rare-Earth Information Center at Iowa State University. Ames, Iowa, which provides a comprehensive service to science and industry by cataloging the vast amount of technical information generated about these elements each year.

Occurrence

Rare-earth minerals exist in many parts of the world; the overall potential supply is essentially unlimited. As a group, these elements rank fifteenth in abundance, somewhat more plentiful than zinc. Rare-earth minerals generally are classified as sources for *light* (La through Gd) or *heavy* (Y plus Tb through Lu). Typical mineral distributions are given in Table 3.

Until 1964, monazite, a thorium-rare-earth phosphate, $REPO_4Th_3(PO_4)_4$, was the main source for the rare-earth elements. Australia, India, Brazil, Malaysia, and the United States are active sources. India and Brazil supply a mixed rare-earth chloride compound after thorium is removed chemically from monazite. Bastnasite, a rare-earth fluocarbonate mineral; $REFCO_3$, is a primary source for light rare earths. From 1965 to about 1985, an open-pit resource at Mountain Pass, California, has furnished about two-thirds of world requirements for rare-earth oxides. In the early

[a] Baiyunebo iron ore mine, Inner Mongolia
[b] Guangdong/Guangxi Provinces
[c] Western Australia

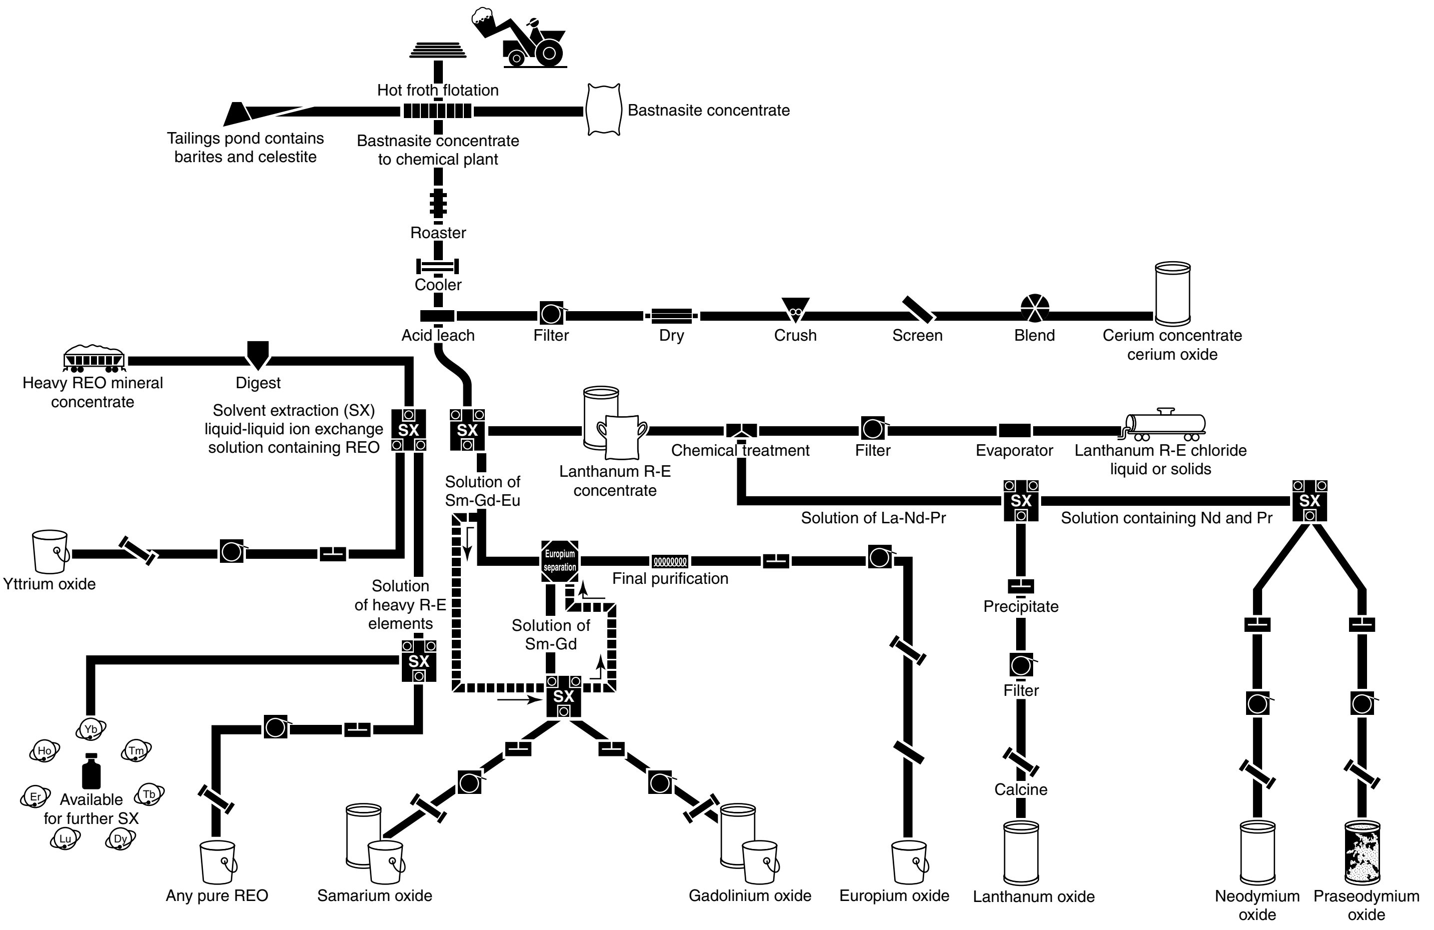

Fig. 3. Separation and purification of rare-earth elements. REO = rare-earth oxides; SX = solvent extraction

1980s the Chinese started to produce rare earths from their Baiyunebo mine, which contains both bastnasite and monazite, located about 100 miles from Baotou, Inner Mongolia. In the early 1990s the rare earth production from this mine exceeded that mined in Mountain Pass. In 1998 the Mountain Pass operation was temporarily closed because of a blocked wastewater pipe. Once the governmental delays due to environmental issues are approved, production will resume. The main source for yttrium and heavy rare-earths is a by-product of uranium mining in the Elliott Lake Region, Ontario. Some xenotime, found in Malaysia, is processed in Japan and Europe.

A highly generalized flowsheet of the production of some of the rare-earth oxides is shown in Fig. 3. Crushed and finely ground bastnasite contain about 70% rare-earth oxides is roasted under oxidizing conditions to convert soluble trivalent cerium compounds to insoluble tetravalent CeO_2. The roasted product is leached with HCl, which dissolves the remaining rare earths (La, Pr, Nd, Sm, Eu, Gd), leaving behind a concentrated cerium product. The solution is passed through liquid-liquid organic solvent extraction (SX) cells, resulting in a primary separation of La-Nd-Pr from Sm-Eu-Gd. Further SX separates a pure lanthanum solution and a

concentrated Nd-Pr solution, which another SX circuit separates. Europium is reduced to a divalent state in solution and precipitated. A final SX system separates and purifies gadolinium and samarium. Pure elements are usually precipitated as oxalates and calcined to oxides.

In connection with production of the heavy rare earths, monazite, containing about 55% rare-earth oxides and 5% thorium, is treated in one of two ways: (1) finely ground particles are leached with hot H_2SO_4, which dissolves thorium and the rare earths, leaving an insoluble residue; or (2) finely ground particles are reacted with hot caustic (NaOH), which dissolves the phosphate, creating a solution of trisodium phosphate, which may be recovered as a by-product. The thorium and rare-earth hydrate cake is then dissolved in H_2SO_4. Thorium sulfate is selectively precipitated by pH adjustment. Separation of the other rare earths in solution is usually completed by selective absorption on ion-exchange resins and elution from ion-exchange columns. After thorium is removed from the H_2SO_4 solution, the rare earths remaining are precipitated, using NaOH, forming a double salt, $NaRESO_4 \cdot xH_2O$, known as pink salt. This salt is dissolved in HCl, treated to remove impurities, and evaporated until the hydrated $RECl_3 \cdot 6H_2O$ can be cast.

In the case of the Canadian yttrium-heavy rare earth concentrate, this is leached with HNO_3, causing all rare earths to go into solution. Solvent extraction separates yttrium from the other heavy rare earths, each of which can eventually be separated by further solvent extraction. In the case of xenotime, this is leached with hot H_2SO_4 and separation of yttrium and the heavy rare earths completed in ion-exchange columns. The liquid-liquid organic solvent extraction cycle is complete within 5–10 days and is a continuous process. The resin ion-exchange cycle requires 60–90 days and is a batch process. Both processes result in pure rare earth oxides and chemicals.

Mischmetal is produced commercially by electrolysis. The usual starting ingredient is the dehydrated rare earth chloride produced from monazite or bastnasite. The mixed rare earth chloride is fused in an iron, graphite, or ceramic crucible with the aid of electrolyte mixtures made up of potassium, barium, sodium, or calcium chlorides. Carbon anodes are immersed in the molten salt. As direct current flows through the cell, molten mischmetal builds up in the bottom of the crucible. This method is also used to prepare lanthanum and cerium metals.

RARE GAS. Any of the six gases composing the extreme right-hand group of the periodic table, namely helium, neon, argon, krypton, xenon, and radon. They are preferably called *noble gases* or (less accurately) *inert gases*. The first three have a valence of 0 and are truly inert, but the others can form compounds to a limited extent.

REACTOR (Nuclear). See **Nuclear Power Technology**.

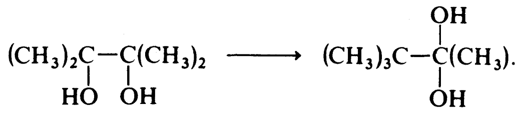
REALGAR. The mineral realgar is a monosulfide of arsenic corresponding to the formula AsS. It is monoclinic, showing short prismatic crystals, or may be in granular or compact masses. It is a soft sectile mineral; hardness, 1.5–2; specific gravity, 3.5; luster, resinous; color, red to orange-yellow; transparent to translucent. Realgar occurs associated with other arsenic minerals and with gold, silver, and lead ores, although not in great quantities. It has been found as a hot-spring deposit and in volcanic sublimations. Realgar has been found in Macedonia, Japan, Switzerland; and in the United States, in Yellowstone National Park, as a hot-spring deposit, and in Utah and Nevada. The name realgar is derived from the Arabic words *rahj al ghar*, which means the powder of the mine.

REARRANGEMENT (Organic Chemistry). These are reactions involving the transfer of an atom or group from one part of the molecule to another. Tautomerism is a special case of rearrangements in which the two forms are in dynamic equilibrium. See "Tautomerism" in entry on **Isomerism**. When such reactions take place, the establishment of structural formulas becomes complex. Some of the better known rearrangements include:

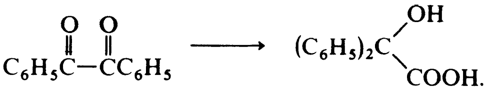
1. *Allyl Rearrangement.*

$$CH_3CH{:}CHCH_2Br \longrightarrow CH_2 \cdot CHCHBrCH_3.$$

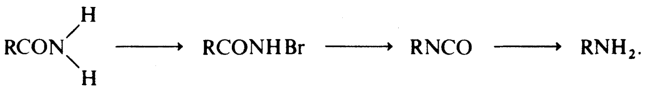
2. *Pinacol Rearrangement* takes place when pinacol is heated with dilute acid, pinacolin formed:



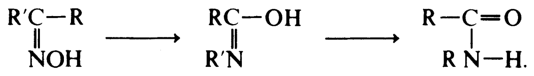
3. *Benzil Rearrangement* into benzylic acid:



4. *Hoffman Rearrangement.*

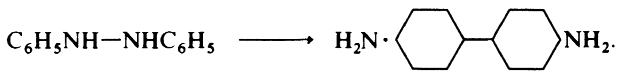


5. *Beckmann Rearrangement* results when oximes of ketones are treated with certain reagents such as phosphorus pentachloride.

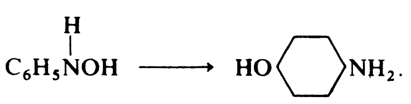


The exchange is between R′ and OH on the opposite sides of the CN bond.

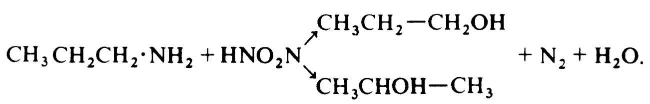
6. *Benzidine Rearrangement.* Treatment of hydrazobenzene with strong acids.



7. *Rearrangement of hydroxylamine derivatives.*



8. *Rearrangement in reaction of nitrous acid and alkyl amines.*



9. *Walden Inversion.* A rearrangement takes place in the reaction of optically active substances. The structural formula does not change but the configuration changes due to the interchange of two groups attached to the asymmetrical carbon atom during the course of the reaction.

REAUMUR. A temperature scale in which 0 is the freezing point of water and 80 is its boiling point.

RECALESCENCE. A phenomenon exhibited by iron and some other ferromagnetic metals. If iron is heated white hot and allowed to cool, it will, at a certain temperature, suddenly evolve enough heat to halt the cooling and even produce a momentary heating. This is easily exhibited by stretching an iron wire against the tension of a spring and arranging a lever index to show slight changes in length. The wire is first heated by an electric current. As it cools and contracts, the index will at a certain point give a perceptible jerk, and then resume its steady motion of contraction. The effect is due to an exothermic change in the crystalline structure. The reverse phenomenon, exhibited on heating, is called "decalescence." For cast iron, the recalescence point is a little below 700°C. Pure iron has two such points, at 780°C and 880°C.

A somewhat analogous effect is exhibited by some amorphous solids upon devitrification, which takes place when the temperature becomes high enough for the substance to crystallize. Noncrystalline sodium silicate, for example, has such a transition point near 500°C, where it suddenly begins to glow.

RECLAIMING. Recovery and reuse of scrap materials, either in low percentage in new product manufacture or in larger proportions in products in which the highest quality is not essential. Among the materials widely reclaimed in industry are aluminum, steel, paper, rubber, glass, crankcase oil, greases, etc. Solid materials are comminuted, the contaminants being removed with organic solvents or strong alkali solutions (paint from metals, ink from paper, fabric and metals from tires). In the case of cross-linked elastomers, more intensive solvent and heat treatment is necessary. The resulting product is used as an adulterant in low-quality scrap rubber to oil, with recovery of carbon black and metal inserts, indicates that substantial value may be obtained by this method. Devulcanization by means of microwave radiation is also under development. The term *reprocessing* refers specifically to the recovery of nuclear fuels from reactor waste.

RECOMBINANT DNA. See **Immune System and Immunochemistry**.

RECOMBINATION. The process by which a positive and a negative ion join to form a neutral molecule or other neutral particle. In the literature of atmospheric electricity, this term is applied both to the simple case of the capture of free electrons by positive atomic or molecular ions, and also to the more complex case of the neutralization of a positive small ion by a negative small ion, or a similar (but much more rare) neutralization of large ions.

Recombination is, in general, a process accompanied by emission of radiation. The light emitted from the channel of a lightning stroke is recombination radiation. The much less concentrated recombinations steadily occurring in all parts of the atmosphere where ions are forming and disappearing does not yield observable radiation. The intermediate ions are forming, and disappearing does not yield observable radiation.

RED TIDE. Yellow-to-reddish discoloration of seawater due to rapid multiplication of various species of plantlike microorganisms, called dinoflagellates, which occurs seasonally in areas of warm water, especially off the coast of or California, Florida and occasionally as far north as New England. Some, though by no means all, of the species are poisonous. Concentration of these organisms (phytoplankton) may be as high as 10^8 units/L. The shellfish are lethal to free-swimming fish. Shellfish are unharmed by them but are able to store and concentrate the toxin, which causes paralytic poisoning when they are eaten by humans. So potent is this poison, that death may result from ingestion of milligram amounts.

REFINING. Essentially a separation process whereby undesirable components are removed from various types of mixture to give concentrated and purified products. Such separation may be effected as follows:

- Mechanically, by pressing, centrifuging, filtering, etc.
- By electrolysis.
- By distillation, solvent extraction, or evaporation.
- By chemical reaction.

One or more of these operations is applied to:

- Food products.
- Petroleum.
- Lubricating oils.
- Metals.

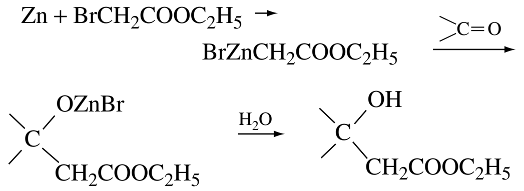
As regards petroleum, refining is generally understood to include not only fractional distillation of crude oils to naphthas, low-octane gasoline, kerosene, fuel oil, and asphaltic residues, but also the processes involved in thermal and catalytic cracking (hydroforming, reforming, etc.) for production of high-octane gasoline.

See also **Petroleum**.

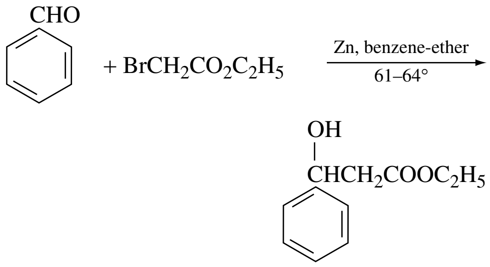
REFINING (Petroleum). See **Petroleum**.

REFLUX. In distillation processes in which a fractionating column is used, the term *reflux* refers to the liquid that has condensed from the rising vapor and been allowed to flow back down the column toward the still. As it does so, it comes into intimate contact with the rising vapor, resulting in improved separation of the components. The separation resulting from contact of the countercurrent streams of vapor and liquid is called rectification or fractionation.

REFORMATSKY REACTION. Dating back to 1887, this reaction depends on interaction between a carbonyl compound, an α-halo ester, and activated zinc in the presence of anhydrous ether or ether-benzene, followed by hydrolysis. The halogen component for example ethyl bromoacetate, combines with zinc to form an organozinc bromide that adds to the carbonyl group of the second component to give a complex readily hydrolyzed to carbinol. The reaction



is conducted by the usual Grignard technique except that the carbonyl component is added at the start. Magnesium has been used in a few reactions in place of zinc but with poor results, for the more reactive organometallic reagent tends to attack the ester group; with zinc this side reaction is not appreciable, and the reactivity is sufficient for addition to the carbonyl group of aldehydes and ketones of both the aliphatic and aromatic series. The product of the reaction is a β-hydroxy ester and can be dehydrated to the α,β-unsaturated ester; thus the product from benzaldehyde and ethyl bromoacetate yields ethyl cinnamate. α-Bromo esters of the types $RCHBrCO_2C_2H_5$ and $RR'CBrCO_2C_2H_5$ react satisfactorily, but



Ethyl β-phenyl-β-hydroxy-propionate (b.p. 130°/6 mm.)

β- and γ-bromo derivatives of saturated esters do not have adequate reactivity. Methyl γ-bromocrotonate ($BrCH_2CH{=}CHCO_2CH_3$), however, has a reactive, allylic bromine atom and enters into the Reformatsky reaction.

REFORMING. Decomposition (cracking) of hydrocarbon gases or low-octane petroleum fractions by heat and pressure, either without a catalyst (thermoforming), or with a specific catalyst. The latter is most extensively used. The principal cracking reactions are (1) dehydrogenation of cyclohexanes to aromatic hydrocarbons; (2) dehydrocyclicization of certain paraffins to aromatics; (3) isomerization, i.e., conversion of straight-chain to branched-chain structures, as octane to isooctane. These result in substantial increase in octane number. Steam reforming of natural gas is an important method of producing hydrogen; steam reforming of naphtha is used to produce substitute natural gas. See also **Ammonia**; **Cracking Process**; **Isomerization**; and **Petroleum**.

REFRACTION. The term refraction properly applies to the change of direction which radiation, especially light, or sound experiences on passing obliquely from one medium to another in which its velocity of propagation is different. The physical nature of the effect can be visualized by considering a regiment marching in columns of platoons across a boundary between smooth turf and freshly plowed ground. If the line of march is perpendicular to the boundary, the platoons are simply slowed up and thus crowded more closely together; but if it is oblique, one end of each platoon is retarded sooner than the other, and the file swings around to a direction nearer the normal. See Fig. 1. A train of waves is similarly affected as it passes into a new medium with change of velocity.

It is easy to show that if i is the angle of incidence and r the angle of refraction at such a boundary (Fig. 2), the refraction is governed by a simple relation known as *Snell's law*:

$$\sin i = n \sin r$$

in which n has the same value for various angles of incidence and refraction. This constant n, known as the refractive index, depends upon the character of the wave train and of the two media. Physically it represents the ratio of the velocity of the disturbance in the first medium to that in the second. For light passing from one medium to another in which its velocity is greater, so that $n < 1$, we may, for a sufficiently large angle of incidence, encounter the curious phenomenon known as total reflection.

Refraction often occurs in a single medium due to variations in its properties resulting from changes in conditions through the portion of the medium traversed by the radiation or sound. The twinkling of stars is caused by differences in refractive index in the atmosphere resulting from differences in temperature. Sound also exhibits this temperature refraction.

Specific refraction is a relationship between the refractive index of a medium at any definite wavelength and its density, of the form

$$r = \left(\frac{n^2 - 1}{n^2 + 2}\right)\left(\frac{1}{\rho}\right)$$

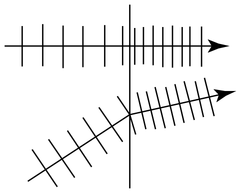

Fig. 1. Change of wavelength and (in general) of direction of wave train upon entering new medium

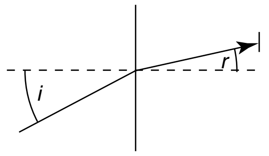

Fig. 2. Angles of incidence (i) and refraction (r)

in which r is the specific refraction of the medium, n is its index of refraction at any definite wavelength, and ρ is its density. The relation does not always give a constant value of r as the density is varied, and hence must be considered as an approximation.

Molar refraction is the product of the specific refraction by the molecular weight. The form of this relationship is

$$R = Mr$$

in which R is the molar refraction, M is the molecular weight, and r is the specific refraction. The direct form of this relationship is

$$R = \left(\frac{n^2 - 1}{n^2 + 2}\right)\left(\frac{M}{\rho}\right)$$

in which R is the molar refraction, n is the index of refraction for any chosen wavelength, M is the molecular weight, and ρ is the density.

An empirical relationship between molar refraction, density, and molar volume, that applies to many liquids over a considerable range of temperatures is that of Eykiman:

$$R = \frac{M(n^2 - 1)}{\rho(n + 0.4)} = \frac{V(n^2 - 1)}{(n + 0.4)}$$

in which R is the molar refraction at a given wavelength, n is the index of refraction at that wavelength, M is the molecular weight, ρ is the density, and V is the molar volume.

Atomic refraction is the product of the specific refraction of an element by its atomic weight.

Standard refraction is the refraction that would occur in an idealized atmosphere in which the refractive index decreases uniformly with height at the rate of 39×10^{-6} per kilometer. Standard refraction may be included in ground wave calculations by use of an effective earth radius of 8.5×10^6 meters, or $\frac{4}{3}$ the geometrical radius of the earth.

REFRACTIVE INDEX. The phase velocity of radiation in free space divided by the phase velocity of the same radiation in a specified medium. Because of the Snell law (see also **Refraction**) the refractive index may also be defined as the ratio of the sine of the angle of incidence to the sine of the angle of refraction.

The absolute index for all ordinary transparent substances is greater than 1 (see Table 1); but there are some special cases (X-rays and light in metal films, which are discussed below) for which the index of refraction is less than unity. Since the absolute index for air exceeds unity by less than 0.0003, the relative indices for solids and liquids in air are very nearly equal to their absolute indices. It should be noted that since the refractive index varies with the wavelength, any exact statement of its value must specify the wavelength to which it refers; in Tables it is usually given for sodium light of frequency 5,893A. See also **Dispersion**.

Various relationships have been used to express the refractive index. Thus there are several semi-empirical relationships expressing the refractive index of a medium as a function of wavelength:

$$n^2 = 1 + \frac{A_1\lambda^2}{\lambda^2 - \lambda_1^2}$$

where A_1 is a constant characteristic of the material and λ_1 is an idealized absorption wavelength of the medium. When $\lambda_1 \ll \lambda$, this reduces to

$$n^2 = 1 + A_1 + \frac{A_1\lambda_1^2}{\lambda^2}$$

TABLE 1. ABSOLUTE INDEX

Substance	Absolute Index
Air	1.0002926
Bromine	1.661
Carbon dioxide	1.00045
Diamond	2.419
Glass	1.5 to 1.9
Glycerine	1.4729
Helium	1.000036
Ice	1.31
Rock salt	1.516
Water (20°C)	1.333

or

$$n = A + \frac{B}{\lambda^2}\text{(Cauchy Formula)}$$

A better approximation is

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} + \cdots$$

For equations for specific and molar refraction, see also **Refraction**.

As a consequence of his electromagnetic theory of light, Clerk Maxwell obtained the relation between the dielectric constant of a medium and its refractive index n:

$$\varepsilon = n^2$$

This relation holds only under rather restrictive conditions, such as measurement with light of long wavelength, absence of permanent dipoles in the substance, etc.

For strongly absorbing media, such as metals, the customary refractive index must be replaced by the complex refraction index $n(1 - i\kappa)$ where κ is called the absorption index. Then the reflectivity for normal incidence is

$$R = \frac{(n-1)^2 + n^2\kappa^2}{(n+1)^2 - n^2\kappa^2}$$

The refractive index for metals varies over a much larger range than for conventional dielectrics, e.g., sodium at $\lambda = 0.546$ micrometer, $n = 0.052$, while for silicon at $\lambda = 0.589$ micrometer, $n = 4.24$. The refractive index is sometimes defined as the relative dielectric constant of a medium, $\sqrt{\varepsilon/\varepsilon_0}$. This expression is invariably a function of the wavelength of the radiation.

REFRACTOMETERS. Several types of instruments, called refractometers, have been devised for measuring the refractive index of any substance. See also **Photometers**. Special forms are used for solids, for liquids, and for gases. Solid and liquid refractometers usually depend upon the principle of total reflection and the fact that the sine of the critical angle is equal to the refractive index for light passing from the more to the less refractive medium. The critical angle is what is measured, or deduced from other measured angles.

Suppose that a specimen of the solid or liquid to be tested is brought into optical contact with one face of a glass prism (or "block") of known, higher refractive index and known angle, and that a slightly convergent pencil of light, entering the test substance, is directed at grazing incidence upon the interface between it and the prism. Those rays incident at less than 90° to the normal of the interface enter the prism; the others do not, and the boundary between is sharply defined. The resulting half-pencil traverses the prism and emerges from the other face where the direction of its cutoff edge can be observed (Fig. 1). The angle between the cutoff boundary of the pencil and the first prism face, inside the prism, is the critical angle, and can be easily calculated from the observations and the known data. This is the principle of the Pulfrich refractometer.

Another form, due to Abbe, is used for liquids. A film of the liquid is enclosed between two similar glass prisms (Fig. 2), and the total reflection

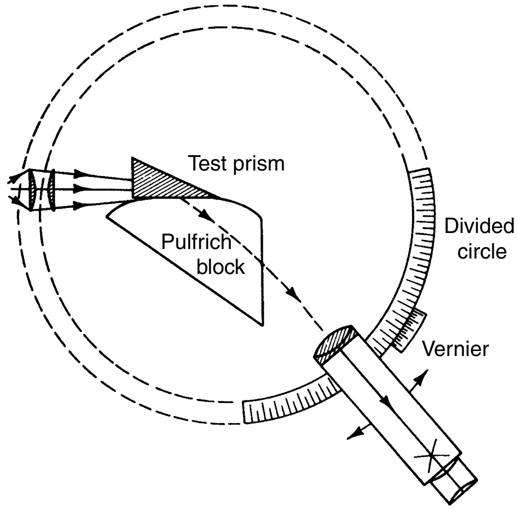

Fig. 1. Pulfrich refractometer

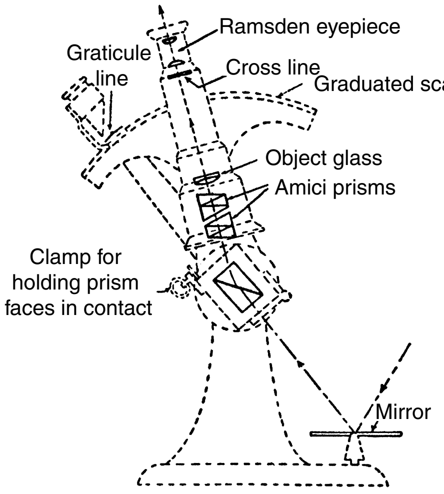

Fig. 2. Optical system of Abbe refractometer

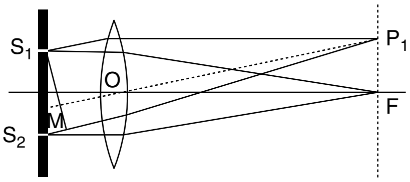

Fig. 3. When a double slit S_1S_2, illuminated by light from a distant narrow source, is placed in front of the objective of a telescope, interference fringes are observed in the focal plane P_1F

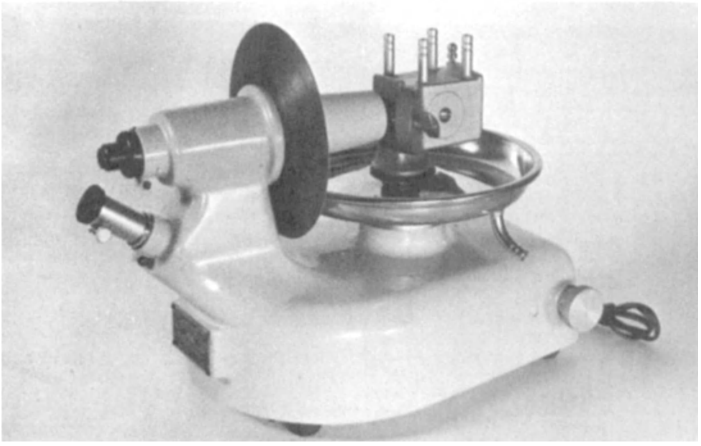

Fig. 4. Abbe refractometer equipped with sodium are for studies of turbid liquids. (*Gaertner Scientific Corp*)

at the interface observed. Any spectrometer, with a pair of good prisms (preferably right-angled) mounted on the prism table, can be used in this way.

Rayleigh utilized an interference method for measuring the indices of gases. Using a collimator to render the rays parallel (Fig. 3), the stream of light entering one of the slits of the apparatus for Young's experiment is passed through a tube of the gas to be tested. The resulting retardation in phase causes a shift of the interference fringes, the amount of which gives the retardation and hence the refractive index of the gas relative to the air outside the tube. See also **Refraction**; and **Refractive Index**.

A chemical analytical technique is based upon measurement of refractive index. The velocity of light in a material, and therefore the refractive index, depends upon several physical properties of the sample. Theoretical studies have indicated that the refractive index is related to the number, charge, and mass of vibrating particles in the material through which the light is passing. Further, it has been possible to relate refractive index to density and molecular weight for classes of compounds that have a relatively

constant number of vibrating particles per unit weight. The number of vibrating particles in a compound is determined by the atoms in the structure and by the type of electronic bonding. Correlations of this sort have been particularly successful for the analysis of hydrocarbon mixtures. Several techniques have been developed and applied in the petroleum industry. See Fig. 4. See also **Analysis (Chemical)**.

REFRACTORIES. Refractories are materials that resist the action of hot environments by containing heat energy and hot or molten materials. There is no well-established line of demarcation between those materials that are and those that are not refractory. The ability to withstand temperatures above 1100°C without softening has, however, been cited as a practical requirement of industrial refractory materials. (See also **Ceramics**). The type of refractories used in any particular application depends on the critical requirements of the process.

Physical Forms

Refractories may be preformed (shaped) or formed and installed on-site. Castables, gunning mixes, and plastic and ramming mixes are used either for repair or for complete new construction of what is known as monolithic linings. The use of monolithics instead of constructions using shaped products has increased; monolithic installations have become as common as conventional shaped product construction.

Brick. The standard dimensions of a refractory brick are 229 mm (9 in.) length, 114 mm (4.5 in.) width, and 64 mm (2.5 in.) thickness. This is known as a standard straight. Quantities of bricks are given in brick equivalents, that is, the number of standard straight bricks that have a volume equal to that of the particular installation.

Other common refractory forms include setter tile and kiln furniture, fusion-cast shapes, cast and hand-molded refractories, insulating refractories, castables and gunning mixes, plastic refractories and ramming mixes, mortars, composite refractories, and refractory coatings.

Raw Materials

In the past, refractory raw materials were used essentially as mined minerals. Selective mining yielded materials of the desired properties and only in cases of expensive raw materials, such as magnesite, was a beneficiation process required. However, demand for high purity natural raw materials and synthetically prepared refractory grain made from combinations of high purity and beneficiated raw materials has increased (Table 1). The material produced upon firing raw as-mined minerals or synthetic blends is called grain, clinker, co-clinker, or grog. Recycled materials produced by the manufacturers and recovered from users are also used to reduce waste. Use of recycled materials is limited in the United States. It is more common in Europe and is expected to increase.

Silica. The most common refractory raw materials are ganister, which is a dense quartzite, and silica gravels.

TABLE 1. PHYSICAL PROPERTIES OF REFRACTORY RAW MATERIALS

Material	Main crystalline phases	Specific gravity, g/cm^3 Bulk	Specific gravity, g/cm^3 True
	SILICA		
ganister	quartz		2.66
gravel	quartz		2.61
	CLAYS		
flint clays	kaolinite, quartz, illite	2.55	
plastic clays	kaolinite, quartz, illite		
kaolin	kaolinite		
fireclay	kaolinite		
plastic	kaolinite, illite		
	HIGH ALUMINA		
natural siliceous bauxite,[a] ca 70% Al_2O_3	mullite	2.85–2.95	3.1–3.2
ca 60% Al_2O_3	mullite	2.75–2.85[b]	2.95–3.95
ca 50% Al_2O_3		2.65	
South American bauxite[a]	corundum, mullite	3.1	3.6–3.7
Chinese bauxite[a]		3.20	
kyanite[b]	kyanite		3.5–3.7
sillimanite[c]	sillimanite		3.23
synthetic fused alumina, black	α-alumina	3.87	4.01
gray	α-alumina	3.95	3.98
sintered alumina	α-alumina	3.45–3.6	3.65–3.80
sintered mullite		2.85	
sintered magnesium aluminate	spinel, periclase	3.33	
fused mullite	mullite	3.1	3.45
calcium aluminate cement, low purity	calcium monoaluminate		
high purity	α-alumina, calcium monoaluminate		
	ZIRCONIUM		
zircon	zircon		4.2–4.6
baddeleyite, ZrO_2	baddeleyite		5.5–6.5
	BASIC RAW MATERIALS		
calcined magnesias			
natural magnesite	periclase	3.2	
	periclase	3.4	
	magnesite, dolomite, calcite	3.40	
	d	3.39	
seawater	periclase	3.44	
brine	periclase	3.41	
dolomite[e]	periclase + CaO		
chrome ore	chromite spinel	4.2	

[a] Calcined.
[b] Another type of ca 60% Al_2O_3 natural siliceous bauxite has a bulk density of 2.70 g/cm^3.
[c] Raw.
[d] Unclassified.
[e] Both regular and low flux dolomite.

Fireclay. Fireclays consist mainly of the mineral kaolinite, $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, with small amounts of other clay minerals, quartzite, iron oxide, titania, and alkali impurities.

Alumina. The naturally occurring raw materials are bauxites, sillimanite group minerals, and diaspore clays (see **Aluminum**).

Mullite. Although mullite is found in nature, for example, as inclusions in lava deposits on the island of Mull, Scotland, no commercial natural deposits are known. It is made by burning pure sillimanite minerals or sillimanite–alumina mixtures.

Zirconia. Zircon (zirconium silicate), the most widely occurring zirconium-bearing mineral, is dispersed in various igneous rocks and in zircon sands. Zircon can be used as such in zircon refractories or as a raw material to produce zirconia, ZrO_2.

Basic Raw Materials. Basic raw materials include magnesite dolomite, forsterite, chrome ore, silicon carbide, beryllia, thoria, and carbon (graphite).

General Properties

Oxides. Beryllium and magnesium oxides are stable to very high temperatures in oxidizing environments. Beryllia has good electrical insulating properties and high thermal conductivities; however, its high toxicity restricts its use. Stabilized cubic or partially stabilized ZrO_2 is the most useful simple oxide for operations above 1900°C.

Carbon, Carbides, and Nitrides. Carbon (graphite) is a good thermal and electrical conductor. It is not easily wetted by chemical action, which is an important consideration for corrosion resistance. As an important structural material at high temperature, pyrolytic graphite has shown a strength of 280 MPa (40,600 psi). It tends to oxidize at high temperatures, but can be used up to 2760°C for short periods in neutral or reducing conditions. When heated under oxidizing conditions, silicon carbide and silicon nitride, Si_3N_4, form protective layers of SiO_2 and can be used up to ca 1700°C. Silicon carbide has very high thermal conductivity and can withstand thermal shock cycling without damage. It also is an electrical conductor and is used for electrical heating elements.

Borides and Silicides. These materials do not show good resistance to oxidation.

Metals. The highest melting refractory metals are tungsten (3400°C), tantalum (2995°C), and molybdenum (2620°C). All show poor resistance to oxidation at high temperatures.

Phase Equilibria. Phase diagrams represent the chemical equilibria that exist among one, two, or three components of a system under the influence of temperature and pressure. Reference to a phase diagram permits the determination of the amount and composition of solid and liquid phases that coexist under certain specified conditions of temperature and pressure for a particular system. Using such information, the occurrence of physical and chemical changes within a system or between systems at high temperatures can be predicted.

Physical Properties. Brick bulk density depends on the specific gravity of the constituents and the porosity. Usually the highest density possible is desired. Upon firing, the grains and matrix form glassy, direct, or solid-state ceramic bonds. Sintering is generally accompanied by shrinkage. Particle size distribution, forming method, and firing process contribute to texture, whereas permeability is related to porosity, which in turn is dependent upon texture.

Mechanical Properties. The transverse strength (modulus of rupture) at room temperature is related to the degree of bonding. Fine-grained refractories generally are stronger than coarse-grained types and those having a low porosity are stronger than those of high porosity.

Generally, high temperature strength is lower than room temperature strength. The development of solid-state or direct-bonded basic brick requires high firing temperatures, and is impeded by glassy phases. By referring to phase diagrams, refractory compositions may be designed that avoid the development of such phases.

The modulus of elasticity (MOE) is related to the strength and can be used as a nondestructive quality control test on high cost special refractory shapes.

Thermal Properties. Refractories, like most other solids, expand upon heating, but much less than most metals. The degree of expansion depends on the chemical composition.

Reheat Change. Most refractory bricks are not chemically in equilibrium before use. During the prolonged heating in service, additional reactions occur that may cause the brick to shrink or expand. Considerable expansion may be caused by gas formation during heating. In general, basic brick exhibits good volume stability at high temperatures.

Thermal Conductivity. The refractory thermal conductivity depends on the chemical and mineral composition of the material and increases with decreasing porosity.

Thermal Spalling. The susceptibility to thermal cracking and spalling depends on certain characteristics of the raw material and the macrostructure of the particular refractory. Spalling resistance may be increased by either preventing cracks from forming or preventing cracks from growing. The approach used to effect spall resistance determines which properties of the refractory are optimized.

Refractoriness. Refractoriness is the resistance to physical deformation under the influence of temperature. It is determined by the pyrometric cone equivalent (PCE) test for aluminosilicates and resistance to creep or shear at high temperature.

Manufacture

Processing. Some materials can be used without further processing, although many must be subjected to heat treatment. In the case of synthetic grain, the selected and beneficiated raw materials are blended in the desired proportions and formed into suitable shapes for calcination by briquetting, pelletizing, or extrusion. The term *Calcination* is used to indicate heat treatment to sinter or burn (dead burn) the refractory grain to a stable dense material as well as to decompose minerals. Calcination may be carried out to rotary kilns, shaft kilns, multiple-hearth furnaces, or fluidized-bed reactors. Both raw and processed materials can be fused or melted in electric-arc furnaces.

Crushing and Grinding. Some raw materials, such as hard clay and quartzite, must first be crushed to grains small enough for the grinding equipment. Almost all raw materials require grinding after primary crushing.

Screening. To obtain a high density product, the mix is made from materials that have been sized into classes by means of standard screens. In a continuous screening operation, the ground raw materials are generally fed to vibrating high capacity screens that may be heated. Material that does not pass the screen is returned to the grinding system for further size reduction. Coarse and medium fine-grain sizing is accomplished by the aforementioned methods, whereas fine-sized materials generated in rod mills, ball mills, ring-roll mills, etc., are classified by air separators.

Mixing. As in other ceramic processes, more than one type of raw material is often required for a refractory product. The purpose of mixing is to uniformly distribute the various ingredients (see **Mixing and Blending**). Although the specific steps and equipment involved in the mixing of batches for fireclay, high alumina, and basic refractories are somewhat different, the general principles are similar. Mixes that are to be dry-pressed contain 2–6% binding liquid, depending on the plasticity of the raw material bond system and the fineness of the mix. The ingredients may be blended in a pug mill, dry pan, or other type mixer and tempered with the bonding ingredients. Tempering, in the sense used here, denotes the kneading action produced on the mix, usually in a muller mixer.

Forming. Most refractory shapes are formed by mechanical equipment, but some very large or intricate shapes require hand molding in wooden, steel-lined molds with loose liners to permit easy removal of plaster of Paris molds.

Refractory shapes are generally produced on a mechanical toggle press, screw press, or hydraulic press. Some special shapes are produced by air-ramming which is similar to hand molding, except that reinforced steel molds are required. Special shapes can also be formed by slip casting and hot pressing.

Drying. The drying step for large shapes is critical. Extremely large fireclay and silica shapes are sometimes allowed to dry on a temperature-controlled floor heated by steam or air ducts embedded in the concrete. Smaller shapes are generally dried in a tunnel dryer. The ware is placed on cars that enter the cold end and exit at the hot end.

Curing. Some chemically bonded bricks require some elevated heat treatment that is typically higher than the tempering process, but at a lower temperature than that required to form ceramic bonds.

Bricks are fired or burned in kilns to develop a ceramic bond within the refractory and attain certain desired properties. This step does not apply to chemically or organically bonded products. Burned brick may be impregnated with tar or pitch to improve corrosion resistance.

Specialty Refractories. Bulk refractory products include gunning, ramming, or plastic mixes, granular materials, and hydraulic setting castables and mortars. These products are generally made from the same raw materials as their brick counterparts.

Economic Aspects

The principal consumers of refractories are the iron and steel industries. There has been a decrease in refractories consumption that coincided with technological changes in the manufacture of steel. Steady improvements in basic oxygen furnace (BOF) practice and improvements in refractory composition and design led to improved refractory performance. More sophisticated ladle metallurgical practice has been employed, leading to improved steel quality and improved refractory performance.

Analytical and Test Methods

The test methods applicable to refractories are summarized in Table 2.

Health and Safety Factors

Industrial refractories are by their very nature stable materials and usually do not constitute a physiological hazard. This is not so, however, for unusual refractories that might contain heavy metals or radioactive oxides, such as thoria and urania, or to binders or additives that may be toxic. Inhalation of certain fine dusts may constitute a health hazard. For example, exposure to silica, asbestos, and beryllium oxide dusts over a period of time results in the potential risk of lung disease.

Selection and Uses

Any manufacturing process requiring refractories depends on proper selection and installation. When selecting refractories, environmental conditions are evaluated first, then the functions to be served, and finally the expected length of service. All factors pertaining to the operation, service design, and construction of equipment must be related to the physical and chemical properties of the various classes of refractories.

By far the most common industrial refractories are those composed of single or mixed oxides of Al, Ca, Cr, Mg, Si, and Zr. These oxides exhibit relatively high degrees of stability under both reducing and oxidizing conditions. Carbon, graphite, and silicon carbide have been used both alone and in combination with the oxides. Refractories made from these materials are used in ton-lot quantities, whereas silicides are used in relatively small quantities for specialty application in the nuclear, electronic, and aerospace industries.

The common industrial refractories are classified into acid, SiO_2 and ZrO_2; basic, CaO and MgO; and neutral, Al_2O_3 and Cr_2O_3. Oxides within each group are generally compatible with each other, whereas mixtures of acid and basic oxides often give low melting products. Neutral oxides are generally compatible with both acidic and basic oxides.

TABLE 2. ASTM TEST METHODS FOR REFRACTORIES

Material	Test identification	Properties
burned brick	C20, C830	apparent porosity, water adsorption, bulk density
brick, various shapes	C133, C607, C93	crushing strength, modulus of rupture
basic brick	C456	hydration resistance
brick and tile	C154	warpage
granules	C357, C493	bulk density
periclase grains	C544	hydration
mortar	C198	cold-bonding strength
air-setting plastics	C491	modulus of rupture
castables	C298	modulus of rupture
granular dead-burned dolomite	C492	hydration
fireclay plastics	C181	workability index
castables	C417	thermal conductivity
plastics	C438	thermal conductivity
general refractories	C288	disintegration in CO atmosphere
	C135	true specific gravity
	C201	thermal conductivity
	C92	sieve analysis and water content

Reactions Between Refractories and Liquids. The response of a refractory to a chemical environment generally depends on its slag resistance which, in turn, depends on the compositions and properties of slag and refractory. Other factors include temperature, severity of thermal cycling or shock of the process, velocity and agitation of the slag in contact with the refractory, and the abrasion to which the refractory is subjected. Thus similar refractories placed in similar furnaces can wear at vastly different rates under different operation practices.

Reactions Between Refractories and Gases. Reactions of refractories and gases can be quite destructive. The gases generally penetrate the pores of the refractory destroying its structure. An example is the disintegration of aluminosilicates in blast furnaces caused by the deposition of carbon from carbon monoxide. The growth of the carbon deposit causes the brick to rupture. Therefore, a brick of low iron and alkali content having a dense, low permeability is preferred.

Reactions Between Refractories. Dissimilar refractories can react vigorously with each other at high temperatures.

REFRIGERANT. Any substance that by undergoing a change of phase (solid to liquid to vapor) lowers the temperature of its environment because of its latent heat. Melting ice, with latent heat of 80 calories per gram removes heat and exerts a considerable cooling effect. Most commercial refrigerants are liquids whose latent heat of vaporization results in cooling.

The specific fluid used to produce refrigeration is a very important consideration. The refrigeration industry uses a variety of compounds that fall into three general categories: halocarbons, hydrocarbons, and inorganic fluids. For saturated and unsaturated aliphatic hydrocarbons and aliphatic halogenated hydrocarbons designated as refrigerants, a numerical coding system has been developed which describes the refrigerant molecular structure by the use of a general designation having the form ABCD, in which A is the number of double bonds, B the number of carbon atoms less one, C the number of hydrogen atoms plus one, and D the number of fluorine atoms.

Inorganic refrigerants are described somewhat differently. They are assigned three-digit numbers the first of which is 7, with the following two numbers comprising the molecular weight.

Refrigerant mixtures are divided into two categories, azeotropes and zeotropes. In zeotropes, the equilibrium vapor and liquid compositions are different, and composition shifting can occur in a refrigeration cycle.

Within the family of halocarbon refrigerants are compounds that contain chlorine, fluorine, and carbon, the chlorofluorocarbons (CFCs). Hydrochlorofluorocarbons (HFCs) contain chlorine, fluorine, carbon and hydrogen. Halocarbons that contain only carbon, fluorine, and hydrogen are called hydrofluorocarbons (HFCs).

See also **Refrigeration**.

REFRIGERATION. A process of cooling or freezing a substance to a temperature lower than that of its surroundings and maintaining that substance in a cold state. Refrigeration can be accomplished by arranging heat transfer from a warm body to a colder body through processes such as convection or thermal conduction. Other, more erotic methods include the exploitation of thermoelectric properties of semiconductors, the magnetothermoelectric effects in semimetals, or the diffusion of ^{3}He atoms across the interface between distinct phases of liquid helium having high and low concentrations of ^{3}He in ^{4}He, among other methods. See also **Thermoelectric Cooling**.

Mainly because of two factors, (1) energy conservation and cost and (2) the desirability of phasing out the use of chlorofluorocarbons (CFCs) in an attempt to slow the deterioration of Earth's ozone layer, refrigeration technology is under intense scrutiny as of the early 1990s.

In an effort to accelerate refrigeration technology, a group of U.S. electric utilities established in 1992 the "Super Efficient Refrigerator Program" (SERP), which will award approximately $30 million to that U.S. manufacturer who first succeeds in producing the most efficient home refrigerator. Targets that must be met include:

1. Consumes as little as 400 kWh per year, compared with 1993 federal efficiency standards of 704 kWh for comparable refrigerators.
2. The refrigerator will be moderately priced.
3. The system will require no chlorofluorocarbons.

In this article, after a review of the common contemporary means of refrigeration, some new or revised innovative methods for refrigeration and cooling systems will be described.

Contemporary Refrigeration Systems

Most commercial refrigeration systems operate on a cyclic basis. A refrigerator operating in this manner may be considered a heat pump, for it continuously extracts heat from a low-temperature region and delivers it to a high-temperature region. It is rated by its *coefficient of performance*, which may be defined as the ratio of the heat removed from the cold region per unit of time to the net input power for operating the device, in symbols $K = Q_t/P$. Vapor-absorption and thermoelectric refrigeration systems have lower coefficients of performance than vapor-compression refrigerators, but they have other characteristics that are superior, such as quietness of operation and compactness.

A *vapor-compression refrigerator* consists of a compressor, a condenser, a storage tank, a throttling valve, and an evaporator connected by suitable conduits with intake and outlet valves. See Fig. 1. The refrigerant is a liquid that partly vaporizes and cools as it passes through the throttling valve. Among the common refrigerants are ammonia, sulfur dioxide, and various halides of methane and ethane.

CFCs have been used widely in all kinds of cooling systems, including automobile air-conditioning systems. But for their atmospheric pollution problems, they are excellent refrigerants.

Nearly constant pressures are maintained on either side of the throttling valve by means of the compressor. The mixed liquid and vapor entering the evaporator is colder than the near-surround; it absorbs heat from the interior of the refrigerator box or cold room and completely vaporizes. The vapor is then forced into the compressor, where its temperature and pressure increase as the result of compression. The compressed vapor then pours into the condenser, where it cools down and liquifies as the heat is transferred to cold air, water, or other fluid medium in the cooling coils. Comparative tests have shown that the coefficient of performance of vapor-compression refrigerators depends very little on the nature of the refrigerant. Because of mechanical inefficiencies, the actual value may be well below an ideal value, which ordinarily lies between 2 and 3.

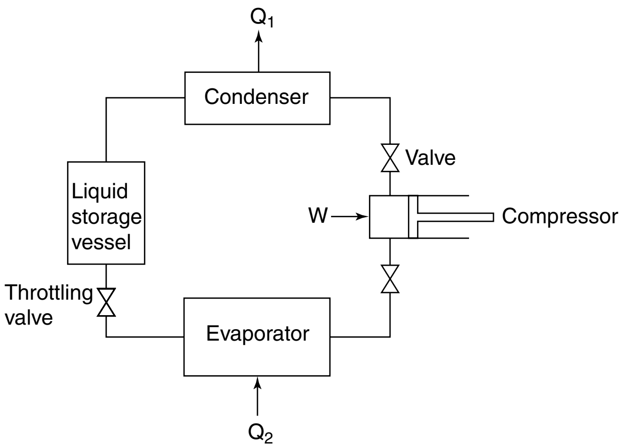

Fig. 1. Vapor-compression refrigeration system

In a *vapor-absorption refrigeration system*, there are no moving parts. The added energy comes from a gas or liquid fuel burner or from an electrical heater, as *heat*, rather than from a compressor, as *work*. See Fig. 2. The refrigerant used in this example is ammonia gas, which is liberated from a water solution and transported from one region to another by the aid of hydrogen. The total pressure throughout the system is constant and therefore no valves are needed.

Heat from the external source is supplied to the generator, where a mixture of ammonia and water vapor with drops of ammoniated water is raised to the separator in the same manner as water is raised to the coffee in a percolator. Ammonia vapor escapes from the liquid in the separator and rises to the condenser, where it cools and liquefies. Before the liquefied ammonia enters the evaporator, hydrogen, rising from the absorber, mixes with it and aids in the evaporation process. Finally, the mixture of hydrogen and ammonia vapor enters the absorber, where water from the separator dissolves the ammonia. The ammonia water returns to the generator to complete the cycle. In this cycle, heat enters the system not only at the generator, but also at the evaporator, and heat leaves the system at both the condenser and the absorber to enter the atmosphere by means of radiating fins.

No external work is done, and the change in internal energy of the refrigerant during a complete cycle is zero. The total heat $Q_a + Q_c$ released to the atmosphere per unit of time by the absorber and the condenser equals the total heat $Q_g + Q_c$ absorbed per unit of time from the heater at the generator and from the cold box at the evaporator. Thus $Q_e = Q_a + Q_c - Q_g$, and therefore, the coefficient of performance is $K = Q_e/Q_g = [(Q_a + Q_c)/Q_g] - 1$.

The vapor-absorption refrigerator is free from intermittent noises, but it requires a continuous supply of heat. Once very popular for households, refrigeration systems of this type are now most frequently found in camping facilities and some rural areas where commercial electric power may not be easily available.

In a *dilution refrigeration system*, the properties of helium are used advantageously for attaining very low temperatures. Below a temperature of 0.87°K, liquid mixtures of ^{3}He and ^{4}He at certain concentrations separate into two distinct phases. One is a concentrated (^{3}He-rich) phase floating on the other, denser (^{4}He-rich) phase with a visible interface between them. The concentrations of ^{3}He in the two phases are functions of temperature, approaching 100% in the concentrated phase and about 6% in the dilute phase at 0°K. The transfer of ^{3}He atoms from the concentrated to the dilute phase, like an evaporation process, entails a latent heat, an increase in entropy, and a lowering of temperature. The main features of a recirculating dilution refrigeration system are shown in Fig. 3. The pump forces helium vapor (primarily ^{3}He) from the still into the condenser, where it is liquefied at a temperature near 1°K in a bath of rapidly evaporating ^{4}He, through a flow controller that consists of a narrow tube of suitable diameter to obtain an optimum rate of flow, and then through the still where its temperature is further reduced to about 0.6°K. The liquefied ^{3}He next passes through a heat exchanger so as to reduce its temperature to nearly that of the dilution chamber, by giving up thermal energy to the counter-flowing dilute phase, before entering the concentrated phase therein.

The diffusion of ^{3}He atoms from the concentrated into the dilute phase within this chamber can produce steady temperatures of very low values (0.01°K or less). Liquid ^{3}He from the dilute phase then passes through the heat exchanger to the still, where it is warmed to transform the liquid to the vapor phase that goes to the pump, thus completing the cycle. Modified versions of this system have been constructed, sometimes with an added single-cycle process for temporarily producing temperatures lower than previously mentioned. The low-temperature limit in any system of this type is governed largely by two important sources of inefficiency that cannot be completely eliminated—heat leakage, especially severe because of the extreme range of temperatures, and recirculation of some ^{4}He with ^{3}He.

Cool-Storage Concept

In a majority of buildings and nearly all residences, automobiles, and other forms of transportation, comfort cooling systems operate on command—that is, the air conditioner is “on” or “off” in obedience to the thermostat. Thus, the air conditioner starts and stops a number of times during a 24-hour period. Studies have shown that the performance of cooling equipment operates at highest efficiency when used continuously. It has been estimated by authorities that about 25% of the total power consumption of an air-conditioning unit can be attributed to discontinuous operation.

Such inefficient operation essentially can be alleviated by converting to a “cool-storage” system. In this concept, a large pool of cooling medium is created during off-peak hours. The medium is stored in fluid or semi-fluid (slushy) form in a holding tank, which becomes the source of very cold water that can be circulated through a structure. There are definite parallels with circulating hot water or steam heat.

The principle of cool storage was used many years ago when motion picture theaters introduced air-conditioning to the general public. Precooling of the theater prior to opening and during off-peak load hours saved on electricity costs and also cut down on the investment in air-conditioning equipment.

In establishing a cool storage system, there is a choice of cooling media that may be used: (1) cold water just above the freezing point; (2) ice (commonly used with blowers in theaters, shops, and railway cars in the earlier days of air conditioning); (3) so-called “slippery ice,” which is comparable to the mixtures containing calcium magnesium acetate used for deicing aircraft; and (4) eutectic salt mixtures. Slippery ice has the desirable property of a flowing slush that does not cling to metal parts.

Many years ago, groups of owners of large adjacent buildings would buy their steam from a district steam plant for heating purposes. This same concept also can be applied to a district cooling system. See Figs. 4 and 5.

Magnetic Refrigeration

The basic physical principle behind magnetic refrigeration (or cooling) is the ability of a ferromagnetic material near its magnetic ordering temperature (called the Curie temperature) to heat-up when magnetized (i.e., placed in a magnetic field), and to cool-off when demagnetized (i.e., the magnetic field is removed). This phenomenon is known as the magnetocaloric effect, which was discovered in 1881. It was first utilized in the mid-1930s to reach temperature below 1°K by cooling a paramagnetic salt [$Gd_2(SO_4)_3 \cdot 7H_2O$] in a large magnetic field to as low a temperature as possible by pumping on liquid He (about 1.5°K), and when salt was thermally isolated and the magnetic field removed the sample cooled to well below 1°K due to the magnetocaloric effect. This one step process is known as adiabatic demagnetization, and it is still used today to reach temperatures in the microkelvin range (the record stands at 0.000025°K).

In order to make magnetic refrigeration practical one must use a continuous cyclic process in which heat must be rejected when the ferromagnet experiences a magnetic field increase (just as the heat is rejected during the compression of a gas in a conventional gas cycle

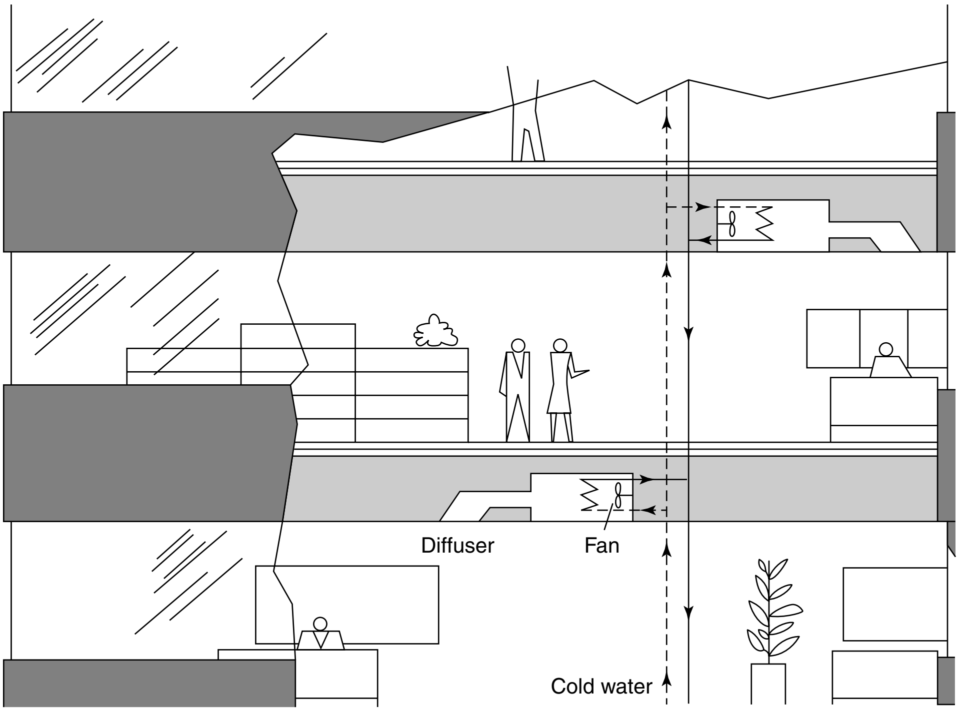

Fig. 4. The cool storage system shown here differs from conventional air conditioners mainly by the inclusion of a storage tank. The tank contains a thermal medium (water, ice, or eutectic salt) that stores cooling generated by the refrigeration unit. When cooling is required, a water solution from the storage tank is circulated in a pipe system that runs throughout the building. The storage capacity effectively decouples the refrigeration process from the building load, allowing building operators to generate cooling during "off-peak" hours of the local electric utility at a time when rates are lower. (*Source: Electric Power Research Institute*)

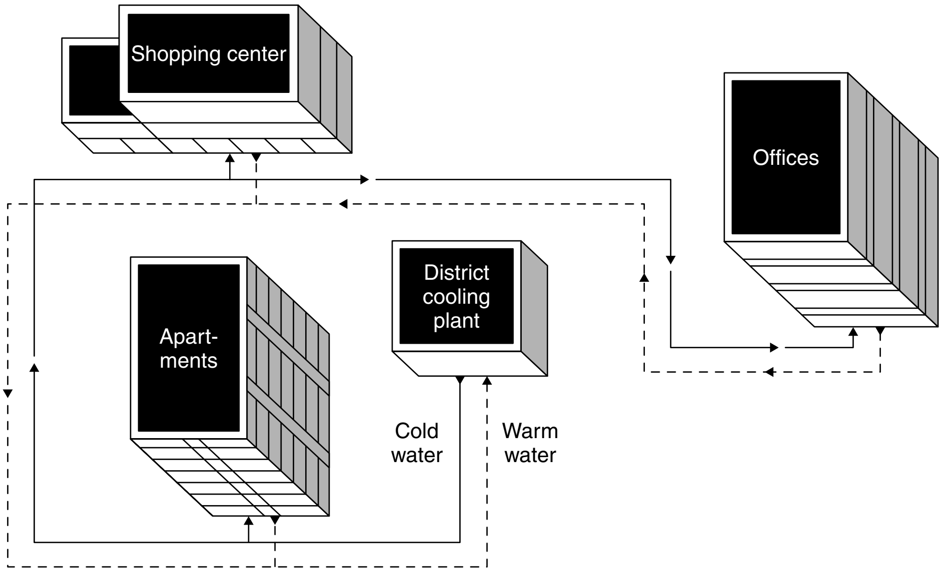

Fig. 5. District cooling. The basic components of cool storage systems also exist in district cooling systems, which use a central plant to cool nearby buildings. Although some systems of this kind are already in use in the United States, they are much more common in Europe. Some authorities believe that district cooling would be a profitable business for many utilities because they could sell cooling while tapping generation capacity that typically goes unused in the off-peak hours. (*Electric Power Research Institute*)

refrigerator). The cooling is achieved by removing the magnetic field experienced by the magnetic refrigerant (this is equivalent to the gas expansion step in the gas cycle refrigerator). One of the first continuously operating magnetic refrigerators, which was used to cool from 1 to 0.2°K, was built and tested in the mid-1950s. Over the next 40 years progress was slow, but in 1997 Zimm and co-authors announced the successful testing of a proof-of-principle continuous near room temperature magnetic refrigerator, which showed for the first time that magnetic refrigeration is a viable technology and competitive with vapor compression cooling. They used gadolinium metal as the magnetic refrigerant and water as the heat transfer medium and were able to cool down to almost 0°C (273°K), while the heat was rejected at a temperature of 38°C from the hot heat exchanger. They achieved a maximum coefficient of performance, COP, (the cooling power divided by the power required to operate the apparatus) of 16 using a maximum field change of 0 to 5 T at a frequency of 0.17 Hz. For smaller field changes the COP was less, about 4 for a 0 to 1.5 T magnetic field change. Gas compression refrigeration has COPs ranging from 2 to 4.

Since magnetic refrigeration uses a non-toxic solid refrigerant, it is an environmentally friendly technology because it replaces the commonly used gaseous refrigerants such as ozone-depleting chemicals (chlorofluorocarbons), hazardous chemicals (ammonia), and greenhouse gases (hydro-chloro-fluorocarbons and hydro-fluorocarbons). Furthermore, since

magnetic refrigeration is expected to be 20 to 30% more efficient than conventional cooling systems this will reduce the amount of energy consumed and in turn reduce the amount of CO_2 (also a greenhouse gas) released into the atmosphere.

Magnetic refrigeration and cooing is expected to be used in household air conditioning and refrigerators/freezers, automotive and aircraft climate control systems, large scale building air conditioning, supermarket chillers, frozen food processing plants, liquefaction of natural gas (methane) and hydrogen gas.

REGELATION. The phenomenon that occurs when two pieces of ice are rubbed together, the pressure causing the ice to melt at the surfaces of contact while the temperature drops, and, on relieving the pressure, the two surfaces freeze together, producing one mass of ice. This phenomenon is due to reduction of the freezing point of water (melting point of ice) under increased pressure. At very high pressures, the relationship changes, and the melting point of ice increases steadily with increasing pressure.

REGENERATION. 1. Restoration of a material to its original condition after it has undergone chemical modification necessary for manufacturing purposes. The most common instance is that of cellulose for rayon production. The wood pulp used must first be converted to a solution by reaction with sodium hydroxide and carbon disulfide; in this form (cellulose xanthate) it can be extruded through spinnerettes. After this operation it is regenerated to cellulose by passing it through acid (viscose process). Collagen can also be regenerated by acid treatment after it has been purified for use in food products by alkaline solution.

2. Renewal or reactivation of a catalyst that has accumulated reaction residues such as coke, usually accomplished by passage of steam or reducing gases over the catalyst bed.

3. Replenishing the sodium ions of a zeolite of similar ion-exchange agent by treatment with sodium chloride solution. Molecular sieves are regenerated by heat removal of the water (200°C), followed by treatment with an inert gas.

REINFORCED PLASTICS. Reinforced plastics are commonly referred to as composites or, more specifically, polymer composites. Not all composites are reinforced plastics; ceramic/metal-matrix composites and concrete are good examples of nonpolymeric composites. Reinforced plastics are also referred to RP, FRP (fiberglass-reinforced plastic), and GRP (glass-reinforced plastic) interchangeably.

Common to all reinforced plastics are two ingredients, resin and reinforcement. Resin is an inorganic material, usually of high molecular weight, that can be molded and set into a final shape. Resins are of two basic types. Thermoplastic resins; soften upon heating, are shaped in a mold, and retain that shape when cooled. Thermosetting resins are placed in a mold and cured by the use of a catalyst, heat, or both, until they harden in the shape of the mold.

The second main ingredient in reinforced plastic is the reinforcement, e.g., fibers of glass, carbon, boron, mineral, cellulose, or polymers. See also **Reinforcing Agent**. Reinforcements can be configured in many ways, such as continuous or chopped strands, milled fibers, rovings, tows, mats, braids, and woven fabrics.

Reinforced plastics may also include fillers (qv), which are inexpensive materials such as calcium carbonate used to displace resin and reduce cost. Curing agents (catalysts), promoters, inhibitors, and accelerators, which affect thermosetting resin cure; colorants. Release agents (qv) to facilitate removal from the mold; and other additives which can impart a wide variety of properties to the finished part, such as fire resistance, electrical conductivity, static dissipation, and ultraviolet resistance.

It is important to note that reinforced plastics remain a combination of materials differing in form or composition on a macro scale. The main constituents (resin, reinforcement, and filler) retain their identities and do not dissolve or merge into each other; rather, they act in concert. These components can be physically identified and exhibit an interface between each other.

See also **Plastics**.

REINFORCING AGENT. 1. One of numerous fine powders used in rather high percentages to increase the strength, hardness, and abrasion resistance of rubber, plastics, and flooring compositions. The reinforcing effect is in general a function of the particle size of the powder. The finest of all is channel carbon black, whose surface area may be as great an 18 acres per pound. Other widely used reinforcing agents are thermal and furnace blacks, magnesium carbonate, zinc oxide, hard clay (kaolin), and hydrated silicas. Though some reinforcing agents have positive coloring properties, the term should not be used as a general synonym for pigment.

2. Fibers, fabric, or metal insertions in plastics, rubber, flooring, etc., for the purpose of imparting impact strength and tear resistance.

See also **Pigments (Inorganic)**; and **Pigments (Organic)**.

RELEASE AGENTS. Release agents are substances that control or eliminate the adhesion between two surfaces. They are used to expedite many industrial handling and processing operations, particularly of polymers (see **Plastics processing**). They are known by a variety of terms descriptive of their effect, including abherents, abhesives, antiblocking agents, antistick agents, external or surface lubricants, mold-release agents, parting agents, and slip agents. They find considerable use in the adhesive, food, furniture, glass, metal, plastics, and rubber industries.

Release agents function by either lessening intermolecular interactions between the two surfaces in contact or preventing such close contact. Thus, they can be low surface-tension materials based on aliphatic hydrocarbon, fluorocarbon groups, or particulate solids. The principal categories of material used are waxes, fatty acid metal soaps, other long-chain alkyl derivatives, polymers, and fluorinated compounds.

Some of these processing aids are incorporated into the bulk of the material rather than being directly applied to the surface and are known as internal release agents. In the process of migration to the surface they have an inevitable internal lubrication effect. Most internal lubricants also have an external lubricant effect, particularly at higher concentrations because usually some material finds its way to the exterior.

Product Types and Requirements

Release agents are available in a wide variety of forms and are formulated for numerous modes of application. Product types include neat liquids, solutions, powders, flakes, pastes, emulsions, dispersions, sprays, and films. Some are general-purpose inert products intended for a broad range of applications, including home consumer uses, whereas others are highly specific, designed to react *in situ* with particular substrates. There is a trend away from products containing volatile organic compounds (VOCs) and ozone-depleting substances, and toward water-based and high solids formulations. Users are also switching from the heavier metal soaps. Many products serve more than one processing function and contain other additives; such products are usually proprietary.

The choice of a release agent depends on the process conditions involved and the nature of the contacting substrates. Apart from the obvious ease of release, other important requirements are minimal buildup of residues on

mold substrate, minimal effect on the molded article, adequate film-forming ability, compatibility with secondary operations and other processing parameters, health and safety requirements, and cost.

Classification of Release Agents

The diversity of release products and the wide range of release problems make classification difficult. One approach is by product form, with subdivisions such as emulsions, films, powders, reactive or inert sprays, reactive coatings, and so on. Another approach is by application, e.g., metal casting, rubber processing, thermoplastic injection molding, and food preparation and packaging.

A classification by chemical type is given in Table 1. It does not attempt to be either rigorous or complete. The broad classes of release materials available are given in the chemical class column, the principal types in the chemical subdivision column, and one or two important selections in the specific examples column.

Mechanism of Release

Release agents are used to reduce the adhesion between materials. The main mechanisms of adhesion are interdiffusion, electrostatic attraction, surface energetics and wettability, and mechanical interlocking. The important surface and interfacial properties include surface topography (composition, structure, and roughness), surface tension or energy and its effect on substrate and adhesive wettability, the thermodynamic work of adhesion, and chemical reactivity at the interface. Nonsurface properties of the thin-film interfacial phase include its ability to set to a cohesive solid after wetting the substrate and its viscoelastic response to deformation controlled by factors such as degree of crystallinity, molecular weight and distribution, number of cross-links, and presence of fillers. Surface treatments that enhance adhesion do so by removing weak boundary layers, changing surface topography, or changing the chemical nature of the surface and by introducing strongly attracting functional groups.

An inversion of these arguments indicates that release agents should exhibit several of the following features: (*1*) act as a barrier to mechanical interlocking; (*2*) prevent interdiffusion; (*3*) exhibit poor adsorption and lack of reaction with at least one material at the interface; (*4*) have low surface tension, resulting in poor wettability, i.e., negative spreading coefficient, of the release substrate by the adhesive; (*5*) low thermodynamic work of adhesion; (*6*) low intermolecular forces across the interface, e.g., an absence of electrostatic or polar attractions; (*7*) display nonsetting or low cohesive interactions within the release phase; and (*8*) provide a weak boundary layer.

TABLE 1. CHEMICAL CLASSIFICATION OF RELEASE AGENTS

Chemical class	Chemical subdivisions	Specific examples
waxes	petroleum waxes	paraffin wax, microcrystalline wax
	vegetable waxes	carnauba wax
	animal waxes	lanolin
	synthetic waxes	polyethylene wax, Fischer-Tropsch wax
fatty acid metal soaps	metal stearates	magnesium stearate, zinc stearate
	other	calcium ricinoleate
other long-chain alkyl derivatives	fatty esters	diethylene glycol monostearate, hydrogenated castor oil
	fatty amides and amines	ethylenebis(stearamide), oleyl palmitamide
	fatty acids and alcohols	palmitic acid, oleic acid
polymers	polyolefins	polypropylene
	silicones	polydimethylsiloxane, polymethyl(nonafluorohexyl)-siloxane
	fluoropolymers	polytetrafluoroethylene, poly(fluoroethers)
	natural polymers	cellophane
	other	polyoxalkylenes, poly(vinyl alcohol)
fluorinated compounds	fluorinated fatty acids	perfluorolauric acid
inorganic materials	silicates	talc
	clays	kaolin, mica
	other	silica, graphite

Many of these features are interrelated. Finely divided solids such as talc are excellent barriers to mechanical interlocking and interdiffusion. They also reduce the area of contact over which short-range intermolecular forces can interact. Because compatibility of different polymers is the exception rather than the rule, preformed sheets of a different polymer usually prevent interdiffusion and are an effective way of controlling adhesion, provided no new strong interfacial interactions are thereby introduced. Surface tension and thermodynamic work of adhesion are interrelated, as shown in equations 1, 2, and 3, and are a direct consequence of the intermolecular forces that also control adsorption and chemical reactivity.

The work of adhesion, W_A, is the change in energy per unit surface area when two interfaces come into contact, as given in equation 1 where σ_1 and σ_2 are the surface energy of each phase and σ_{12} the interfacial energy between them.

$$W_A = \sigma_1 + \sigma_2 - \sigma_{12} \tag{1}$$

For liquid systems these surface energies expressed in mJ/m^2 are numerically equivalent to the surface tensions in mN/m(=dyn/cm). If the adhesive is phase 1 and the release coating is phase 2, then the spreading coefficient, S, of 1 on 2 is as given in equation 2.

$$S = \sigma_2 - \sigma_1 - \sigma_{12} \tag{2}$$

Because the work of cohesion, W_C, of the adhesive is 2 σ_1, equation 3 follows.

$$W_A - W_C = S \tag{3}$$

This simple yet fundamental relationship states that when the forces of adhesion are less than those of cohesion, i.e., when W_A is less than W_C, the spreading coefficient is negative and failure will be at the interface between the adhesive and release coating, the desired situation in a release coating application. Conversely, when the spreading coefficient is positive, undesirable cohesive failure in the adhesive or release coating will be the case. These equations clearly demonstrate the importance of the release coating surface tension being lower than that of the adhesive.

The intermolecular forces of adhesion and cohesion can be loosely classified into three categories: quantum mechanical forces, pure electrostatic forces, and polarization forces. Quantum mechanical forces give rise both to covalent bonding and to the exchange interactions that balance the attractive forces when matter is compressed to the point where outer electron orbits interpenetrate. Pure electrostatic interactions include Coulomb forces between charged ions, permanent dipoles, and quadrupoles. Polarization forces arise from the dipole moments induced in atoms and molecules by the electric fields of nearby charges and other permanent and induced dipoles.

The forces involved in the interaction at a good release interface must be as weak as possible. They cannot be the strong primary bonds associated with ionic, covalent, and metallic bonding; neither are they the stronger of the electrostatic and polarization forces that contribute to secondary van der Waals interactions. Rather, they are the weakest of these types of forces, the so-called London or dispersion forces that arise from interactions of temporary dipoles caused by fluctuations in electron density. They are common to all matter. The surfaces that are solid at room temperature and have the lowest dispersion-force interactions are those comprised of aliphatic hydrocarbons and fluorocarbons.

Among the hydrocarbons, the lowest surface tension values are found for surfaces comprising closely packed methyl groups. This is a characteristic of waxes and oriented long-chain alkyl derivatives.

Because the forces of attraction prevail when molecules are brought into sufficiently close proximity under normal conditions, release is best effected if both the strength of the interaction and the degree of contact are minimized. Aliphatic hydrocarbons and fluorocarbons achieve the former effect, finely divided solids the latter. Materials such as microcrystalline wax and hydrophobic silica combine both effects.

REMSEN, IRA (1846–1927). An American chemist born in New York. He began his career in medical practice but abandoned it for chemistry and went to Germany to study. He received his doctorate in chemistry from the University of Gottingen in 1870. Returning to the U.S. he taught physics and chemistry at Williams. He was later invited to join the staff of John Hopkins University where he became head of the department of chemistry. There he established the first graduate curriculum in chemistry in the U.S. based on the system then in use in Germany. In 1879, saccharin was discovered in his research laboratory. He wrote several widely used textbooks and founded the *American Journal of Chemistry*, which later merged with JACS. Remsen served as President of Johns Hopkins from 1901–1912. He was also recognized as one of the great teachers of chemistry.

REPELLENT. 1. A substance that causes and insect of animal to turn away from it or reject it as food. Repellents may be in the form of gases (olfactory), liquids, or solids (gustatory). Standard repellents for mosquitos, ticks, etc., are citronella oil, dimethyl phthalate, *n*-butylmesityl oxide oxalate, DEET, and 2-ethyl hexanediol-1,3. Actidione is the most effective rodent repellent, but is too toxic and too costly to use. Copper naphthenate and lime/sulfur mixtures protect vegetation against rabbits and deer. Shark repellents are copper acetate or formic acid mixed with ground asbestos. Bird repellents are chiefly based on taste, but this sense varies widely with the type of bird so that generalization is impossible. α-Naphthol, naphthalene, sandalwood oil, quinine, and ammonium compounds have been used, with no uniformity or result.

2. A substance that, because of its physicochemical nature, will not mix or blend with another substance. All hydrophobic materials have water-repellent properties due largely to differences in surface tension or electric charges, e.g., oils, fats, waxes, and certain types of plastics. Silicone resin coatings can keep water from penetrating masonry by lining the pores, not by filling them; they will not exclude water under pressure.

REPPE PROCESS. Any of several processes involving reaction of acetylene (1) with formaldehyde to produce 2-butyne-1,4-diol which can be converted to butadiene; (2) with formaldehyde under different conditions to produce propargyl alcohol and, form this, allyl alcohol; (3) with hydrogen cyanide to yield acrylonitrile; (4) with alcohols to give vinyl ethers; (5) with amines or phenols to give vinyl derivatives; (6) with carbon monoxide and alcohols to give esters of acrylic acid; (7) by polymerization to produce cyclooctatetraene; and (8) with phenols to make resins. The use of catalysts, pressures up to 30 atm, and special techniques to avoid or contain explosions are important factors in these processes.

See also **Acetylene**.

RESINS (Acetal). These are thermoplastic resins, obtainable both as homopolymers and copolymers, and produced principally from formaldehyde or formaldehyde derivative. Acetal resins have the highest fatigue endurance of commercial thermoplastics. A variety of ionic initiators, such as tertiary amines and quaternary ammonium salts, are used to effect polymerization of formaldehyde. Chain transfer, shown by the following reactions, controls the molecular weight of resulting resins:

Step 1, initiation of new chain:

$$-CH_2OCH_2O^- + H_2O \longrightarrow -CH_2OCH_2OH + OH^-$$

Step 2, reaction of growing chain with H_2O, releasing hydroxyl ion:

$$OH^- + CH_2O \longrightarrow HOCH_2O^-$$

Step 3, end-capping of high-molecular-weight polyoxymethylene glycol to provide stable commercial resin:

$$HOCH_2O^- + nCH_2O \longrightarrow HOCH_2O(CH_2O)_{n-1}CH_2O^-$$

Starting ingredients may be formaldehyde or the cyclic trimer trioxane, $CH_2OCH_2OCH_2O$. Both form polymers of similar properties. Boron trifluoride of other Lewis acids are used to promote polymerization where trioxane is the raw material.

Acetals provide excellent resistance to most organic compounds except when exposed for long periods at elevated temperatures. The resins have limited resistance to strong acids and oxidizing agents. The copolymers and some of the homopolymers are resistant to the action of weak bases. Normally, where resistance to burning, weathering, and radiation are required, acetals are not specified. The resins are used for cams, gears, bearings, springs, sprockets, and other mechanical parts, as well as for electrical parts, housings, and hardware.

RESINS (Acrylonitrile-Butadiene-Styrene). Commonly referred to as ABS resins, these materials are thermoplastic resins which are produced by grafting styrene and acrylonitrile onto a diene-rubber backbone. The usually preferred substrate is polybutadiene because of its low glass-transition temperature (approximately −80°C). Where ABS resin is prepared by suspension or mass polymerization methods, stereospecific diene rubber made by solution polymerization is the preferred diene. Otherwise, the diene used is a high-gel or cross-linked latex made by a hot emulsion process.

ABS resins possess an attractive balance of impact resistance, hardness, tensile strength, and elastic modulus properties. The temperature range is wide—from −40 to 107°C (−40 to 225°F). Other advantages include chemical resistance, high gloss, and nonstaining properites. The dimensional stability of ABS is good and creep resistance is excellent. The resins exhibit low water absorption or volume change at varying humidities.

Commercial ABS is in the form of custom color-matched compounded pellets, or granular resin for compounding or alloying with other plastics. A representative alloying ingredient is polyvinyl chloride (PVC). Almost all standard thermoplastic converting processes can be used with ABS plastics. Injection-molded parts include telephone sets, refrigerator parts, plumbing fixtures, fittings, radio, television, and appliance housings, and auto parts. ABS can be extruded into sheet, pipe, and various cross sections.

Thermoforming of large surface areas and deep draws from sheet stock are possible. Examples of parts which involve extrusion and subsequent thermoforming include lawnmower housings, refrigerator liners, pipe and conduit, vehicle bodies, snow-mobile shrouds, and camper bodies. The various thermoforming techniques applicable include plug and air assist, vacuum snapback, vacuum-plug forming, and drape forming.

The compatibility of ABS with other plastics makes them useful as impact modifiers and as processing additives with many other polymers to achieve a variety of final product specifications. Substitution of α-methyl styrene for styrene increases heat-distortion temperatures; or of methacrylonitrile for acrylonitrile improves barrier properties to gases such as carbon dioxide in connection with carbonated beverage containers. Over 75 grades of ABS are commercially available, including self-extinguishing, electroplating, antistatic expandable, glass-rein-forced, high-heat, cold-forming, and low-gloss sheet grades.

Three polymerization steps are involved in ABS manufacture. The process is shown in block diagram format in Fig. 1.

STEP 1—Polybutadiene rubber is formulated by feeding butadiene, water, an emulsifier, and catalyst into a glass-lined reactor. This is an exothermic reaction. About 80% conversion is achieved in a period of about 50 hours. The residual butadiene monomer is recovered by steam-stripping and recycled.

STEP 2—Polybutadiene rubber is further polymerized, but in the presence of styrene and acrylonitrile monomers. This is done in low-pressure reactors under a nitrogen atmosphere. In this operation, the monomers are grafted onto the rubber backbone through the residual unsaturation remaining from the first step.

STEP 3—In a separate step, styrene-acrylonitrile (SAN) resin is prepared by emulsion, suspension, or mass polymerization by free-radical techniques. The operation is carried out in stainless-steel reactors operated at about 75°C (167°F) and moderate pressure for about 7 hours. The final chemical operation is the blending of the ABS graft phase with the SAN resin, plus adding various antioxidants, lubricants, stabilizers, and pigments. Final operations involve preparation of a slurry of fine resin particles (via chemical flocculation), filtering, and drying in a standard fluid-bed dryer at 121–132°C (250–270°F) inlet air temperature.

Assistance of the Marbon Division, Borg-Warner Corporation in preparation of this entry is appreciated.

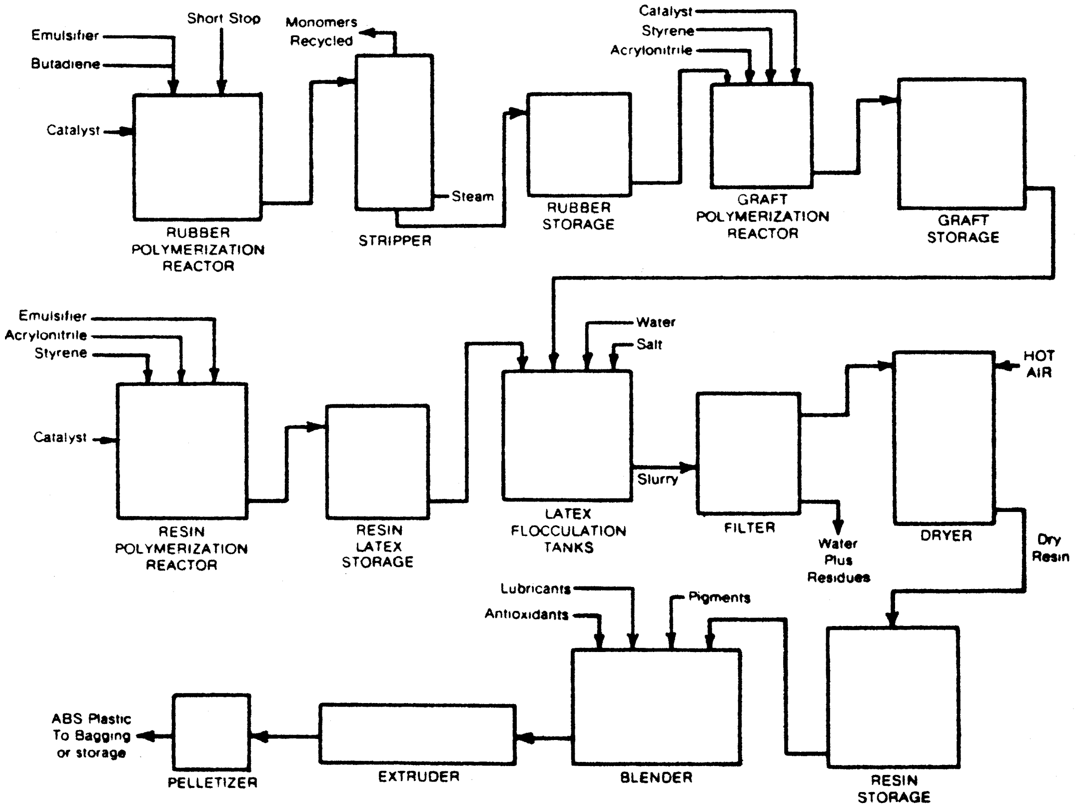

Fig. 1. Process for manufacturing acrylonitrile-butadiene-styrene (ABS) resins. (*Marbon Div., Borg-Warner Corp.*)

RESINS (Natural). Complex compounds composed of carbon, hydrogen, and relatively small amounts of oxygen, which are secreted in various tissues of many plants. In the pine family, where resins are very common, they are secreted as oleoresins in resin canal cells, which break down finally, producing resin canals. These canals appear as longitudinal ducts in the sapwood and inner bark, connected laterally by resin canals in the compound wood rays, thus forming an extensive network. A common name given to the oleoresin in this group is pitch, the sticky juice that exudes from the plant wherever it is wounded. On exposure to the air the volatile oil in this pitch (oil of turpentine) gradually evaporates, leaving a clear hard glassy substance, the resin, which forms a protective coating over the wound.

Most resins have the same physical properties, being clear, translucent, and of a yellow or brownish color. Amber, a fossil resin, is a more or less familiar example. Resins are insoluble in water, but soluble in common organic solvents such as ether and alcohol. All resins burn with a sooty flame. Resins seem to be mainly of value to the plan in that they form protective coverings against the entrance of disease-producing organisms and also prevent excessive loss of water from the thin-walled tissues exposed in the wound.

Resins are separated into several classes. Many of the resins contain almost no volatile oil and are hard, without taste or odor. These are the varnish or hard resins. Other resins, when removed from the plant in which they are formed, and dissolved in volatile oils, form a thick semi-solid mass: these are the oleoresins. In still other cases the resin occurs in combination with a gum, forming a gum resin.

Hard Resins

Several of the hard resins, used mainly for making varnishes, are called copals. Most of them come from Africa and are either found in fossil form or obtained from living plants. Other copals come from Australia, New Zealand and East Indian Islands. The plants that form them are members of the legume and pine families. The African copals are products of several species of *Trachylobium*, fairly large trees growing in east Africa and Madagascar. The best resin from these trees occurs in a fossil form, often deeply buried in the ground—sometimes in regions where the trees no longer grow. These resins dissolve slowly and are used in making varnishes, which are very durable. A South American tree of large size, *Hymenaea courbaril*, also of the Leguminoseae, yields a very similar resin, which is also found in lumps in the ground around the trees, and used in varnishes.

Another copal is obtained from *Agathis australis*, a very large coniferous tree native in Australia and New Zealand, where it is known as the Kauri pine. Like the other copals, that from the Kauri pine is found in lumps buried in the ground. Most of these lumps are 1 or 2 inches in diameter, but some are much larger, weighing up to 100 pounds. Nearly all of this resin comes from the northern part of North Island of New Zealand. It is frequently called Kauri gum, though it is not a gum, but a true copal resin. Another group of hard resins, known as dammar resins, is obtained from many different trees growing in southern Asia and the East Indian Islands. These resins dissolve readily in alcohol, forming spirit-varnishes.

One of the commonest and most important of the hard resins is rosin, obtained by distilling the pitch, or turpentine, which is a product of several of the native pines of the southeastern United States. This rosin, also known as colophony, is a very important product of that region. Originally the turpentine was obtained by chopping a deep hollow in the base of the trunk of the tree and allowing it to fill up with the turpentine, which was then scooped out. This method was very destructive and wasteful, since much of the oleoresin, turpentine, was lost during the process. The weakened trees were easily blown down.

Now turpentine is obtained by cutting V-shaped gouges in the bark and inserting metal gutters beneath the gouges. These gutters carry the turpentine to a cup placed underneath. As soon as the cut is made, turpentine begins to flow and continues to do so for two or three days, gradually slowing as the drying turpentine allows resin to accumulate and plug the wounds. A new flow is obtained by cutting off a narrow strip of bark from the upper edge of the cut. The process is continued as long as the pitch will flow, which is usually all summer and well along into the late fall. Each tree may be turpentined for 6 to 7 successive years or even longer before it ceases to be profitable.

The crude turpentine collected in the cups and the product that has dried on the wound of the tree are removed and carried to the still. Here the turpentine, to which a little water is added, is carefully heated to drive off the oil of turpentine present, together with the water added. The distillate is condensed by passing it through a coil around which cold water is flowing. It is collected in a barrel or any suitable container. The two substances, water and oil of turpentine, which make up the distillate, are immiscible and soon separate, the lighter oil of turpentine rising to the top and floating

on the water, which is drawn off from the bottom. Oil of turpentine is often called spirits of turpentine, or, in the paint trade, turpentine. In medicine the word turpentine is reserved for the oleoresin which upon distillation yields oil of turpentine and rosin.

The residue remaining in the tank at the end of the distillation is skimmed to remove any impurities such as twigs, bits of bark and dirt, and run into vats to cool. Then it is put into barrels and allowed to harden, forming rosin.

Oil of turpentine is used principally as a solvent for paints and varnishes, because it mixes readily with the various substances used and also because it evaporates quickly, causing the paint or varnish to dry. It is also used in making such things as sealing wax and shoe polish. Very pure grades of turpentine (the oleoresin) are used medicinally.

Large quantities of rosin are used in sizing paper, which makes it take ink without spreading or blotting, gives it a smoother surface and makes it heavier. Rosin is also used in cheaper varnishes, in paints, and in soap making. It is furthermore used as an adulterant of the more expensive resins. Linoleum manufacturers use large amounts of rosin.

In early times, large quantities of crude turpentine were used to waterproof the rigging of the sailing vessels and to calk the seams of the hull.

Mastic is a hard resin exuding from the branches of one of the Pistachio trees, *Pistacia lentiscus*, native of Mediterranean Europe and southern Asia. Formerly, it was extensively used medicinally, for stomach troubles and dysentery, as well as other ailments. Now it is used in making varnishes and in lithographic work. Natives of the region in which it is found chew mastic, which has a pleasant taste.

Since turpentine is a mixture of a volatile substance, spirits of turpentine and a hard resin, it is one of the oleoresins.

Oleoresins

Canada balsam is one of the oleoresins. It is obtained from the bark of *Abies balsamea*, the common balsam fir of northern North America. Canada balsam, because its refractive index is so near that of glass, is much used in optical work and in preparing materials for examination with a microscope.

Little used today is Dragon's blood, an oleoresin obtained from the fruits of *Daemonorops draco*, a native palm of southeastern Asia and the Molucca Islands. The resins exudes from the surface of the ripening fruits. It is removed from them by boiling in water. The resin is then moulded into balls or long sticks. It is sometimes used in making varnishes and lacquers.

True lacquer, obtained from the juice of *Rhus verniciflua*, a sumac tree of southeastern Asia, is another oleoresin. To obtain the juice lateral cuts are made in the bark. The exuded sap is collected not only from these cuts but from small branches which are cut off and soaked in water. The juice is cleaned of any foreign substances by straining it through hemp cloth. By slow heating, either artificial or by the sun, the juice is evaporated and stored until used. Lacquer is a poisonous substance, causing intense irritation of the skin in many people. Others seem to be immune. Lacquer is usually applied over some soft wood, commonly soft pine, the pores of which have first been filled by rubbing in a paste of rice and resin, followed by a paste of soft clay and resin. The surface is then covered with cloth and layer after layer of lacquer put over that. Each layer is allowed to dry and rubbed down very smooth before the next layer is added. Any color to be added is mixed with the lacquer, with each colored layer covered by a clear layer before another is put on. The final product is a thick covering composed of many thin layers of lacquers. If this is carved the edges of the carving, on careful examination, will show the fine lines separating the different layers. Lacquering is a very old industry, having been carried on in China since the sixth century.

Certain resins occur in combination with fragrant volatile oils. One of these is benzoin, obtained from *Styrax benzoin* by cutting notches in the bark and allowing the resin to collect in them. It is used in making perfumes, in incense, and as a source of benzoic acid, used medicinally.

Another fragrant oleoresin is storax, obtained from *Liquidambar orientalis*, a medium-sized tree growing in southwestern Asia. The resin is obtained by boiling the bark and wood of young branches. It is used medicinally and also in incense.

Gum Resins

Gum resins include myrrh, which exudes from the trunk and branches of *Commiphora myrrha*, a tree growing in the region around the Red Sea. The lumps of resin are used medicinally, and also in making incense. Another gum resin is frankincense, obtained by cutting notches in the stem of *Boswellia carterii*, which grows in northeastern Africa and in Arabia. This resin is used in incense. *Asafoetida* is also a gum resin. See also **Gums and Mucilages**.

RESINS (Synthetic). A manufactured high polymer resulting from a chemical reaction between two (or more) substances, usually with heat or a catalyst. This definition includes synthetic rubbers and silicones (elastomers), but excludes modified, water soluble polymers (often called resins). Distinction should be made between a synthetic resin and a plastic; the former is the polymer itself, whereas the latter is the polymer plus such additives as filters, colorant, plasticizers etc. See also **Elastomers**; and **Plasticizers**.

The first truly synthetic resin was developed by Baikeland in 1911 (phenol-formaldehyde). This was soon followed by a petroleum-derived product called *coumarone-indene*, which did indeed have the properties of a resin. The first synthetic elastomer was polychloroprene (1931) originated by Nieuwland and later called neoprene. Since then many new types of synthetic polymers have been synthesized perhaps the most sophisticated of which, are nylon and its congeners (polyamides, by Carothers), and the inorganic silicone group (Kipping). Other important types are alkyds, acrylics, aminoplasts, polyvinyl halides, polyester, epoxies, and polyolefins. In addition to their many applications in plastics, textiles, and paints, special types of synthetic resins are useful as ion-exchange media. See also **Paints and Coatings**.

Note: Because the term *resin* is so broadly used as to be almost meaningless, it would be desirable to restrict it application to natural, organ-soluble, hydrocarbon-based products derived from trees and shrubs. But in view of the tendency of inappropriate terminology to "gel" irreversibly, it is a losing battle to attempt to replace "synthetic resin" with the more precise "synthetic polymer." See also **Gums and Mucilages**; and **Resins (Natural)**.

RESONANCE. 1. In chemistry, resonance (or mesomerism) is a mathematical concept based on quantum mechanical considerations (i.e., the wave functions of electrons). It is also used to describe or express the true chemical structure of certain compounds that cannot be accurately represented by any one valence-bond structure. It was originally applied to aromatic compounds such as benzene, for which there are many possible approximate structures, none of which is completely satisfactory. See also **Benzene**.

The resonance concept indicates that the actual molecular structure lies somewhere between these various approximations, but is not capable of objective representation. The idea can be applied to any molecule, organic or inorganic in which and electron pair bond is present. The term *resonance hybrid* denotes a molecule that has this property. Such molecules do not vibrate back and forth between two or more structures, nor are they isotopes or mixtures. The resonance phenomenon is rather an idealized expression of an actual molecule that cannot be accurately pictured by any graphic device.

2. In the terminology of spectroscopy, resonance is the condition in which the energy state of the incident radiation is identical with that of the absorbing atoms, molecules or other chemical entities. Resonance is applied in various types of instrumental analysis such as nuclear resonance absorption and nuclear magnetic resonance. See also **Absorption (Process)**; and **Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)**.

Note: The multiple meanings of *nucleus* and *resonance* can be a source of confusion, especially when these terms are closely associated, as in *nuclear magnetic resonance* and *resonance of molecular nucleus*. In the first of these expressions, *nucleus* is used in sense (1) under "nucleus," and *resonance* in sense (2) under "resonance." In the second expression, *nucleus* is used in sense (3) under "nucleus" and resonance in sense (1) under *resonance*.

RETIFICATION. The enrichment or purification of the vapor during the distillation process by contact and interaction with a countercurrent stream of liquid condensed from the vapor.

See also **Reflux**.

RETORTING. 1. A process much used in the early years of chemistry for destructive distillation of heavy organic liquids and for laboratory

separations. It involves the use of a cylindrical vessel made of glass (for laboratory work), fireclay, or metal, with a neck bent at a downward angle to facilitate distillation. For gas manufacture, the equipment is built on a heavier scale to handle destructive distillation of coal. 2. Processing shale oil. 3. Heating canned or pouched foods with steam to stop bacterial growth. 4. Volatilization of mercury from gold and silver amalgams.

REVEGETATION. Generally refers to the purposeful seeding and planting of an area that once was covered with grass, trees, shrubs, forbs, etc., but which was denuded of vegetation because of a natural disturbance, such as a lightning-caused fire, or because of an artificial disturbance, such as mining and construction projects. A great deal of attention has been given to seeding and planting programs in connection with large areas that have become barren as the result of unplanned strip mining of the coal fields, notably in Appalachia.

Extraction of coal by surface mining has disturbed about two million acres of land in 26 states of the United States, approximately 50% of this disturbance taking place between 1965 and 1975. Ninety percent is on land owned by mining companies, farmers, and other private interests. Even though there has been extensive damage, most of the mining was done under then existing state laws and regulations. Regulations are becoming more rigid. Land disturbed by surface mining is generally an undeveloped land resource. Evidence indicates, however, that all but a small percentage of such land is capable of producing some tangible or intangible societal benefit. Mined sites, appropriately reshaped, can be developed for many uses. In the Midwestern and Appalachian coal fields, they have been developed, in relatively few instances to date, into successful and profitable production of agricultural and horticultural crops. Conversion of such areas into recreational and wildlife developments is a popular target. Industrial and residential sites have been established on areas disturbed by surface mining. Sites planted to trees yield various forest products. As of the early 1980s, some progressive mining companies have identified opportunities and have developed areas that provide social and economic benefits. Such reclamation and revegetation programs, coupled with superior surface mining methods (See also **Coal**), can yield vitally needed coal without extensive spoiling of the land.

Spoil Evaluation

In evaluating old sites that were mined by conventional methods, prior to the use of such techniques as haulback methods, (valley fill or head-of-the-hollow method, mountaintop leveling, etc.), it is necessary to determine both chemical and physical characteristics of the spoil. Chemical factors include toxic ion concentrations and availability of nutrients. The important physical features include particle size, texture, and color of the spoil. Spoil evaluations are often complicated by changes that occur in weathering. Each rock stratum has distinct chemical and physical characteristics. Many of these properties change when fragments of rock are exposed to moisture, light, air, and temperature variations. Release of iron, sulfur, manganese, and aluminum compounds may result in off-site pollution and failure of vegetation. The release of essential nutrients, such as phosphorus, potassium, calcium, and magnesium may, on the other hand, improve the growth of vegetation, reduce acidity problems, and increase the possibilities of reclamation.

Physically, the spoil is a heterogeneous mass of rock fragments derived from the rock strata above the coal. The size of rock fragments after mining and reshaping depends on the size of the basic particles and the strength of the cementing materials, which naturally hold small mineral particles together. Fine-grained shales strongly bonded together may break into hard, platy fragments that resist weathering. Coarse-grained sandstones weakly cemented together may disintegrate rapidly into sand. Spoil may be a dynamic material, more reactive than natural soils that have been exposed to the process of soil genesis for centuries. The chemical and physical properties of a spoil may change rapidly for several years. The rate of change will gradually lessen as characteristics of natural soils develop. Needless to say, however, time required for natural reclamation processes is exceedingly long and provides no relief to the immediate problem.

Evaluations of the chemical properties of a soil could be perplexing if an attempt were made to include all components that affect plant growth. Methods in use today rely on indicators for judging the interaction of many factors at one time. Soil reaction or hydrogen ion concentration (expressed as pH) is the most widely used indicator. Acidity alone may or may not affect the establishment of plants. Changes in acidity determine the concentration of toxic ions and nutrients in the soil solution. At pH levels below 4.0, two chemical changes may occur: Toxic ions, such as manganese, aluminum, and iron, become more available to plants and some essential nutrients become less so. When the pH of a spoil is between 5.5 and 7.0, the concentration of toxic ions in the soil solution decreases and more essential nutrients become available. A soil classification system for acidic spoils is given in Table 1. No system has been proposed for the alkaline or sodic spoils in the western U.S. coal fields. The same principles can be applied, but the toxic ions or cations may differ.

Other chemical analyses have been considered for identifying characteristics that result in specific nutrient deficiencies or toxicities. Phosphorus is often deficient (0 to 7 parts per million) in spoil material. Several laboratory analyses provide estimates of plant-available phosphorus. Total soluble salts in the soil solution may be important for the very strongly acid or alkaline spoils. This does not necessarily mean high concentrations of sodium salts, but salts of all anions and cations in the soil solution. Some consideration has been given to laboratory analyses that give concentrations of exchangeable aluminum, manganese, and hydrogen. These analyses can identify specific toxicities and thus permit the selection of tolerant plant materials. Research has been initiated to determine whether the heavy metals, such as copper, zinc, nickel, mercury, and cobalt, occur in concentrations toxic to plants.

Texture and clay mineralogy influence the degree of compaction that results from heavy equipment passing over the surface during mining and reshaping. There is evidence that compaction may limit plant growth by reducing water infiltration and nutrient release. Texture may also determine the rate of release of toxic ions or nutrients from soil particles. Smaller particles expose a larger surface area per unit volume to the forces of weathering than coarse fragments. This results in a more rapid release of chemicals. Surface color is important because it influences heat exchange at the spoil surface. Dark materials absorb solar energy so the spoil may attain temperatures lethal to plants. The degree of risk depends on the season of the year, the slope of the exposed surface, and the exposure of the site. The highest risk may occur during summer months on steep slopes of black or dark gray material facing south or west.

Preparation of the Site

Treatments to prepare the site for seeding or planting are determined after evaluation of site data and establishment of the land-management options and objectives. Grass and legumes often require more surface preparation than trees and shrubs. Uncompacted fill slopes and freshly reshaped surfaces may make acceptable seedbeds. Hard crusts form on many spoils; fine clay-size particles are consolidated by the drying action of wind and sun. This crust may be broken by rainfall, frost, or mechanical scarification. In many cases, ground cover will be denser if it is seeded into fresh spoil or where spoil surfaces have been broken by natural or mechanical scarification.

TABLE 1. SYSTEM FOR CLASSIFYING SPOILS (ACIDIC)

Acidity			
Class number	Description	pH value	Extent on area sampled
1	Toxic	Less than 4.0	More than 75%
2	Marginal	Less than 4.0	50 to 75%
3	Acid[a]	4.0 to 6.9	50 to 75%
4	Calcareous	7.0 or more	More than 50%
5	Mixed	(Too varied to be classified as any above)	—

Texture	
Group	Description of texture
A	Chiefly sand, sandstones, or sandy shales
B	Chiefly loamy materials and silty shales
C	Chiefly clay and clay shales

Combine acidity and textural classes to describe spoil type.

[a] Acid spoils may be subdivided into two classes: pH 4.1 to 5.4; and pH 5.5 to 6.9.
Source: Northeastern Forest Experiment Station, Forest Service, U.S. Department of Agriculture.

Treatment to create special surface configurations may be required on toxic spoils, on steep slopes, or in geographical locations where precipitation is low or unfavorably distributed throughout the year. Rows or depressions, made by machinery, trap precipitation, moderate wind velocities, reduce evapotranspiration rates, and moderate spoil temperature extremes. The orientation of the furrows with respect to direction of slope, exposure to sun, or prevailing winds may determine the effectiveness of the treatment. Amendments to modify acidity should be applied weeks or months before seeding. Scarification will mix the ameliorating material into the top 6 to 8 inches of spoil and create a neutralized layer for root development. On extremely rocky spoils where scarification is not practical, frost action and infiltrating water may carry the neutralizing materials below the spoil surface. The rate of application of neutralizing material depends on the type of vegetation to be seeded, the present and predicted acidity of the surface spoil, and the neutralizing capacity of the material used. Agricultural limestone is preferred for most treatments, but it can be used only in areas accessible to application equipment. No practical system has been developed for applying large amounts of agricultural limestone to steeply sloping land. Small quantities of lime can be applied with a hydroseeder to steep slopes. Finely ground limestone or hydrated lime may be mixed with water to form a slurry. Repeated applications may be necessary to achieve high rates per acre. The cost of repeated treatments could make this procedure impractical. Alkaline power plant fly ash and bottom ash are neutralizing materials, but they are usually not as effective as limestone. Fly ash contains various quantities of essential plant nutrients, such as phosphorus, zinc, molybdenum, and boron. However symptoms of boron toxicity have been observed on plants growing on sites treated with large amounts of fly ash. Rock phosphate provides a slowly available source of phosphorus and helps to neutralize acidity. Spoil acidity may react with rock phosphate to slowly release plant-available phosphorus.

Fertilization is generally recommended for grass and legume crops. Nitrogen and phosphorus have been used to accelerate the growth of trees on spoils. Tests show that most spoils are deficient in nitrogen. Phosphorus occurs in various concentrations, but deficiencies often limit plant growth. Potassium is usually adequate. There is little information about the concentrations of other nutrients. For most land-management objectives, the formulation of the fertilizer makes little difference when equivalent rates are applied. High-analysis fertilizers, ammonium nitrate, triple superphosphate, and ammonium phosphate are often preferred. Using low-analysis fertilizers on sites that require high rates of application may increase the total soluble-salt concentration to levels toxic to some plants.

Rates of fertilization vary with the seeded crop, the inherent fertility of the spoil, and the land-management objective. Nitrogen and phosphorus at 50 and 22 pounds per acre (56 and 246 kilograms per hectare) respectively, are sufficient to establish grass on many spoils. Higher rates of phosphate are important for legumes. More consideration is being given to retreatment at regular intervals. Multiple treatments are attractive because they reduce the chance of unacceptable cover and increase the probability of achieving land use objectives within the shortest time.

Much research on fertilizer application remains to be done. Research results thus far show that placing selected fertilizers in or near the planting hole increases the growth of black locust. This leguminous species responded to additions of nitrogen and phosphorus placed near seedlings on extremely acid spoil. In other trials, direct-seeded black locust made more rapid growth after surface applications of nitrogen and phosphorus. Five tons of lime per acre per foot of soil increased the growth of loblolly, shortleaf, Virginia, and a hybrid (pitch/loblolly) pine planted in extremely acid spoil. Pitch pine did not respond to the liming treatments. Ten tons of lime per acre-foot reduced the growth of the pines.

Municipal waste products have been considered for surface-mine reclamation. Waste applications could improve soil texture, add essential plant nutrients, and provide mulch for seed and seedlings. Shredded or composited waste could be applied to the surface, and mechanical methods could be used to incorporate it into the spoil. Sewage sludge can be applied in water slurry or in dried form. Mixtures of shredded or composted waste and sewage sludge offer another possibility. Thus far, use of these materials has been restricted to relatively small demonstration areas for public health reasons.

Seeding and Planting

For each of the major coal-producing regions in the United States, there is a group of preferred plant species. These may be grouped under four major categories: (1) grasses; (2) forbs; (3) trees; and (4) shrubs. The grasses and forbs may be further classified as (a) temporary; (b) semipermanent; and (c) permanent, depending on life expectancy of the plant. Temporary species give prompt and effective site protection by reason of quick growth, fibrous roots, and ability to endure unfavorable site conditions. Semipermanent species are perennials that will be ultimately replaced by permanent vegetation. Under favorable conditions, permanent species will persist for many years.

The grasses are a varied group of plant species well suited to surface-mine restoration. Experience has shown that many grasses are adapted to wide ranges of climate, spoil texture, nutrient regimes, and toxic ion concentrations. Germination is usually rapid, and growth often produces a crop, or at least site protection, during the first growing season. Annual grasses often grown as agricultural crops may be used to provide quick site protection. These temporary quick-cover crops also may serve as nurse crops for slower-developing perennials. Some species are better adapted to summer seeding; others should be seeded in the fall.

Leguminous forbs are considered by many to be essential components of ground-cover mixtures. The fixation of atmospheric nitrogen by the legumes benefits associated plants. This assists in maintaining a vigorous ground cover and may reduce the need for retreatment. The leguminous forbs generally are less tolerant of toxic ion concentrations and require more phosphorus than the grasses.

Forbs not classified as legumes are being evaluated in the western United States. The emphasis is on species that are components of natural vegetative cover and are common invaders of disturbed areas. Initial evaluations indicate that some species may be useful for surface-mine revegetation.

Inoculation with specific strains of rhizobium bacteria stimulates nodulation on leguminous forbs. Commercial inoculants are available for the important legume species. Rhizobium bacteria may not survive or produce effective nodules in acidic spoils with pH below 5.0.

Grass and legume ground covers reduce tree growth, but this is often unavoidable because some state laws and regulations require a herbaceous cover. Manipulation of the species composition and reduction of ground-cover density may minimize the adverse effects.

Trees are often planted by hand, using one of several planting tools. On selected spoils, machine planting is possible. Most planting stock is small, 1 to 2 years old, and bare-rooted. Spacing between trees varies by species, site characteristics, and end-objectives. Plantings may be mixtures of several species, or pure plantings of one species. The arrangement may be random or designed to protect seedlings from environmental extremes. There is increasing interest in the establishment of trees by direct seeding. Success has been achieved with several pine species in Alabama. Black locust is used in West Virginia and Kentucky, The planting of shrub species has not been emphasized in surface-mine revegetation. Shrubs have little tangible value; benefits accrue from site protection, wildlife food and cover, and aesthetics.

Costs of Refuse Disposal and Land Reclamation

A predominant advantage of so-called strip mining over underground mining over the years and particularly with reference to smaller, previously unestablished mining operations, has been one of economics. Obviously, as costs of reclamation of stripped areas and of improved surface mining techniques are added to strip mining costs, the differential becomes much less. Past despoilage of the land thus has resulted from comparative economics. While some progressive operators have reduced their profits in order to lessen the damage to the land, such voluntary action is simply more than can be expected on a massive scale. Concerns with land spoilage prevention and reclamation of spoiled lands, unfortunately, are coincident timewise with a growing demand for coal. This, in the early 1980s, hardly felt the impact of the numerous coal conversion programs most of which were still under test and development for the gasification and liquefaction of coal in terms of the new coal technology for supplanting waning supplies of natural gas and petroleum energy sources. The practical, interim solution to the energy/environment problem must be one of compromise.

Note: See references listed at end of article on **Coal**.

The cooperation of W. T. Plass of the U.S. Dept. of Agriculture Forest Service, Northeastern Forest Experimentation, Princeton, West Virginia in making information available for this summary is gratefully acknowledged.

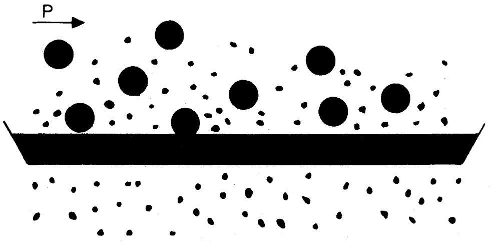
REVERSE OSMOSIS. A method for separating inorganic salts and simple organic compounds under pressure. The size of the species usually is considered in terms of molecular weight. Solvent transport through reverse-osmosis membranes is substantially diffusive in nature. The membranes used are anisotropic (thin-skinned, overlaying a porous substructure). In all probability, the skin contains no pores. If water is the solvent phase, the water passes through the membrane by true diffusion. At some point in its passage through the membrane, the solvent water actually becomes a part of the membrane water structure. As low-molecular-weight solutes exhibit osmotic pressure when concentrated, system pressure in excess of the osmotic pressure of the concentrated solutes must be applied to create a pressure driving force. Depending upon materials being separated and membrane used, reverse osmosis system pressures may range from 200 to nearly 1500 pounds per square inch (13.6 to 102 atmospheres), but the lower values are most frequently encountered.

It has been well appreciated for many years that reverse osmosis concentration has considerable potential in the chemical and food processing field. Reverse osmosis is used for processing whey. A new approach to the production of protein isolates and concentrates from oilseed flour combines ultrafiltration and reverse osmosis. See also **Ultrafiltration**. In 1977, this process was optimized for use with soy flour. The process uses semipermeable membranes to directly process protein extracts from defatted soy flour. Some researchers have found that essentially all the solubilized protein is recovered and the generation of wheylike products is avoided. Other desirable features of the combined ultrafiltration/reverse osmosis process include its shorter time span, increased yield of isolate (since whey proteins are harvested along with proteins normally precipitated), and the enhanced nitrogen solubility of the products. For the ultrafiltration part of the system, second-generation, noncellulosic membranes have been used. The membranes used in reverse osmosis are cellulose-based because noncellulosic reverse osmosis membranes have not been fully developed. Cellulose acetate membranes are generally restricted to operating temperatures below about 50°C and a pH of less than 9.

Japanese researchers have developed a method for washing membranes and overcoming the adhesive effects of mandarin orange juice fouling on reverse osmosis membranes. The importance of keeping fluxes high by controlling concentration polarization and membrane fouling has been observed by several researchers. Other observers have noted that high axial velocities and turbulence promoters minimize the flux decrease caused by concentration polarization and fouling. Considerable research has been undertaken as regards the energy requirements for reverse-osmosis process and these are reviewed in some of the references listed.

Molecular diffusion in reverse osmosis is represented schematically in the accompanying diagram.



Schematic representation of molecular diffusion in reverse osmosis.

REYNOLDS NUMBER. A dimensionless number that establishes the proportionality between fluid inertia and the sheer stress due to viscosity. The work of Osborne Reynolds has shown that the flow profile of fluid in a closed conduit depends upon the conduit diameter, the density and viscosity of the flowing fluid, and the flow velocity.

Pipe Reynolds number, R_D, is the dimensionless ratio, $VD\gamma/g\mu_e$,

where V = Velocity in any units consistent with the rest of the equation
D = Inside diameter of the conduit (pipe)
γ = Specific weight in any units consistent with the rest of the equation
g = Acceleration of gravity, feet/second^2
μ_e = Absolute viscosity, pound-second/feet^2

The foregoing equation is inconvenient for commercial use because commonly used units of measurement are rarely consistent. Two alternative equation forms are:

$$R_D = \frac{6.32 \times \text{Rate of Flow (pounds/hour)}}{\text{Pipe Diameter (inches)} \times \text{Absolute Viscosity (centipoise)}} \quad (1)$$

$$R_D = \frac{52.77 \times \text{Rate of Flow (gallons/hour at flowing temperature)}}{\text{Pipe Diameter (inches)} \times \text{Kinetic Viscosity (centistokes)}} \quad (2)$$

Flow generally is considered to be fully laminar at Reynolds numbers below 1500; in transition between 1500 and 4000; and turbulent above 4000. Thus, the Reynolds number is a most useful tool in constructing piping system designs and in sizing flowmeters. Orifice or throat Reynolds number, $R_d = R_D/d/D$, where d = diameter of orifice bore (inches); D = inside diameter of conduit or pipe (inches).

Another general way of expressing Reynolds number is by the ratio

$$\frac{\text{Scale Velocity} \times \text{Scale length}}{\text{Kinematic Viscosity}}$$

This also is referred to as the Reynolds criterion. Reynolds numbers are only comparable when they refer to geometrically similar flows; and, provided that all the boundary conditions can be described by the scale velocity and scale length, flows of the same Reynolds number are dynamically similar. For an airfoil, it is

$$\frac{\text{Air Velocity} \times \text{Chord of the Airfoil}}{\text{Kinematic Viscosity of the Air}}$$

Reynolds numbers are of value in the various fields because tests of models are directly comparable to full-scale results of geometrically similar shapes if the Reynolds ratio for the model equals that of the actual or full-scale project. This has its practical applications in the field of hydrodynamics, in the study of water resistance of hulls or floats, and in the study of water velocities, levee problems, etc., of large rivers. It is used also to establish the best proportions of hydraulic turbines through the use of models. Much of the science of aeronautics rests upon experimental data obtained in wind tunnels. Dangerous inaccuracies might exist in drawing conclusions for actual construction from model tests, unless either the model were tested at a Reynolds number equal to that of the completed project, or due corrections and allowances were made for the Reynolds number. See also **Heat Transfer**.

RHENIUM. [CAS: 7440-15-5]. Chemical element, symbol Re, at. no. 75, at. wt. 186.2, periodic table group 7, mp 3180°C, bp 5627°C, density

21.04 g/cm^3 (20°C). Elemental rhenium has a close-packed hexagonal crystal structure.

Rhenium is a platinum-white, very hard metal; stable in air below 600°C (at this temperature, the metal begins to generate a white, nonpoisonous, vaporous oxide, Re_2O_7); practically insoluble in HCl or hydrofluoric acid, but soluble in HNO_3 with the formation of perrhenic acid; forms sodium rhenate when fused with NaOH and nitrate. Discovered by Noddack and Tacke in 1925 in tantalite, wolframite, and columbite by the Moseley X-ray spectrographic method of analysis, and later found present in molybdenite, from which rhenium is obtained. Predicted by Mendeleev, in 1871, as an element to be discovered with properties resembling manganese, and named by him dvi-manganese.

There are two natural isotopes, ^{185}Re and ^{187}Re, of which the latter is radioactive with respect to beta decay, having a half-life of 5×10^{10} years reverting to ^{187}Os. Other radioactive isotopes include ^{177}Re, ^{178}Re, ^{180}Re, ^{183}Re, ^{184}Re, ^{186}Re, ^{188}Re, and ^{189}Re. The latter isotope has a long half-life, something less than 10^3 years; the half-lives of the remaining isotopes are comparatively short, measured in minutes, hours, or days.

Because Re and Os are highly refractory and siderophilic elements, the Re-Os isotope system is important in studies concerned with metal phases and high-temperature inclusions of meteorites. R.J. Walker (Carnegie Institute of Washington) and J.W. Morgan (U.S. Geological Survey) observe, "Potential applications of the system include dating meteorites, especially with respect to the chronology of the assembly and subsequent metamorphism of genetically disparate components, and providing estimates of the initial Os isotopic composition and Re/Os ratio of the early earth. This ratio is an important chemical tracer for understanding the formation of the earth's core and the chemical evolution of the mantle and crust."

In terms of abundance, rhenium ranks 75th among the elements, based upon estimated contents of the universe. Rhenium is not plentiful in the earth's crust, being essentially confined to association with the mineral molybdenite. First ionization potential, 7.87 eV. Oxidation potentials $Re + 4H_2O \rightarrow ReO_4^- + 8H^+ + 7e^-$, −0.15 V; $Re + 8OH^- \rightarrow ReO_4^- + 4H_2O + 7e^-$, 0.81 V. Other important physical properties of rhenium are given under **Chemical Elements**.

Rhenium is a minor constituent (100 ppb) of molybdenite-bearing porphyry copper ores, of which there is extensive mining in the United States and South America. Commercial rhenium is recovered from by-product molybdenum. As the result of roasting MoS_2 and MoO_3, the rhenium is concentrated to levels of 300–1,000 ppm. At the high process temperatures, the rhenium is oxidized and volatilized as rhenium heptoxide, Re_2O_7. This compound is recovered from flue gases by way of wet scrubbing and chemical separation techniques as the relatively crude ammonium perrhenate. The latter compound is reduced with hydrogen to produce rhenium metal.

Uses

Rhenium finds rather wide use as a catalyst in selective hydrogenation and other chemical reactions. It sometimes is used in conjunction with platinum in reforming operations. Additional processes for which rhenium has been tested and used as a catalyst include alkylation, de-alkylation, dehydrochlorination, dehydrogenation, dehydroisomerization, enrichment of water, hydrocracking, and oxidation. The outstanding feature of rhenium catalysts is their high selectivity, very important in hydrogenation reactions. Rhenium catalysts also resist such catalyst poisons as nitrogen, sulfur, and phosphorus. In terms of activity, rhenium commonly surpasses cobalt, molybdenum, and tungsten type catalysts and approximates palladium, nickel, and platinum catalysts.

Because of the very heavy ionic weight (250) of the perrhenate ion, it is one of the heaviest simple anions obtainable in readily soluble salts. It has found use as a precipitant for potassium and some other heavy univalent ions; also as a precipitant for such complex ions as $Co(NH_3)_6^{2+}$, and for the separation of alkaloids and organic bases. Perrhenate also is used in the fractional crystallization of the rare-earth elements.

When rhenium is added to other refractory metals, such as molybdenum and tungsten, ductility and tensile strength are improved. These improvements persist even after heating above the recrystallization temperature. An excellent example is the complete ductility shown by a molybdenum-rhenium fusion weld. Rhenium and rhenium alloys have gained some acceptance in semiconductor, thermocouple, and nuclear reactor applications. The alloys also are used in gyroscopes, miniature rockets, electrical contacts, electronic-tube components, and thermionic converters.

Because rhenium is very difficult to machine with carbide tools and other conventional methods, electrical-discharge machining (EDM), electrochemical machining (ECM), abrasive cutting, or grinding is recommended.

Rhenium can be consolidated by powder metallurgy techniques, inert-atmosphere arc melting, and thermal decomposition of volatile halides. In the powder metallurgy process, bars are pressed at 200 MPa, and this is followed by vacuum sintering at 1200°C and hydrogen sintering at 2700°C. Rhenium is usually fabricated from sintered bar by cold working, following by annealing. Reductions of 10–20% can be taken with intermediate anneals for one to two hours at 1700°C. Primary working is by rolling, swaging, or forging. Wire drawing is possible down to 2 mils for strip and wire. Because of its excellent ductility at room temperature, rhenium is suitable for forming of complex shapes (Knipple, 1979).

The cost and scarcity of pure rhenium preclude its extensive use for large structural components. Typical applications include wear-resistant electrical contacts and mass spectrometer cathodes. Rhenium also is being studied for use in the reactor core of space nuclear power systems as, for example, fuel-pin liners that prevent interaction with the fuel and also provide high neutron capture under some operating conditions. Rhenium coatings are used to enhance the heat resistance of carbon and graphite parts in low-oxygen environments. Tungsten and molybdenum alloys containing rhenium have been used for heating elements, compact electromagnetic coils, high-temperature thermocouples, anti-friction and wear parts, and high-temperature elastic elements. Rhenium and rhenium-containing alloys are principally produced by powder metallurgy. The use of vacuum or inert-gas atmosphere melting or chemical vapor deposition processes tend to be cost prohibitive.

As observed by B.D. Bryskin (Sandvik Rhenium Alloys Inc., Elyria, Ohio), "Rhenium has poor oxidation resistance, but is chemically inert in most oxygen-free atmospheres. When it oxidizes in air, Re_2O_7 is emitted as a white smoke. When hot worked in air, rhenium is embrittled by grain boundary penetration of liquid-phase oxide. Consequently, hot deformation of Re is practical only in a nonoxidizing protective atmosphere (hydrogen or vacuum), or if the workpiece is encapsulated by an oxidation-resistant material. Rhenium is unique among refractory metals in that it does not form a stable carbide. The solubility for carbon is rather high, resulting in a eutectic melting point at about 2773 K (2500°C; 4530°F) and 0.085% (wt) carbon." Further excellent application information is given in the Bryskin reference listed.

Chemistry and Compounds

Rhenium has a $5d^5 6s^2$ electron configuration and all oxidation states from 0 to 7+ are known, although the heptavalent is the most stable state.

The supposed compounds of Re(−I), formulated as $M^I\ Re(H_2O)_4$, have been shown actually to be tetrahydrorhenates(III), e.g., potassium tetrahydrorhenate, $KReH_4$. These compounds are obtained by reducing potassium perrhenate, in a solution of water and ethanolamine, with the alkali metal. In addition to these compounds, however, rhenium differs from its congener manganese in that it forms more compounds that are in the higher valence group. Instead of the larger number of divalent compounds formed by manganese, the stable compounds of rhenium begin with the trivalent ones. The oxides include Re_2O_3, ReO_2, ReO_3, and Re_2O_7. The heptoxide differs from the corresponding manganese compound in its stability, as does the acid obtained by its reaction with water, perrhenic acid, $HReO_4$. Perrhenic acid is a strong acid ($pK_A = 1.25$), but not as strong an oxidizing agent as the permanganic acid. Rhenium dioxide is obtained by reduction of perrhenic acid or rhenium heptoxide, and thermal decomposition of the dioxan addition product of the latter yields rhenium trioxide, ReO_3.

Rhenium forms a number of halides and oxyhalides. Direct reaction by heating with chlorine yields $ReCl_5$, but heating that compound in a nitrogen atmosphere yields $ReCl_3$. $ReCl_4$ and $ReCl_6$ are also known. Direct reaction by heating with fluorine carries the halogenation further, to ReF_6 and ReF_7, which may be reduced to ReF_4. Direct reaction by heating with bromine yields $ReBr_3$. Reaction of the halides with oxygen, or the oxides or oxyacid salts with halogen-containing substances yields a considerable number of oxyhalogen compounds, e.g., $ReOF_4$, ReO_2F_2, ReO_2Cl_2, ReO_2Br_2, ReO_3F and $ReO_3Cl \cdot ReO_3F$ may also be prepared by the action of liquid HF on $KReO_4$ and ReO_3Cl may be prepared by reaction of ReO_3 and Cl_2.

The complexes of rhenium have not been studied as extensively as those of manganese. Among the known complex ions are $Re(NH_3)_6^{3+}$,

$Re(CN)_6^{3-}$, $Re(CN)_8^{4-}$, $Re(CN)_8^{3-}$, $ReO_2(CN)_4^{2-}$, $ReCl_4^-$, ReF_6^{2-}, $ReCl_6^{2-}$, $ReBr_6^{2-}$ and ReI_6^{2-}.

The sulfides include ReS_2 and Re_2S_7.

Unlike manganese, rhenium is reported to form an alkyl compound, trimethyl rhenium, $Re(CH_3)_3$. Like manganese, it forms a dirhenium compound with carbon monoxide, $(CO)_5ReRe(CO)_5$, as well as hydrogen-halogen and alkyl-carbonyl compounds. It also forms a dicyclopentadienyl compound, $(C_5H_5)ReH$.

RHEOLOGY. The study of the response of materials to an applied force. Rheology deals with the deformation and flow of matter.

Heraclitus, a pre-Socratic metaphysician, recognized in the fifth century B.C. that *πάνταρεί*, or "everything flows." Long before Heraclitus, the prophetess Deborah, fourth judge of the Israelites, had sung that "the mountains flowed before the Lord" in celebrating the victory of Barak over the Canaanites (*Judges* 5:5). Reiner (1964) proposed the dimensionless quantity D (for *Deborah*), where:

$$D = \frac{\text{time of relaxation}}{\text{time of observation}} = \frac{\tau}{t} \tag{1}$$

The difference between solids and liquids is found in the magnitude of D. Liquids, which relax in small fractions of a second, have small D. Solids have a large D. A sufficient time span can reduce the Deborah number of a solid to unity, and impact loading can increase D of a liquid. Viscoelastic materials are best characterized under conditions in which D lies within a few decades of unity.

Force Balance Equation

When a force f is applied to a body, four things may happen. The body may be accelerated, strained, made to flow, or slide along another body. If these four responses are added, one can write an expression for motion in one direction:

$$f = m\ddot{x} + r\dot{x} + sx - f_0 \tag{2}$$

where m is the mass, r is a damping parameter related to viscosity, s to elasticity, and f_0 to the yield value. Evaluation of the coefficients $m, r,$ and s involves the measurement of displacements x and their time derivatives in a manner which links these kinematic variables via an equation of state, such as given in Eq. (2), to stress σ (force per unit area) and its time derivatives.

Scope of Rheology

In contrast to the discipline of mechanics, wherein the responses of bodies to unbalanced forces are of concern, rheology concerns balanced forces which do not change the center of gravity of the body. Since rheology involves deformation and flow, it is concerned primarily with the evaluation of the coefficients r and s of Eq. (2). The coefficients account for most of the energy dissipated and stored, respectively, during the process of distorting a body. Most rheological systems lie between the two extremes of ideality—the Hookean solid and the Newtonian liquid.

Measurements of Viscosity and Elasticity in Shear (Simple Shear)

Shear viscosity η and shear elasticity G are determined by evaluating the coefficients of the variables $\dot{x}$ and x, respectively, which result when the geometry of the system has been taken into account. The resulting equation of state balances stress against shear rate $\dot{\gamma}$ (reciprocal seconds) and shear γ (dimensionless) as the kinematic variables. For a purely elastic, or Hookean, response:

$$\sigma = G\dot{\gamma} \tag{3}$$

and for a purely viscous, or Newtonian response:

$$\sigma = \eta\dot{\gamma} \tag{4}$$

As a consequence, G can be measured from stress-strain measurements, and η from stress-shear rate measurements.

Elasticoviscous behavior is described in terms of the additivity of shear rates:

$$\dot{\gamma} = \frac{\sigma}{\eta} + \frac{\dot{\sigma}}{G} \tag{5}$$

whereas viscoelastic behavior is characterized by the additivity of stress, according to Eq. (2);

$$\sigma = G\gamma + \eta\dot{\gamma} \tag{6}$$

Relaxation

Numerous attempts have been made to fit simplified mechanical models to the two behavior patterns described by Eq. (6). One can picture the elastic element as a spring-arrayed network parallel with the viscous element to give essentially a (Kelvin) solid with retarded elastic behavior, wherein:

$$\frac{\eta_k}{G_k} = \text{retardation time (sec)} \tag{7}$$

or as a (Maxwellian) series network which flows when stressed or relaxes, under constant strain:

$$\frac{\eta_m}{G_m} = \text{relaxation time (sec)} \tag{8}$$

and transient experiments may be designed to measure these parameters singly. In real systems, a single relaxation (or retardation) time fails to account for experimental results. A distribution of relaxation time exists.

Dynamic Studies

When Eq. (2) is written in the form:

$$\ddot{x} + 2k\dot{x} + \omega_1^2 x = 0 \tag{2b}$$

the equation suggests that the variation in stress should be cyclic. Rheometers are designed so that the system may oscillate in free vibration of natural resonant frequency ω_1, or else so that a cyclic shearing stress of the form $f_0 \cos \omega t$ is impressed on the sample over a frequency range which spans ω_1. In neither case is the material strained beyond its range of linearity. Equation (2b) represents a damped harmonic oscillator, providing that the coefficients are constant (i.e., providing that they do not depend on the strain magnitude). Not all systems meet this requirement in the strict sense, with the result that one of the first checks the experimenter makes is for linearity. Doubling the amplitude of oscillation should double the stress and should not change the phase relationships between the cyclic stress and the deformation.

Time-Temperature Equivalence (Steady-State Phenomena)

The creep of a viscoelastic body or the stress relaxation of an elasticoviscous one is employed in the evaluation of η and G. In such studies, the long-time behavior of a material at low temperatures resembles the short-time response at high temperatures. A means of superimposing data over a wide range of temperatures has resulted which permits the mechanical behavior of viscoelastic materials to be expressed as a master curve over a reduced time scale covering as much as twenty decades (powers of ten).

Polymeric materials generally display large G values (10^{10} dynes/cm^2 or greater) at low temperatures or at short times of measurement. As either of

these variables is increased, the modulus drops slowly at first, then attains a steady rate of roughly one decade drop per decade increase in time. If the material possesses a yield value, this steady drop is arrested at a level of G which ranges from 10^7 downward.

Dynamic Behavior

The application of sinusoidal stress to a body leads inevitably to the complex modulus G^*, where

$$G^* = G' + iG'' = G' + i\omega\eta' \tag{9}$$

where G' is the in-phase modulus $(\sigma/\dot{\gamma})$ which represents the stored energy, and G'' is the out-of-phase modulus $(\sigma/\dot{\gamma})$ representing dissipated energy (as its relation to η suggests); the variable against which G' and η' are determined is the circular frequency ω. Superposition of variable temperature data or variable frequency data provides a master curve of the type previously described for steady-state parameters.

Problems in Three Dimensions (State of Stress)

The forces and stresses applied to a body may be resolved in three vectors, one normal to an arbitrarily selected element of area and two tangential. For the yz plane, the stress vectors are σ_{xx} and σ_{xy}, σ_{xz}, respectively. Six analogous stresses exist for the other orthogonal orientations, giving a total of nine quantities, of which three exist as commutative pairs $(\sigma_{rs} = \sigma_{sr})$. The state of stress, therefore, is defined by three tensile or normal components $(\sigma_{xx}, \sigma_{yy}, \sigma_{zz})$ and three shear or tangential components $(\sigma_{xy}, \sigma_{xz}, \sigma_{yz})$. The shear components are most readily applicable to the determination of η and G.

Strain Components

For each stress component σ there exists a corresponding strain component γ. Even for an ideally elastic body, however, a pure tension does not produce a pure γ_{xx} strain; γ components exist which constrict the body in the y and z directions.

The complete stress-strain relation requires the six σs to be written in terms of the six γ components. The result is a 6×6 matrix with 36 coefficients k_{rs} in place of the single constant. Twenty-one of these coefficients (the diagonal elements and half of the cross elements) are needed to express the deformation of a completely anisotropic material. Only three are necessary for a cubic crystal, and two for an amorphous isotropic body. Similar considerations prevail for viscous flow, in which the kinematic variable is $\dot{\gamma}$.

Applications

The study of rheology is important to many sciences and technologies. Numerous instruments have been constructed to make manual, semiautomatic, and automatic measurements (and control) of such variables as viscosity, and consistency (flowability). These variables are particularly important in the food processing, chemical, and plastics industries, where many of the products and intermediates lie between Hookean solids and Newtonian liquids. Consistency measurement is of large importance in the paper manufacturing industry. See also **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

Some terms commonly used in industry include:

Newtonian Substance. Fundamentally, liquids or suspensions in liquids when subjected to a shear stress behave in two ways: (1) A Newtonian substance undergoes deformation, the ratio of shear rate (flow) to shear stress (force) is constant. See Fig. 1.

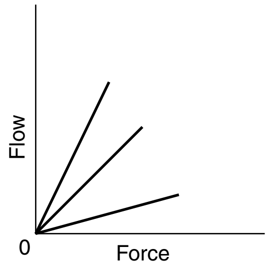

Fig. 1. Behavior of Newtonian substances

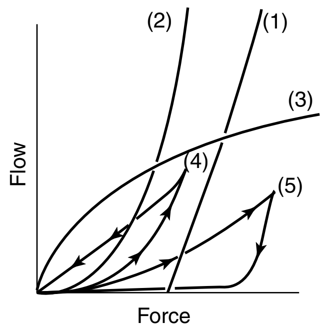

Fig. 2. Behavior of non-Newtonian substances: (1) true plastic (sometimes called a Bingham body); (2) pseudo plastic; (3) dilatant; (4) thixotropic; and (5) rheopectic

Non-Newtonian Substance. (2) In a non-Newtonian substance, the ratio of shear rate to flow is not constant. See Fig. 2.

Dilatant. The initial flow of a dilatant substance under a low shear stress is at a high rate; further increases in shear stress result in a lower flow rate. A dilatant substance is sometimes called an inverted plastic or inverted pseudoplastic.

Pseudoplastic. A material of this type appears to have a yield stress beyond which flow commences and increases sharply with increase in stress. In practice, such substances are found to exhibit flow at all shear stresses, although the ratio of flow to force increases negligibly until the force exceeds the apparent yield stress.

Thixotropic. The flow rate of a thixotropic substance increases with increasing duration of agitation, as well as with increased shear stress. When agitation is stopped, internal shear stress exhibits hysteresis. Upon reagitation, generally less force is required to create a given flow than is required for first agitation.

Rheopectic. If certain thixotropic suspensions are rhythmically shaken or tapped, they will "set" or build up very rapidly, a phenomenon termed rheopexy. Apparent viscosity of a rheopectic substance increases with time (duration of agitation) at any constant shear rate.

See Table 1. See also **Colloid Systems**; **Fluid and Fluid Flow**; **Stoke's Law**; **Viscoelasticity**; and **Viscosity**.

RHODIUM. [CAS: 7440-16-6]. Chemical element, symbol Rh, at. no. 45, at. wt. 102.906, periodic table group 9, mp. 1,963 to 1,969°C, bp. 3,627 to 3,827°C, density 12.44 g/cm^3 for solid (20°C). Elemental rhodium has a face-centered cubic crystal structure. The one stable isotope is ^{103}Rh. The seven unstable isotopes are ^{99}Rh through ^{101}Rh and ^{104}Rh through ^{107}Rh. In terms of earthly abundance, rhodium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for rhodium at 0.0067. No notable presence of rhodium in seawater has been found.

Electronic configuration is $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^85s^1$. Ionic radii Rh^{3+} 0.75 Å, Rh^{4+} 0.65 Å. Metallic radius 1.345 Å. First ionization potential 7.7 eV. Other physical properties of rhodium will be found under **Platinum and Platinum Group**. See also **Chemical Elements**.

Rhodium was discovered by Wollaston (England) in 1803. Compact Rh is almost insoluble in all acids at 100°C, including aqua regia. Hot concentrated H_2SO_4 will slowly dissolve the finely divided metal. When alloyed with 90% or more of Pt, it is soluble in aqua regia. The metal is attacked by fused bisulfates. Rh is soluble in molten Pb. This is the basis of the classic separation of Rh and Ir.

Rh compounds exhibit valences of 2, 3, 4, and 6. The trivalent form is by far the most stable. When Rh is heated in air, it becomes coated with a film of oxide. Rhodium(III) oxide, Rh_2O_3, can be prepared by heating the finely divided metal or its nitrate in air or O_2. The rhodium(IV) oxide is also known. Rhodium trihydroxide may be precipitated as a yellow compound by adding the stoichiometric amount of KOH to a solution of $RhCl_3$. The hydroxide is soluble in acids and excess base. When the freshly precipitated $Rh(OH)_3$ is dissolved in HCl at a controlled pH, a yellow solution is first obtained in which the aquochloro complex of Rh behaves as a cation. The hexachlororhodate(III) anion is formed when the solution is boiled for 1 hour with excess HCl. The solution chemistry of $RhCl_3$ is often very complex. Two trichlorides of Rh are known. The trichloride formed by high-temperature combination of the elements is a red, crystalline, nonvolatile compound, insoluble in all acids. When Rh is heated in molten NaCl and treated with Cl_2, Na_3RhCl_6 is formed, a soluble salt that forms a hydrate in solution. Rhodium(III) iodide is formed by the addition of KI to a hot solution of trivalent Rh.

Rhodium(III) sulfate exists in yellow and red forms. If $Rh(OH)_3$ is dissolved in cold H_2SO_4, the product is the yellow form, in which the sulfate is ionic. If this solution is evaporated in hot H_2SO_4, the product is a red, nonionic sulfate. When Rh is treated with F_2 at 500–600°C, RhF_3 is slowly formed. This compound is practically insoluble in water, concentrated HCl, HNO_3, H_2SO_4, HF, or NaOH.

If a solution of $RhCl_3$ is treated with $NaNO_2$, the very soluble sodium hexanitritorhodate(III), $Na_3Rh(NO_2)_6$, is formed. The solubility of this compound in alkaline solution makes it useful for refining, as many base metals are precipitated as their hydroxides under these conditions. The analogous ammonium and potassium salts are relatively insoluble.

When H_2S is passed into a solution of a trivalent Rh salt at 100°C, the hydrosulfide, $Rh(SH)_3$, is formed. This black precipitate is insoluble in $(NH_4)_2S$. Rh forms many complexes with NH_3, amines, cyanide, chloride, bromide, and numerous polynitrogen and polyoxygen chelating agents.

EDITOR'S NOTE: In 1982, J. Halpern (University of Chicago) reported that rhodium complexes containing chiral phosphine ligands catalyze the hydrogenation of olefinic substrates such as alpha-aminoacrylic acid derivatives, producing chiral products with very high optical yields. Elucidation of the mechanisms of such reactions leads to the conclusion that the stereoselection is dictated not by the preferred initial binding of the substrate to the chiral catalyst, but rather by the much higher reactivity of the minor diastereomer of the catalyst-substrate adduct corresponding to the less favored binding mode. In the Halpern 1982 reference listed, a relatively restricted class of asymmetric catalytic reactions, namely, the hydrogenation of alpha-acylaminoacrylic acid derivatives and related substrates, catalyzed by rhodium complexes containing chiral phosphine ligands, is discussed.

RHODOCHROSITE. Rhodochrosite, manganese carbonate, $MnCO_3$, is a rose-pink to red hexagonal mineral, occurring as small crystals, in cleavable masses, granular or compact. It is a brittle mineral; hardness, 3.5–4; specific gravity, 3.7 (pure $MnCO_3$, usually 3.4–3.6); luster, vitreous to pearly; color, various shades of pink, red and reddish-brown; transparent to opaque; streak, white. Rhodochrosite has a perfect rhombohedral cleavage. Rhodochrosite is a product of high-temperature metamorphic deposits; as a gangue mineral in ore veins of hydrothermal origin, and as secondary residual deposits from bodies of manganese or iron oxides, and in sedimentary deposits precipitated like siderite by organic matter acting, in the absence of oxygen, upon bicarbonates.

Spectacular, gemmy red rhombohedrons, up to 3 inches (7.5 centimeters) on an edge occur at the Sweet Home Mine, Alma, Colorado, and the John Reed Mine, Alicante, Colorado. Exceptionally fine stalactitic formations are found in Catamarca Province, Argentina. Recently the most beautiful, large transparent gem red scalenohedron crystals ever found have come from Hotazel and the Kalahari manganese field in northern Cape Province, South Africa. This region encompasses one of the largest and richest known manganese deposits in the world. Other localities for this mineral are in Rumania, Saxony, Westphalia, and Cornwall, England. In the United States rhodochrosite is found at Franklin, New Jersey; Butte Montana; and in various localities in Colorado and Nevada. The name rhodochrosite is derived from the Greek meaning rose, and color.

RHODONITE. The mineral rhodonite, manganese metasilicate, (Mn,Fe, Mg)SiO_3, crystallizes in the triclinic system forming large, irregular tabular crystals but usually occurring massive. Prismatic and basal cleavages excellent; fracture conchoidal to uneven; hardness, 5.5–5.6; specific gravity, 3.57–3.76; luster, vitreous to pearly on cleavage faces; color, red to brownish-red; rarely yellow to gray; streak, white; transparent to translucent. A variety containing much calcium is called bustamite. Zinc may replace the manganese in rhodonite; it is then known as fowlerite. Rhodonite is found in the Harz Mountains, Germany; in the Urals of the former U.S.S.R.; in Hungary, Italy, and Sweden. Bustamite from Mexico, Franklin and Sterling Hill, New Jersey, occurs with fowlerite.

Rhodonite has been occasionally used for an ornamental stone. Its name is derived from the Greek meaning a rose, because of the color.

RIBONUCLEASE. An enzyme that causes splitting of ribonucleic acid. Pancreatic ribonuclease for example, cleaves only phosphodiester bonds

that are linked to pyrimidine-3′-phosphates. It is a critical regulator of life processes in the cell. The first enzyme to be synthesized (1969), it is composed of 124 amino acid residues. It is one of the proteins for which the sequence of amino acids has been elucidated (the order of sequence of amino acids is of critical importance in the functioning of enzymes, genes, and nucleotides).

See also **Genetic Code**; and **Genetics and Gene Science (Classical)**.

RIBONUCLEIC ACID (RNA). See **Genetics and Gene Science (Classical)**.

RIBOSOME. A ribonucleoprotein, the smallest organized structure in the cell. Ribosomes occur in all cells including bacteria, fungi, algae, and protozoa. They are the central point of protein synthesis. They contain from 45 to 60% of ribonucleic acid (RNA), the balance being proteins. Ribsome crystals have been produced; in the electron microscope these appear as sheets of black dots, each sheet (one ribosome thick) containing hundreds of ribosomes in recurring groups of four.

See also **Genetics and Gene Science (Classical)**.

RICHARDS, THEODORE W. (1868–1928). An American chemist born in Germantown, PA. He was the first American to receive the Nobel prize in chemistry (in recognition of his accurate determinations of the atomic weight of a large number of chemical elements). He studied chemistry at Haverford and Harvard, with a doctorate in chemistry from Harvard where he later became Erving Professor of Chemistry. An outstanding experimental chemist, his major interests were atomic weights, thermochemistry, and thermodynamics. He was also a brilliant teacher. He was president of the ACS in 1914, and the recipient of many honorary awards, including the Davy, Faraday, and Gibbs medals.

RIEBECKITE. The mineral riebeckite, essentially sodium iron silicate, $Na_2(Fe_3^{2+}, Fe_2^{3+})_5Si_8O_{22}(OH)_2$, is a monoclinic member of the amphibole group, usually in prismatic crystals. It has a prismatic cleavage; hardness, 5; specific gravity, 3.32–3.382; vitreous luster; color dark bluish to black. It occurs in granites and syenites chiefly. It is found in Greenland, Portugal, Madagascar, and South Africa (crocidolite), and in the United States at Quincy, Massachusetts; near Pikes Peak, Colorado, and the San Francisco Mountains, Arizona.

RNA. See **Genetics and Gene Science (Classical)**; **Nucleoproteins and Nucleic Acids**.

ROBINSON, SIR ROBERT (1886–1975). An English chemist who won the Nobel prize for chemistry in 1947. His work began on plants with biological significance, particularly those containing alkaloids. He synthesized brazilin and haematoxylin. In organic chemistry he discovered an important qualitative electronic theory. He explicated the penicillin structure as well. His education, which began at the University of Manchester, took him throughout Europe.

ROCKET PROPELLANTS. Chemical rocket propellant can be classified in several ways, including liquid or solid, monopropellant, bipropellant or tripropellant, cryogenic or storable, hypergolic or nonhypergolic, double-base, composite or composite double-base. Propellant classification frequently influences the classification of rocket engines—for example, monopropellant rocket, liquid rocket, solid rocket, and hybrid rocket (usually using a liquid oxidizer and a solid fuel). Propellants for chemical rockets serve two primary functions as contrasted to one function for nuclear, solar, electrical or laser heated rockets. In chemical propellant rockets, the propellant is both the energy source and the ejected mass or "working fluid."

Compared with the almost limitless number of chemical compounds that exist or can be formed, the number of chemical propellants in common use is relatively few. This situation arises from criteria including costs, source availability, toxicity, resistance to shock, and other requirements imposed by the vehicle application and the propulsion system design. Another practical reason is that extensive overlap of physical, chemical, and economic properties are displayed by many of the theoretically possible propellants. During the 1960s, the universities, industry, and government in the United States pursued extensive research programs for synthesizing new chemical compounds viewed as candidate propellants, which would increase the performance capability of chemical rockets. Although dozens of compounds were synthesized, few results reached the production line. This does not mean, however, that a scientific breakthrough in increasing the molecular energy of a propellant may not be ultimately obtainable.

The characteristics desired of a rocket propellant are several in number and can be divided into economic, safety, materials compatibility, engine-cycle needs and vehicle requirements.

In general terms, the engine-cycle needs ideally are: (1) a propellant or propellant combination that has a high heat of reaction per unit weight (also called heat of combustion). Most vehicles add a requirement for high heat of reaction per unit volume of propellant to minimize the vehicle size. (2) reaction products that are all gaseous, that have a very low molecular weight and that have a very high temperature of dissociation.

In addition to specific impulse, the vehicle requirements usually influence propellant selection in terms of storability, density, toxicity, and other hazards, and other application-sensitive factors, including exhaust plume properties and radar cross section and radiation emissions. Other factors being essentially equal, the higher the heat of reaction of a propellant (or combination), the more attractive the propellant. Sharp exceptions to this rule occur in some missiles because of volume limitations, the need for smokeless exhaust or similar restraints.

The heat released by a propellant is the difference in heat between the constituents and the end-products of combustion.

$$\Delta H_r^\circ = \left[\sum_{k,\ \text{products}} \eta_k(\Delta H_f^\circ)_k - \sum_{j,\ \text{reactants}} \eta_j(\Delta H_f^\circ)_j\right]$$

where ΔH_r° is the heat generated; ΔH_f° is the standard heat of formation of the constituent at reference temperature (298K); and η is the number of moles of each j reactant or k product. Large heat release is afforded by reaction products having large negative values, while the reactants should have positive, or at least small negative values, if possible. The heat of reaction is often noted in energy/weight units, such as kilocalories/gram.

Specific impulse, I_{sp}, the universally accepted measure of rocket engine performance, can also be used to indicate the performance of propellants. The most commonly stated expansion ration is $1,000 \rightarrow 14.7$ giving "sea-level specific impulse at 1,000 psi chamber pressure." Sometimes the expansion ratio is $1,000 \rightarrow 0.2$ to indicate specific impulse for high-altitude or space flight.

By definition, specific impulse I_{sp} is:

$$I_{sp} = \frac{F}{\dot{W}}$$

with the I_{sp} units being seconds; the short designation for units of thrust (force) per units of propellant mass flow per second.

For an ideal rocket with the nozzle exhaust pressure being the ambient pressure, the thrust, recognizing Newton's second law of motion, is:

$$F = \frac{\dot{W}c_e}{g}$$

where W is propellant flow rate in pounds per second; c_e is exhaust velocity in feet per second; and g is the gravitational constant in feet/second/second.

In practice, only about 10% of the elements on the periodic chart are adaptable to chemical rocket propellants. Propellants have made little use of elements other than hydrogen, carbon, nitrogen, oxygen, chlorine, fluorine, aluminum, boron, and beryllium.

Liquid propellants fall into two broad classes: (1) earth storable (monopropellants and bipropellants), and (2) cryogenic, depending upon whether they can be kept in the vehicle tankage for months and years, or must be used in a few hours or days. The theoretical performances of storable and cryogenic bipropellants combusting ideally at 1,000 psia chamber pressure and expanding to sea-level pressure without loss, assuming shifting chemical equilibrium of the combustion products during expansion in the engine exhaust nozzle, are listed in Tables 1 and 2. For comparison purposes, a few properties of the more common monopropellants are listed in Table 3. Water (not listed) as a source of hydrogen and oxygen via electrolysis has merit as a propellant in long-life satellites (5 years plus), equipped with solar electric cells.

Solid propellants fall into three general types: (1) double-base, (2) com posite; and (3) composite double-base. Double-base propellants form a

homogeneous cured propellant, usually a nitrocellulose-type of gunpowder dissolved in nitroglycerin plus minor percentages of additives. Both the major ingredients are explosives and both contribute to the functions of fuel, oxidizer, and binder. Composite propellants form a heterogeneous propellant grain with the oxidizer crystals and a powdered fuel (usually aluminum) held together in a matrix of synthetic rubber (or plastic) binder such as polybutadiene. Normally, composite propellants are less hazardous to manufacture and handle than double-base propellants. Composite double-base propellants are a combination of the two aforementioned types—usually a crystalline oxidizer (ammonium perchlorate) and powdered aluminum fuel held together in a matrix of nitrocellulose-nitroglycerin. The hazards of processing and handling this type of propellant are similar to those experienced with the double-base propellants. The characteristics of several common solid propellants are given in Table 4.

Ingredients are generally classified according to their function, e.g., fuel, oxidizer, binder, curing agent, burn-rate catalyst, etc. Ingredients used in small amounts are called additives and usually have functions other than the fuel, oxidizer, or binder. For example, an additive can reduce the viscosity of the propellant during mixing and casting (pouring) of the propellant, increase the burning rate of the propellant, or improve the storage stability. Often an ingredient serves or affects more than one function, the most diffused situation relating to composite double-base ingredients where the binder is a nitrocellulose-nitroglycerine complex with each of these two ingredients having its own fuel and oxidizer chemical elements. The binder contributes also as a fuel and in some propellant formulations, such as asphalt-base nonmetallized propellants, the binder is the fuel.

Ammonium perchlorate, NH_4ClO_4, is the most widely used crystalline oxidizer in solid propellants. Because of its characteristics, including compatibility with other propellant materials, specific impulse performance, quality uniformity and availability, it dominates the solid oxidizer field. Both ammonium and potassium perchlorate are only slightly soluble in water, a favorable trait for propellant use. Nitronium perchlorate is objectionably hygroscopic, is relatively incompatible with available binders, and detonates easily. All of the perchlorate oxidizers produce hydrogen chloride in their reaction with fuels. Their exhaust bases are toxic and corrosive to the extent that care is required in firing rockets, particularly the very large rockets, to safeguard operating personnel and communities in the path of exhaust clouds. Ammonium perchlorate is available in the form of small white crystals and close control of the size range and percentage of several sizes present in a given quantity or batch is required, since particle size influences propellant processing and the physical and ballistic properties of the finished propellant.

Inorganic nitrates are relatively low-performance oxidizers as compared with the perchlorates. However, ammonium nitrate is used in some applications for economy and because of its smokeless and relatively nontoxic exhaust. Its main use is in low-burning rate, low-performance applications, such as gas generators for turbine pumps.

[c] AP/Al optimized with 15% binder.

One or two crystalline high explosives, such as HMX (cyclotetramethylene tetranitramine) and RDX (cyclotrimethylene trinitramine), are sometimes included in a propellant formulation to achieve a specific performance characteristic. Depending upon the objectives, the percent can range from 5 to 50%.

The one prominent solid fuel is powdered aluminum, and it is used in a wide variety of composite and composite double-base propellant formulations, usually being between 14 and 22% of the propellant by weight.

Boron, even though it appears as one of the high-energy fuels and is lighter than aluminum, has not proven to be a practical fuel because it is so difficult to burn with high efficiency in combustion chambers of reasonable length. Beryllium burns much more easily than boron and improves the specific impulse of a solid propellant motor, usually by about 15 seconds, but as a powder or dust it is highly toxic to animals and humans. The technology with composite propellants using powdered beryllium fuel is sufficiently advanced for vehicle application, with space travel being the most likely appli cation.

Theoretically, both aluminum hydride, AlH_3, and beryllium hydride, BeH_2, are attractive fuels because of their high heat release and gas volume contribution. Both are difficult to manufacture and both deteriorate chemically during storage due to loss of hydrogen. Because of these difficulties, coupled with relatively modest I_{sp} gains, these compounds remain experimental.

Hybrid rocket propellants are various combinations of solid and liquid propellants, usually a solid fuel and a liquid oxidizer. Sometimes, a third propellant, liquid hydrogen, is added, not for energy release, but as a low-molecular-weight working fluid. The main advantages of a hybrid rocket are: (1) use of liquid and solid propellant combinations offering the highest performance attainable with chemical rockets; (2) simplicity of a solid grain (usually fuel); (3) a liquid for nozzle cooling and thrust modulation (compared with a solid rocket); (4) restart capabilities; and (5) good storability and safe storage characteristics.

The chemical bond energy present in propellant molecules is the energy source used by chemical rocket engines to date. This source affords energy densities of approximately 3 kilocalories/gram in the liquid hydrogen/liquid oxygen combination, and up to about 5.7 kilocalories/gram with the lithium/fluorine combination. Theoretically, supplemental energy can be added to molecules or molecular fragments that, upon recombination or relaxation to their normal energy state, release significant amounts of energy. For example, 52 kilocalories/gram is theoretically released when two hydrogen atoms (free radicals) recombine to form hydrogen. Even higher energy densities, as much as 100 kilocalories/gram, are theoretically available from lightweight molecules, such as helium, that are in an excited state.

Metastable, in the sense of propellant ingredients, means that the "energized" molecule, atom, or molecular fragment, tends to promptly return to its normal state. Some molecular species distinctly assume a metastable state upon excitation with the lifetime at room temperature being 10^{-3} to 10^{-2} second as compared with less than 10^{-6} for nonmetastable excited species. Atoms subjected to excitation move into a more energetic state of translational motion of vibration or into a high-energy electron orbital state; diatomic molecules do likewise. Molecules containing more than two atoms can experience higher translational rotational motion, as well as higher electron orbital state.

Most of the research to date on metastable propellants has been with gaseous atoms and molecules. Obviously, energized ingredients in a condensed phase, solid or liquid, would be needed for most rockets. The primary objectives to be reached, if metastable ingredients are to benefit rocket propulsion, are: (1) an efficient process for energizing the ingredients; and (2) a means of storing the ingredients for days at a time without appreciable energy loss. Actual use of metastable ingredients in a rocket is envisioned in the company of liquid hydrogen, or other low-molecular-weight working fluid.

Limited research has been conducted on two approaches to generating and storing (stabilizing) metastable propellant ingredients: (1) free radicals, specifically, atomic hydrogen; and (2) helides, which are excited states of helium. In the late-1950s, the U.S. National Bureau of Standards produced low concentrations of free radicals and stored them in inert matrices at very low temperatures. More recently, an approach has been taken to generate hydrogen atoms, immediately condensed at liquid-helium temperature, in the presence of a high density (70 to 100 kilogauss) magnetic field for the purpose of stabilizing the hydrogen atoms. Theoretically, the high-strength magnetic field is capable of aligning the spin of the electron of the hydrogen atom so as to prevent recombination into the hydrogen molecule.

Triplet helium has a theoretical energy level of 114 kilocalories/gram above the ground state. Assuming release of this energy and subsequent expansion through a rocket nozzle gives a specific impulse of 2,800 seconds. Techniques for generating activated helium and other noble gases are well known, but concentrating and storing these metastable species is quite another matter inasmuch as they revert to their ground

state by collision processes. Experimental approaches to activating helium and trapping the helium molecules in a hydrocarbon wax have been reported.

The creation and use of metallic hydrogen (hydrogen derived from normal hydrogen subjected to about 2 megabars pressure) should release about 52 kilocalories/gram upon transitioning from the metallic to the normal solid form. The concept dates back to 1935, but interest has been renewed because some scientists believe that metallic hydrogen exists in some large planets.

Antimatter Rockets

Sufficient atomic particle research has been accomplished to warrant discussion of possible methods of applying energy available from particle mass annihilation to rocket propulsion. Complete conversion of matter to energy would allow exhaust velocities near that of light to be obtained from a propulsion device. Antimatter, by definition is matter made up of antiparticles, such as antineutrons, negatrons (antiprotons), and positrons (antielectrons). An annihilation property is known to exist between particles with one particle termed the antiparticle of the other.

Rocket design concepts envisioned for utilizing the reaction between atomic particles and antiparticles (matter and antimatter) are based upon the following postulations: (1) annihilation products can be accelerated using electrical and magnetic forces (consider the annihilation reaction of a neutrino with an antineutrino, yielding a proton and an electron); (2) annihilation products can be used indirectly to heat a working fluid for thermal expansion through a nozzle (consider the annihilation reaction of hydrogen and antihydrogen, leaving high-energy gamma rays); (3) antimatter possesses negative gravitational mass although its inertial mass may be positive. This could give rise to antigravity propulsion; and (4) annihilation products of ordinary quanta give rise to the possibility of a photon-expelling beam for the direct generation of thrust.

Before any form of antimatter rocket can exist, a lightweight method must be developed for producing antiparticles at a flow rate of grams/second in contrast with the few dozen of antiparticles produced in research laboratory generators. Also, a practical storage or containment method must arise inasmuch as antiparticles explode violently upon contact with normal matter. Reference 5 gives a performance estimate of an I_p of 3.06×10^7 seconds for a rocket propelled vehicle with a thrust/weight ratio of 10^{-7}.

Multiple Uses of Propellants

Propellants, both solid and liquid, are used in many secondary propulsion applications, including crew capsule ejection, attitude control and station-keeping of satellites, braking of reentry vehicles, extravehicular space operations—as well as being essential in rocket engine igniters, signal and illumination flares, and fuel-cell type electric generators. New developments, such as the high-powered gas dynamic laser[6] continue to broaden the field of applications.

ROENTGEN. A unit of radiation, that quantity of X-rays or gamma rays which will produce, as a consequence of ionization, 1 electrostatic unit of electricity in 1 cubic centimeter of dry air measured at 0 degrees C and standard atmospheric pressure. See also **Radioactivity**.

RONTGEN, WILHELM CONRAD (1845–1923). Rontgen became one of the outstanding experimental physicists of his time. In 1869, he received his doctorate in mechanical engineering from the University of Zurich. He held various positions at higher institutions throughout Germany until, in 1888, he became the chair for the physics department at the University of Wurzburg.

In 1895, Rontgen was the first scientist to observe and record X-rays. While experimenting with a cathode ray discharge tube that was completely enclosed in cardboard so no light could escape, he observed that a sheet of barium platino-cyanide coated paper lying several feet away from the discharge tube was glowing in the dark. Rontgen realized the importance of this accidental discovery and he devoted six straight weeks of working in his laboratory investigating the X-ray. While investigating, he actually saw the image of his bones within his fingers and deduced that his X-rays must be a very short wavelength form of electromagnetic radiation. He published his work in a series of classic papers and the phenomenon of his X-rays had immediate use in hospitals in the diagnosis and treatment of fractures. His discovery could have been patented, but Rontgen gave it to humanity. Later, when he received a cash prize for receiving the first Nobel Prize (1901) in Physics, Rontgen gave the money to the University of Wurzburg.

Rontgen was truly a great scientist and great humanitarian. His discovery of the X-ray changed the world and today it has universal usage.

J.M.I.

ROTATION AXIS. A symmetry element possessed by certain crystals, whereby the crystal can be brought into a physically equivalent position by rotation about an axis which can be onefold, twofold, threefold, fourfold, or sixfold, according to whether the crystal can be brought into self-coincidence by the operations of rotation through 360, 180, 120, 90, or 60 degrees about the rotation axis. See also **Mineralogy**.

ROWLAND, FRANK SHERWOOD (1927–). An American who won the Nobel prize for chemistry along with Paul Crutzen and Mario Molina in 1995 for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone.

ROXEL PROCESS. A process for increasing the flame resistance of cotton by chemically modifying the fiber, i.e., by applying a formulation consisting of tetrakis(hydroxymethyl)phosphonium chloride (THPC), triethylolamine, and urea in aqueous solution. These substances cross-link with the hydroxyl groups of the cellulose to form an efficient and durable protective medium. This process is used in the manufacture of blankets, curtains, bed linen, and the industrial safety garments.

RUBBER (Natural). *Natural rubber* is the name applied to the polymer *cis*-polyisoprene obtained chiefly from the *Hevea brasiliensis* tree.[1] Originally, the tree grew wild in the Amazon valley, but during the last part of the 19th century it was planted in well-organized plantations in tropical lands of the Far East and later in Africa. See Table 1. The average rubber trees stand about 40–50 feet (12–15 meters) high. For optimum growth, a tropical climate having 80 inches (203 centimeters) or more of annual rainfall is required.

Rubber comes from the tree as a milky white fluid, which is a colloidal suspension of rubber in a liquid consisting mostly of water. The tree is tapped by well-trained workers, who use a sharp-edged tool, and the cutting action goes at an angle of 30° from top left to bottom right. It is important that the rubber latex-bearing cells be cut, but that the blade not wound the inner cambium layer, as this would harm the tree. A cup is hung below the cut to collect the white, milklike latex, which contains about 35% rubber,

[1] It is alleged that English scientist Joseph Priestly observed that the material could be used for rubbing out lead pencil marks and thus gave the material the name rubber. ("Introduction to the Theory of Perspective," Joseph Priestly, 1835.)

TABLE 1. NATURAL RUBBER EXPORTED

Producing area	Quantity produced (1000 long tons)				
	1940	1960	1970	1975	1979
Malaysia	547	775	1304	1424	1595
Indonesia	543	587	755	788	866
Other Asian countries, including Oceania	283	400	484	525	704
Africa	16	149	207	197	141
Tropical America	26	15	10	12	19

Note: 1 long ton is slightly more than 1 metric ton (1016 kilograms).

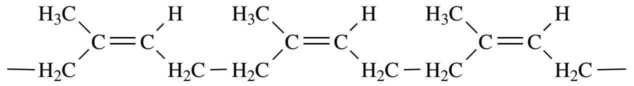
the remainder being water, protein, resins, organic materials, and other plant substances.

The yield of the *Hevea* tree can be increased by applying chemicals to the bark. These include 2-chloroethylphosphonic acid, which supplies small quantities of ethylene gas. This type of chemical is applied in a high-viscosity liquid form, usually mixed with palm oil or other diluent. The function of it is to stabilize the latex so that it continues to flow for a longer time and thus increases rubber yield. Because of the higher rubber yield per tapping operation, the cost of tapping labor is reduced. When stimulants are used, the tree is given a longer rest period between tappings to avoid diseases that would eventually kill it. See also **Plant Growth Modification and Regulation**.

During the 1980s, the annual yield for Malaysian plantations was about 1010 pounds/acre (1133 kilograms/hectare), which includes high-yielding trees which produce 1500 pounds/acre (1680 kilograms/hectare), as well as older, lower-yielding clones.

Properties of Natural Rubber

Chemically, natural rubber or *cis*-polyisoprene, has a broad molecular-weight distribution, ranging from several million to about one hundred thousand.



Natural rubber is soluble in practically all aromatic and aliphatic hydrocarbons and particularly in halogenated hydrocarbons. When cements and solvent adhesives are made using natural rubber, methylethylketone (MEK) frequently is used to reduce viscosity. Although MEK is not a solvent, it tends to disperse large molecular particles, resulting in lower-viscosity dilution. Crude rubber is decomposed by heat and can be cyclized at 250°C. It can easily be hydrogenized and reacts readily with halogens. The stress-strain properties of natural rubber are the best of all the elastomeric polymers. In vulcanized films made by the latex process, the tensile strength may exceed 6000 pounds per square inch (41 mPa), and ultimate elongation is as high as 700% or more.

Natural rubber is readily attacked by oxygen. Copper and manganese, if present in amounts greater than the specified 0.001%, greatly accelerate oxidation. There are, however, naturally occurring antioxidants in natural rubber that help preserve it until vulcanization. All vulcanized natural-rubber products contain added antioxidants to ensure satisfactory life.

Rubber burns quite readily and generates more than 10,000 cal/g. The specific gravity of rubber is 0.934, a property utilized in concentrating natural-rubber latex by the centrifuge process. The serum, which is mostly water and has a specific gravity of about 1.0, tends to separate readily from the rubber. The liquid concentrated latex is used in making foam rubber, dipped goods, adhesives, and carpet backing for nonwoven carpets. An industry has developed around this application, which involves spreading foamed latex onto the underside of carpeting, making an integral carpet-foam system.

Compounding and Vulcanization

Crude rubber in the raw state has few applications with the exception of crepe soles for shoes. To make commercial rubber products, the material must be mixed with a variety of chemicals and vulcanized into desirable end shapes. Charles Goodyear discovered in 1839 that adding sulfur to rubber and heating the mixture greatly enhances the physical properties of rubber. The material no longer becomes tacky in warm weather and in cold weather it does not become brittle. The material is much tougher, and the quality of products made this way results in service for a much longer period of time. In addition to sulfur, which crosslinks the large rubber molecules and makes it a giant organic molecule, zinc oxide, organic accelerators, antioxidants, reinforcing pigments, and other processing aids are used in compounding rubber for useful vulcanized products.

The function of the antioxidant is to improve service life of the product against such well-known degrading agents as oxygen, light, and nitroso compounds. One theory is that the antioxidant selectively reacts with the degrader, slowing down its reaction with the rubber molecule, which would result in scission and eventually poorer physical properties. During recent years, considerably aggravated by air pollution, degradation of vulcanized rubber by small quantities of ozone (a few parts per million) in the air has become a serious problem. Ozone has little noticeable effect on unstretched rubber, but even under slight stretch it causes cracks in the surface, which grow perpendicularly to the direction of extension. Hundreds of different antioxidants and antiozonants are employed, amine and phenol complexes being the basis of most. See also **Antioxidants**.

Accelerators act as catalysts of vulcanization, but, unlike most catalysts, they undergo chemical change during the reaction. Benzothiazyl disulfide is one of the oldest types, dating back to 1925, but it still accounts for the greatest use in the industry today. Besides the thiazole types, other popular accelerators are sulfenamides, aryl guanidines, dithiocarbames (extremely fast accelerators used mostly in latex compounds), and thiurams (also very fast and often used as a secondary accelerator to hasten the vulcanization rate). Accelerators also contribute to improved ageing properties of the end product.

Stearic acid is an activator of vulcanization, as is zinc oxide, both reacting to form zinc stearate, which enhances the activity of the organic accelerators. Zinc stearate is impractical to add directly to the rubber because its slippery, lubricating nature makes it difficult to mix in the batch (see Fig. 1).

With an accelerated system, a simple network structure with dialkenyl mono- and disulfide crosslinks and conjugated triene units as main-chain modifications is obtained:

With an unaccelerated sulfur-natural-rubber system, the poor crosslinking efficiency results in sulfur being incorporated into the rubber network as long polysulfide crosslinks, cyclic monosulfides, and vicinal crosslinks, which are very close together and act physically as a single cross-link (see Fig. 2).

It is theorized that between the complex network structure of the unaccelerated system and the simpler network structure of the accelerated system, structures made up of the two models represent natural-rubber vulcanizates made at various times and temperatures of cures, with different reactant concentrations, and showing the effects of other variants.

At any given degree of crosslinking, the tensile strength is highest with polysulfide bonds. High elongation at break is obtained by slightly decreasing the crosslinking action. If lower elongation is required, slightly excessive crosslinking is used, usually accompanied by higher tensile strength. Vulcanization of rubber decreases its solubility in solvents, and this property frequently is used as a qualitative measure of cure.

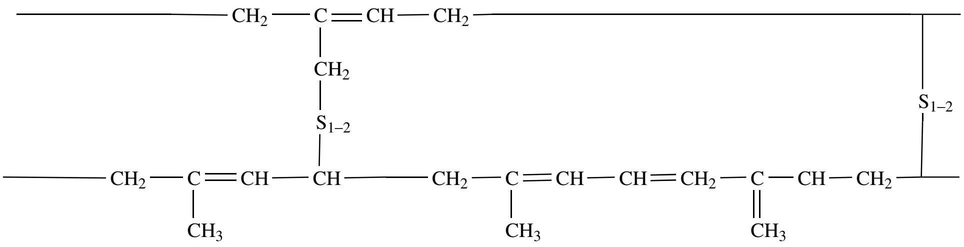


Fig. 1. Accelerated system

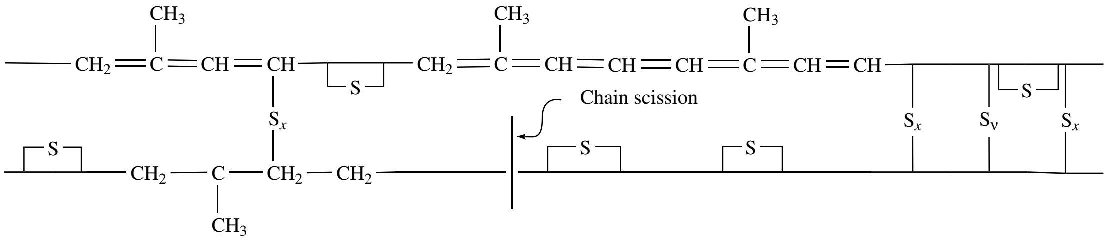

Fig. 2. Unaccelerated system

Vulcanization by sulfur accounts for practically all the commercial products. However, peroxide types of curing systems may be used, especially for some of the synthetic rubbers.

Ultrahigh-frequency (UHF) energy may be used for preheating and precuring rubber compounds for continuous vulcanization (CV) of rubber, containing carbon black, for such applications as weather stripping, tubing, hose, and, in some instances, tire tread compounds.

Carbon black is the major reinforcing pigment used, not only for natural rubber, but for practically all the synthetic rubbers. As much as 40–50 parts by weight, based upon 100 parts of rubber, is used in all tire-tread compounds. Carbon black greatly increases tensile strength at low elongations (modulus) and results in longer-wearing tires. Colloidal silica contributes some reinforcing properties to rubber, but not to the same degree as carbon black. See also **Carbon Black**.

Uses of Natural Rubber

Thousands of flexible products requiring top performance characteristics are made of natural rubber, e.g., huge earthmover tires, truck tires, tires for large aircraft, bridge supports, and surgeons' gloves. The treads of most passenger car tires in the United States consist mainly of styrenebutadiene synthetic rubber because of lower cost and lower temperature buildup during use.

The use of natural rubber in passenger car tires has increased in recent years due to the industry going from bias to radial types which, in North America, now account for 75% of the total. Higher degree of tack or cohesive bonding during the building of the radial tire, as compared with that of styrene-butadiene rubber, is largely responsible for this.

Because of its excellent high- and low-temperature properties, many products used in the arctic and tropical areas of the world are made from natural rubber. However, it is not suitable for applications where there is contact with naphtha, e.g., gasoline hoses, because the solvent swells the material. Almost all elastic bands are made from natural rubber. Because of its excellent tack properties, the material is used in solvent and latex form as the base for adhesives.

With the dependence of synthetic rubber on petroleum, natural rubber, which is produced by solar energy, may look increasingly attractive over the years ahead.

Processing Raw Materials

Field latex is bulked in large tanks at a factory adjacent to the rubber estate. If a high-solids latex is desired, the field latex is strained, stabilized with ammonia or other chemicals, such as soap and bactericide, and either centrifuged or creamed to 62–68% total solids.

Smoked Sheet. For making ribbed smoked sheet, the field latex is immediately mixed with dilute formic acid in long horizontal tanks. Because fresh latex is somewhat protected by a protein surface layer, it does not coagulate or gel immediately on addition of the acid. Within a few hours, however, the rubber particles in the latex gel form a spongy mass which is then run through a series of smooth metal rolls with clearance decreased from one set to the next, an arrangement that squeezes out the serum and densifies the wet rubber. Water is run over the wet coagulum to wash out non-rubber materials and dirt. The last unit consists of ribbed rolls, which imprint ribbed markings on the sheet. After drying in air for a few hours, the sheets are hung in a drying shed at 40–50°C until dry. Modern installations use efficient drying tunnels. Sheets are inspected by holding them over a strong light to determine clarity, color, presence of dirt and other factors. The rubber is classified by various grades. Sheets then are piled up and squeezed in a baling machine to form 250-pound (~113-kilogram) bales that measure 19 × 19 × 24 inches (~ 48 × 48 × 61 centimeters).

Crepe. Another popular type of commercial rubber, known as crepe, consists of two major classes—*pale crepe* and *thick blanket crepe*. Pale crepe is made by adding sodium hydrogen sulfite, $NaHSO_3$, to field latex to inhibit discoloration and softening during processing. Formic acid is used as the coagulant. The wet coagulum is passed through rolls with longitudinal grooves, which give the rubber a crepe-like appearance. Water running over the surface cleans out dirt and other nonrubber ingredients. Sheets are hung up to dry in circulating warm air. The quality of pale crepe is assessed on its whiteness and how good the finished rubber appears.

Blanket crepes are of lower quality and are made from wet slabs obtained usually from small landholders. These are creped, dried, and baled. Other types of crepe are made from coagulum left in collection cups and from dried skin remaining from the tapping incision. In addition to collecting latex, a tapper collects all dried and coagulated rubber that remains from the previous round, usually as skin in the cup or on the tapping panel.

Grading of Rubber. Commercial grades of natural rubber are classified into two main groups: (1) "Green Book International Grades," and (2) "Technically Specified Forms." The former depends on a visual grading system, the source of the rubber and the method of preparation. This system, dating back many years and kept current by the International Rubber Quality and Packing Conference Committee, consists of 35 grades under 8 major types, such as Ribbed Smoked Sheets, White and Pale Crepe, Estate Brown Crepes, Compo Crepes, Thin Brown Crepes (Remills), Thick Blanket Crepes, and Pure Smoked Blanket Crepe. Publisher of the "Green Book" is the Rubber Manufacturers Association, Inc., New York.

Technically Specified Rubbers (TSR), originated by the Malaysian Rubber Producers Association, classifies rubber not only on the basis of the source of rubber, but on its physical properties, such as dirt content, ash, and nitrogen content, volatile matter, plasticity, and, with the higher-quality grades, cure rate and color are standardized. This type of rubber is packaged in 75-pound (34-kilogram) bales, wrapped in transparent plastic, and the color of the printing on the bale identification strips indicate whether the source is latex grade, sheet material grade, blended grades, or field grades. An additional convenience of this rubber is that the bales can be charged into the mixing machine (Banbury) without removing the wrapper. This is in contrast with the Green Book grades, which are bonded together by a press, with the outside layer treated with soapstone to keep the bales from sticking together. These larger bales require cutting before they can be charged into the mixer.

Guayule

During the past few years, natural rubber from the desert shrub *Parthenium argentatum* has been under intensive study by scientists in the United States and Mexico as a possible domestic source of natural rubber. This plant grows wild in the arid areas of Mexico and the United States. In 1910, guayule produced 10% of the world's rubber, but lower-cost Hevea rubber from the Far East displaced it from the market. Rubber in the guayule plant is present in the roots and branches of the shrub and must be separated and purified by a flotation and solvent system. The purified product is equivalent in chemical properties to the Hevea rubber. An advantage of guayule is that it can be grown on semiarid land that is not suitable for other crops. Presently, agricultural experimentation on increasing rubber yield of the plant is underway. The U.S. government has passed legislation providing funds to help in developing an American-based guayule industry. Several large rubber product manufacturers have experimental plots planted with the shrub. The National Research Council, Washington, DC., published a report, "Guayule: An Alternative Source of Natural Rubber," in 1977.

RUBBER (Synthetic). Any of a group of manufactured elastomers that approximate one or more of the properties of natural rubber. Some of these are: sodium polysulfide ("Thiokol"), polychloroprene (neoprene), butadiene-styrene copolymers (SBR), acrylonitrilebutadiene copolymers (nitril rubber), ethylenepropylene-diene (EPDM) rubbers, synthetic polyisoprene ("Coral," "Natsyn"), butyl rubber (copolymer of isobutylene and isoprene), polyacrylonitrile ("Hycar"), silicone (polysilorane), epichlorohydrin, polyurethane ("Vulkollan").

The properties of these elastomers are widely different. All require vulcanization. In general, sulfur is used only for unsaturated polymers, peroxides, quinones, metallic oxides, or diisocyanates effect vulcanization with saturated types. Many are special-purpose rubbers, some can be used in tires when loaded with carbon black, others have high resistance to attack by heat and hydrocarbon oils and thus are superior to natural rubber for steam hose, gasoline and oil-loading hose. Most are available in latex form.

See also **Elastomers**.

RUBIDIUM. [CAS: 7440-17-7]. Chemical element symbol Rb, at. no. 37, at. wt. 85.468, periodic table group 1, mp 38.9°C, bp 686°C, density 1.53 g/cm^3 (20°C). Elemental rubidium has a body-centered cubic crystal structure.

Rubidium is a silver-white, very soft metal; tarnishes instantly on exposure to air, soon ignites spontaneously with flame to form oxide; best preserved in an atmosphere of hydrogen rather than in naphtha; reacts vigorously with H_2O forming rubidium hydroxide solution and hydrogen gas. Discovered by Bunsen and Kirchhoff in 1860 by means of the spectroscope.

There are two naturally occurring isotopes ^{85}Rb and ^{87}Rb, of which the latter is unstable with respect to beta decay ($t_{12} = 5 \times 10^{10}$ years) into ^{87}Sr. There are eight other known radioactive isotopes ^{81}Rb through ^{84}Rb, ^{86}Rb, and ^{88}Rb through ^{90}Rb, all with comparatively short half-lives, measured in terms of minutes, hours, or days. In terms of abundance, rubidium ranks 34th among the elements in the earth's crust. In terms of content in seawater, the element ranks higher (18th) with an estimated 570 tons of rubidium per cubic mile of seawater. First ionization potential 4.176 eV; second, 27.36 eV. Oxidation potential $Rb \rightarrow Rh^+ + e^-$, 2.99 V. Other important physical properties of rubidium are given under **Chemical Elements**.

Rubidium occurs in lepidolite (lithium aluminosilicate, in amount up to 1% Rb), in certain mineral waters and rare minerals. Rubidium salts may be recovered from the mother liquor upon crystallization of (1) lithium salts, (2) potassium salts. Rubidium metal is obtained by electrolysis of the fused chloride out of contact with air.

Uses

The main uses of rubidium are in photocathodes and photo-electric cells. However, rubidium cells are inferior to cesium cells in their sensitivity and range. Although very small quantities are involved, rubidium gas cells now perform as secondary time standards, on the order of quartz crystal oscillators, inasmuch as they must be referenced to more accurate systems. The rubidium systems have a characteristic resonance at 6,835 MHz and, unlike other atomic frequency standards, require little power and are relatively compact. Portable rubidium atomic clocks were introduced by the U.S. Army in 1963. They weight as little as 44 pounds (20 kilograms) and occupy a volume of only about 1 cubic foot (0.028 cubic meter). The units operate on 110-V current, on the 24-V output of military vehicles, or both. Clocks of this type are used to synchronize radar nets, to assist in the accurate tracking of missiles and satellites, and to set precise radio broadcasting frequencies. Rubidium-vapor instruments also were developed as absolute-type magnetometers and introduced in 1958 by U.S. government scientists. The rubidium-vapor magnetometer uses a rubidium lamp, mounted in the tank coil of a radio-frequency oscillator. After collimating and filtering, the rubidium light is circularly polarized and then passed through a rubidium-vapor cell, after which it is focused on a sensitive photocell. Numerous combinations of amplifier parameters and various rubidium isotopes permit considerable range in the measurement of ambient magnetic fields. Inasmuch as the total world range is from 15,000 to 80,000 gammas, a system capable of this span finds use anywhere in the world.

Potential uses of rubidium include use as a fuel for ion-propulsion engines and as a heat-transfer medium.

Rubidium alloys easily with potassium, sodium, silver, and gold, and forms amalgams with mercury. Rubidium and potassium are completely miscible in the solid state. Cesium and rubidium form an uninterrupted series of solid solutions. These alloys, in various combinations, are used mainly as getters for removing the last traces of air in high-vacuum devices and systems.

Small quantities of rubidium are found in certain foods, including coffee, tea, tobacco, and several other plants. There is evidence indicating that trace quantities of the element are required by living organisms.

Chemistry and Compounds

Rubidium is more electropositive than potassium (or the lower alkali metals) as is consistent with its position in main group 1. It reacts more vigorously with H_2O, and ignites on exposure to oxygen.

Because of the ease of removal of its single 5*s* electron (4.159 eV) and the difficulty (27.36 eV) of removing a second electron, rubidium is exclusively monovalent in its compounds, which are electrovalent.

In its solutions in liquid NH_3, rubidium is, like the other alkali metals, a powerful reducing agent, so that in such solutions titrations of rubidium polysulfide with rubidium are made by electrometric methods. The solubility of rubidium salts in liquid NH_3 increases markedly with the radius of the anion (rubidium chloride, RbCl, 0.024 moles per kilogram, rubidium bromide, RbBr, 1.35 moles per kilogram, and rubidium iodide, RbI, 10.08 moles per kilogram). However, in water they exhibit minimum solubility at cation: anion radius ratio of 0.75 (rubidium fluoride, RbF, 12.5 moles/kilogram, RbCl 6.8 moles/kilogram, RbBr, 6.6 moles/kilogram, RbI 7.2 moles/kilogram).

As in the case of the other alkali metals, rubidium forms compounds generally with the inorganic and organic anions; for a general discussion of these compounds, see the entry on **Sodium**, because the sodium compounds differ principally in their greater extent of hydration and greater number of hydrates. However, rubidium coordinates with large organic molecules, such as salicylaldehyde, even though it does not with H_2O.

One respect in which rubidium and cesium are outstanding among the alkali metals is the readiness with which they form alums. Rubidium alums are known for all of the trivalent cations that form alums, Al^{3+}, Cr^{3+}, Fe^{3+}, Mn^{3+}, V^{3+}, Ti^{3+}, Co^{3+}, Ga^{3+}, Rh^{3+}, Ir^{3+}, and In^{3+}.

As in the case of potassium and cesium, rubidium forms a superoxide on reaction of the metal with oxygen. The compound is dark brown in color and paramagnetic, and hence believed to contain the $O_2{}^-$ ion with an odd electron, and to have the formula RbO_2. On heating, it loses oxygen to form Rb_2O_3. Rubidium also forms a peroxide Rb_2O_2, and a normal oxide, Rb_2O, which is prepared by heating rubidium nitrite with metallic rubidium.

Rubidium hydroxide, [CAS: 1310-82-3]. RbOH, is the strongest, except for cesium hydroxide, CsOH (and francium hydroxide, FrOH), of the alkali hydroxides, as would be expected from its position in the periodic table. For the same reason, it has the next smallest lattice energy (146.6 kilocalories per mole).

The most numerous organic compounds of rubidium are those of oxy compounds, such as the salts of organic acids, the alcohols and phenols (alkoxides, phenoxides, etc.). An ethyl rubidium-zinc diethyl adduct has been reported, $RbZn(C_2H_5)_3$, which is certainly the true salt, rubidium triethylzincate, $Rb[Zn(C_2H_5)_3]$.

RUTHENIUM. [CAS: 7440-18-8]. Chemical element, symbol Ru, at. no. 44, at. wt. 101.07, periodic table group 8 (platinum metals), mp 2,310°C, bp 3,900°C, specific gravity 12.41 (20°C). Elemental ruthenium has a close-packed hexagonal crystal structure. The seven stable isotopes are 96Ru, 98Ru through 102Ru, and 104Ru. The five unstable isotopes are 95Ru, 97Ru, 103Ru, 105Ru, and 106Ru. In terms of earthly abundance, ruthenium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for ruthenium at 0.019. No notable presence of ruthenium in seawater has been found. Ruthenium was discovered by Claus (Germany) in 1844.

Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^7 5s^1$. Ionic rad ius Ru^{4+} 0.60 Å. Metallic radius 1.3251 Å. First ionization potential 7.5 eV. Other physical properties of ruthenium will be found under **Platinum and Platinum Group**. See also **Chemical Elements**.

The chemistry of Ru is still poorly understood. The existence of at least eight valence states, coupled with the tendency to complex with many ions, often results in the presence of several different complexes in a given solution.

Ru metal is quite refractory. It is not significantly soluble in any single acid; even aqua regia has little effect. At room temperature, the metal does not react with O_2, but, when heated in air, a film of the dioxide appears. The metal is insoluble in fused sulfates. Molten alkali slowly dissolves the metal. The rate of attack is rapid under oxidizing conditions, and a molten mixture of NaOH and Na_2O_2 will readily dissolve the metal.

The finely divided metal is soluble in hypohalites if an excess of alkali is present. At red heat, the metal combines with Cl_2 to form the dichloride. Ruthenium(VIII) oxide is formed when an alkaline ruthenium solution is treated with a strong oxidant, such as chlorine, or bromate ion when the Ru is in acid solution.

Ruthenium(III) hydroxide is formed by the action of alkali on a solution of ruthenium(III) chloride. It is easily oxidized by air to the tetravalent state. The dioxide, RuO_2, forms when the metal is heated in air. Hydrous ruthenium(IV) oxide can be precipitated by adding alcohol to a less than 3-*M* NaOH solution of ruthenium(VIII) oxide, followed by boiling. Above 3-*M* NaOH, complete reduction is not obtained. The hydrous oxide that is soluble in concentrated HCl tends to occlude impurities.

The only known octavalent Ru compound is the tetroxide, RuO_4, which exists in a yellow and a brown form. The volatile and poisonous tetroxide melts at about 25°C and sublimes readily. It may explode in contact with oxidizable substances or when heated above 100°C. It is formed by distillation from either an alkaline or acid solution under strongly oxidizing conditions. The tetroxide is moderately water-soluble. When dissolved in alkali, it initially forms a green solution of heptavalent perruthenate of the form $MRuO_4$, which further reduces to the orange ruthenate M_2RuO_4. The reduction to the hexavalent state is quicker in strong alkali. The ruthenates also are made by fusing finely divided metal with a mixture of alkali hydroxide and nitrate or peroxide.

Anhydrous ruthenium(III) chloride, $RuCl_3$, is made by direct chlorination of the metal at 700°C. Two allotropic forms result. The trihydrate is made by evaporating an HCl solution of ruthenium(III) hydroxide to dryness or reducing ruthenium(VIII) oxide in a HCl solution. The trihydrate, $RuCl_3$. $3H_2O$, is the usual commercial form. Aqueous solutions of the trihydrate are a straw color in dilute solution and red-brown in concentrated solution. Ruthenium(III) chloride in solution apparently forms a variety of aquo- and hydroxy complexes. The analogous bromide, $RuBr_3$, is made by the same solution techniques as the chloride, using HBr instead of HCl.

Ruthenium(III) iodide, RuI_3, is a black, insoluble compound precipitated by the addition of iodide ion to a solution of $RuCl_3$.

Tetravalent ruthenium chloride, $RuCl_4$, and the hydroxychloride, $Ru(OH)Cl_3$, are intermediate products when $RuCl_3$ is prepared by evaporating the tetroxide in HCl. When the hydroxychloride in hot HCl is treated with Cl_2, it is converted to the tetrachloride. The anhydrous tetrachloride also is known. The tetrabromide and tetraiodide have not been isolated; attempts to prepare these compounds result in the formation of the respective trihalides.

The only pentavalent Ru compounds known are the fluorides; RuF_5 is made by combining the elements. The compound melts at 107°C and boils at 313°C. The salt $NaRuF_6$ was recently made by mixing $RuCl_3$, with NaCl and treating the mixture with BrF_3.

Ru forms many complex ions. The nitrosyl compounds are frequently encountered by accident due to the great affinity of Ru for the nitrosyl group. Ruthenium(III) nitrosylchloride, Ru(NO) Cl_3. $4H_2O$, is a by-product of most solutions of $RuCl_3$ in aqua regia or solutions containing HNO_3. It also is present in HCl solutions resulting from a KOH and nitrate fusion of the metal. The chloride and bromide are respectively raspberry and violet in solution. Alkaline chlorides form complex salts of the type $M_2Ru(NO)Cl_5$, which can be crystallized from solution. A black gelatinous precipitate of the nitrosylhydroxide, $RuNO(OH)_3$, is slowly formed when a solution of the nitrosylchloride is heated with a strong base. A series of nitrato- and nitro-derivatives of nitrosylruthenium also have been described and separated.

It is generally accepted that the disulfide is the only certain sulfide of Ru. It is formed by the action of H_2S on a solution of Ru or from the elements at about 1000°C. When ruthenium(IV) sulfide is treated with HNO_3, the sulfate is formed.

Dichlorodicarbonylruthenium(II), $Ru(CO)_2Cl_2$, is formed when $RuCl_3$ is heated above 210°C in the presence of CO. It is a yellow, insoluble, volatile compound. The bromine and iodine analogs are similarly formed.

When finely divided Ru metal is heated at 180°C under 200 atm of CO, pentacarbonylruthenium(0), $Ru(CO)_5$, is formed.

Ruthenium forms a large number of complex ions with amines.

Recently, a new group of organometallic sandwich compounds, called *metallocenes*, has been discovered. Ruthenocene is made in about 50% yield by reacting RuCl3 with cyclopentadienylsodium in tetrahydrofuran. After refluxing and distilling the solvent, the light-yellow crystals of ruthenocene are sublimed. The compound, $Ru(C_5H_5)_2$, undergoes a large number of substitution reactions typical of aromatic systems.

Ruthenium is commonly used with other platinum metals as a catalyst for oxidations, hydrogenations, isomerizations, and reforming reactions. The synergetic effect of mixing ruthenium with catalysts of platinum, palladium, and rhodium has been found for the hydrogenations of aromatic and aliphatic nitro compounds, ketones, pyridine, and nitriles.

RUTHERFORD, ERNEST (1871–1937). Rutherford was a British physicist who was born in the South Island of New Zealand and is famous for his pioneering work in nuclear physics and for his theory of the structure of the atom.

Rutherford was awarded a scholarship to be a research student at the University of Cambridge and began research under J.J. Thomson. He soon abandoned research on his radio wave detector to work on the power of X-rays to confer electric charge on gases but soon turned to researching the problem of the rays emitted by thorium. Rutherford found three kinds of radiation, which he named alpha, beta, and gamma. In collaboration with Frederick Soddy, he was able to isolate a substance, thorium X, and identify the phenomenon of radioactive half-life and formulated an explanation of radioactivity. Rutherford was awarded the 1908 Nobel Prize for chemistry for his work in radioactivity.

In 1907, Rutherford moved to the University of Manchester and in 1909 he discovered the atomic nucleus. In 1911 he announced his revolutionary idea on the nature of the atom and he developed a model of the atom showing it similar to the solar system. He proposed the idea that almost all the mass and all the positive electricity in an atom was densely concentrated in a tiny nucleus and the electrons circled around it like planets around the sun.

While at Manchester, Rutherford produced the first human "nuclear reaction" with the disintegration of a non-radioactive atom, dislodging a single particle. He became famous as the man who "split the atom." In 1919, Rutherford succeeded J.J. Thomson as Cavendish Professor of Physics at Cambridge. He was a leader of a research team encouraging others in the investigation of the nucleus.

RUTILE. A mineral, composed of titanium dioxide, which occurs in three distinct forms: as rutile, a tetragonal mineral usually of prismatic habit, often twinned; as octahedrite (anatase), a tetragonal mineral of pseudo-octahedral habit; and as brookite, an orthorhombic mineral. Both octahedrite (anatase) and brookite are relatively rare minerals.

Rutile has a sub-conchoidal fracture; is brittle; luster, metallic-adamantine; color, commonly reddish-brown but sometimes yellowish, bluish or violet; streak, brown; transparent to opaque. Rutile may contain up to 10% of iron.

Experiments in the artificial preparation of titanium dioxide appear to show that rutile is the most stable form and produced at the highest temperature, brookite at a lower temperature, and octahedrite (anatase) at a still lower temperature.

Rutile is found as an accessory mineral in many kinds of igneous rocks, and to some extent in gneisses and schists. In groups of acicular crystals it is frequently seen penetrating quartz as the "flèches d'amour" from Grisons, Switzerland, and Brazil. Rutile is found also in Austria, Italy, Norway, South Australia, and Brazil. In the United States it occurs in Vermont, Massachusetts, Connecticut, New York, Pennsylvania, Virginia, Georgia, North Carolina, and Arkansas.

Rutile derives its name from the Latin *rutilus*, red, in reference to the deep red color observed in some specimens when viewed by transmitted light.

RUZICKA, LEOPOLD (1887–1976). A chemist who won the Nobel prize in 1939 with Adolf Friedrich Johann Butenandt. His work involved research in organic synthesis including polymethylenes and higher terpenes. He was the first chemist to synthesize musk, androsterone, and testosterone from cholesterol. His medical degree was awarded at the University of Basel, Switzerland, although he was born in Croatia and educated partially in Germany.

S

SABATIER, PAUL (1854–1941). A French chemist who received the Nobel prize in Chemistry in 1912 along with Victor Grignard. His work involved the behavior of oxides as oxidizing catalysts and as agents for dehydrating and dehydrogenating. He received his PhD. In Nimes, France, and went on to become lecturer and faculty member in Toulouse, France.

SABATIER-SENDERENS REDUCTION. Catalytic hydrogenation of organic compounds in the vapor phase by passage over hot, finely divided nickel (the oldest of all hydrogenation methods).

SACCHARIDE. See **Carbohydrates**.

SACCHARIMETER. An instrument for the measurement of sucrose solutions. A saccharimeter differs from a polarimeter in that the saccharimeter uses white light, whereas a polarimeter is operated with sharply monochromatic light. Consequently, a saccharimeter can only be used with sugar solutions (in which case the quartz compensates for the rotatory dispersion of sucrose). Conversely, a polarimeter is suitable for the measurement of optical rotation of any solution, including sugar. However, saccharimetric sugar determinations are the basis of internationally accepted *sugar degrees* (°S), and saccharimeters are appropriately calibrated. When a polarimeter is employed that utilizes monochromatic light rather than a quartz wedge, deviations from sugar degrees will be found in some solutions, and they may not be inconsequential. The International Sugar Scale assigns 100°S to a pure sucrose solution of normal weight (26 grams in 100 milliliters of pure water) at 20°C and a 200-millimeter light path, measured in a saccharimeter with white light and a dichromate filter. Of course, an exact numerical conversion from sugar degrees to angular degrees is possible with pure sucrose (100°S corresponds to $\alpha = 34.6°$), but in practical, more or less impure solutions, the relationship is not exactly predictable, and the sugar scale is conventionally and legally binding. It is not surprising, then, that virtually all sugar laboratories use visual saccharimeters (also called polariscopes). They differ in vintage, the half-shade presentation, and in construction features, but they all use the quartz-wedge compensating principle, and they read out in sugar degrees. A typical instrument will have a split half-shade field or a triple field for observation. The quartz wedge is equipped with a fine scale that is read off a second observation tube. It is graduated in °S (e.g., −30 to +110°S) and comes with a vernier, readable to 1/10°S.

SALICYLIC ACID AND RELATED COMPOUNDS. [CAS: 69-72-7]. Salicylic acid or $C_6H_4(OH)(COOH)$ is a white solid, melting points 159°C, sublimes at 76°C, insoluble in cold water, soluble in hot water, alcohol, or ether. With ferric chloride solution, salicylic acid solutions are colored violet (distinction from benzoic acid).

Salicylic acid may be obtained (1) from oil of wintergreen, which contains methyl salicylate, or (2) by heating dry sodium phenate C_6H_5ONa plus carbon dioxide under pressure at 130°C and recovering from the resulting sodium salicylate by adding dilute sulfuric acid.

Uses of Salicylic Acid

Approximately 60% of the salicylic acid produced in the United States has been consumed in the manufacture of aspirin. However, several applications of the acid are growing. Salicylic acid USP, EP, and other pharmacopeial grades are used medically as antiseptic, disinfectant, antifungal, and keratolytic agents. Carbonless copypaper using salicylic acid and alkyl salicylic acid derivatives has become an active application area. The salicylic acid is incorporated into a resin or is encapsulated as one of the agents for pressure or thermally activated imaging.

Salicylic acid derivatives form surfactants that can influence the rheologic properties of solutions. They impart controllable and useful viscous and elastic properties to aqueous liquids.

Salts of Salicylic Acid. A large number of salts of salicylic acid have been prepared and evaluated for therapeutic or other commercial use. Sodium salicylate has analgesic, antiinflammatory, and antipyretic activities. Magnesium salicylate, an analgesic and antiinflammatory agent, appears to have exceptional ability to relieve backaches. It is also used for the symptomatic relief of arthritis. Bismuth subsalicylate is taken orally in combination with other ingredients for protective, antacid action as well as antidiarrheal and antiseptic effects.

Esters of Salicylic Acid. The esters of salicylic acid are commercially produced by esterification of salicylic acid with the appropriate alcohol using a strong mineral acid such as sulfuric as a catalyst. To complete the esterification, the excess alcohol and water are distilled away and recovered. The main commercial applications for salicylate esters are as uv sunscreen agents and as flavor and fragrance agents. Several have application as topical analgesics.

Other Derivatives of Salicylic Acid. *p*-Aminosalicylic acid and its salts have been used in the treatment of tuberculosis. *p*-Aminosalicylic acid can be prepared by the carboxylation of m-aminophenol. Methylene-5,5-disalicylic acid, produced by heating two parts salicylic acid with 1–1.5 parts of 30–40 wt % formaldehyde in the presence of an acid catalyst, is used as an intermediate in the production of bacitracin methylenedisalicylate.

Salicylamide, prepared by the reaction of methyl salicylate with ammonia, has mild analgesic, antiinflammatory, and antipyretic properties. Salicylanilide, prepared by heating salicylic acid and aniline in the presence of phosphorus trichloride, is used as an intermediate in the production of other chemicals and as a slimicide, fungicide, and medicament.

Acetylsalicylic Acid (Aspirin). Acetylsalicylic acid, (*o*-acetyoxybenzoic acid) was first synthesized in 1853 by reaction of acetyl chloride with sodium salicylate. As a drug, acetylsalicylic acid was introduced in Germany in 1899 and into the United States in 1900. Aspirin is a registered trademark of Bayer in many nations, but in the United States and the United Kingdom, aspirin is accepted as the generic name for acetylsalicylic acid. See **Acetylsalicylic Acid**.

m-Hydroxybenzoic Acid. Of the three hydroxybenzoic acids, the metaisomer is of least commercial importance.

Unlike salicylic acid, m-hydroxybenzoic acid does not undergo the Friedel-Crafts reaction. It can be converted in 80% yield to m-aminophenol by the Schmidt reaction, which involves treating the acid with hydrazoic acid in trichloroethylene in the presence of sulfuric acid at 40°C. *m*-Hydroxybenzoic acid is reported as an intermediate in the manufacture of germicides, preservatives, pharmaceuticals, and plasticizer.

p-Hydroxybenzoic Acid. *p*-Hydroxybenzoic acid is of significant commercial importance. The most familiar application is the use of several of its esters as preservatives, known as parabens. See also Anticrobial Agents (Foods). Also of interest is the use in liquid crystal polymer applications.

Salicyl Alcohol. Salicyl alcohol [CAS: 90-01-7]: (saligenin, *o*-hydroxybenzyl alcohol) crystallizes from water in the form of needles or white rhombic crystals. It occurs in nature as the bitter glycoside, salicin [CAS: 138-52-3], which is isolated from the bark of *Salix helix, S. pentandra, S. praecos*, some

other species of willow trees, and the bark of a number of species of poplar trees such as *Polpulus balsamifera, P. candicans*, and *P. nigra*.

The alcohol, which sublimes readily and is very soluble in alcohol and ether, has the following properties: melting point, 86°C; density 13°/25°, 1.161 g/cm^3; heat of combustion, 3.542 mJ/mol (846.6 kcal/mol); and solubility in 100 mL water at 22°C, 6.7 g.

Saligenin has been used medically as an antipyretic and appears to possess marked topical analgesic powers in concentrations of 4–10%. Saligenin's taste is pungent at first and then numbing. Unsymmetrical diphenylolmethanes prepared from salicyl alcohol and substituted phenol at 160–170°C in the presence of alkaline catalysts have been claimed as resin components and resin-hardening agents.

Thiosalicylic Acid. Thiosalicylic acid, [CAS: 147-93-3], (*o*-mercaptobenzoic acid), a sulfur-yellow solid that softens at 158°C, has a melting point of 164°C. It sublimes, is slightly soluble in hot water but freely soluble in glacial acetic acid and alcohol, and yields dithiosalicylic acid, CAS 527-89-9, upon exposure to air.

Thiosalicylic acid has been used as an anthelmintic, bactericide, and fungicide. It has also been used as a rust remover, a corrosion inhibitor for steel, and a polymerization inhibitor. In photography, it has application in print-out emulsions and as an activator for photographic emulsions.

SALT. A compound formed by replacement of part or all of the hydrogen of an acid by one (or more) element(s) or radical(s) that are essentially inorganic. Alkaloids, amines, pyridines, and other basic organic substances may be regarded as substituted ammonias in this connection. The characteristic properties of salts are the ionic lattice in the solid state and the ability to dissociate completely in solution. The halogen derivatives of hydrocarbon radicals and esters are not regarded as salts in the strict definition of the term.

In the classical concept of the process of neutralization, whereby an acid and a base in solution react to form a salt, the proton of the acid and hydroxyl ion of the base react to form water, leaving the cation of the base and the anion of the salt by recombination.

Upon evaporation of the solvent, the salt is obtained as such, frequently as crystals, sometimes with and sometimes without water of crystallization. A salt, when dissolved in an ionizing solvent, or fused (e.g., sodium chloride in water), is a good conductor of electricity and when in the solid state forms a crystal lattice (e.g., sodium chloride crystals possess a definite lattice structure for both sodium cations (Na^+) and chloride anions (Cl^-), determinable by examination with x-rays).

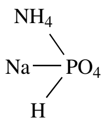
A broader definition than that confined to solutions is demanded in some fields of chemistry (e.g., in high temperature reactions of acids, bases, and salts). In the formation of metallurgical slags, at furnace temperatures, calcium oxide is used as base and silicon oxide and aluminum oxide as acids; calcium aluminosilicate is produced as a fused salt. Sodium carbonate and silicon oxide when fused react to form the salt sodium silicate with the evolution of carbon dioxide. In this sense:

$$\begin{bmatrix}\text{Oxide of any}\\ \text{element functioning}\\ \text{as a metal-that is,}\\ \text{as a base}\end{bmatrix} \text{plus} \begin{bmatrix}\text{Oxide of any}\\ \text{element functioning}\\ \text{as a nonmetal-that}\\ \text{is, as an acid}\end{bmatrix} \text{yields[Salt]}$$

Iron and sulfur when heated react to form the salt ferrous sulfide. In this sense:

metal plus nonmetal yields salt

Salts therefore, are prepared (1) from solutions of acids and bases by neutralization and separation by evaporation and crystallization; (2) from solutions of two salts by precipitation where the solubility of the salt formed is slight (e.g., silver nitrate solution plus sodium chloride solution yields silver chloride precipitate [almost all as solid], and sodium nitrate present in solution as sodium cations and nitrate anions [recoverable as sodium nitrate, solid by separation of silver chloride and subsequent evaporation of the solution]); (3) from fusion of a basic oxide (or its suitable compound—sodium carbonate above) and an acidic oxide (or its suitable compound—ammonium phosphate), since ammonium and hydroxyl are volatilized as ammonia and water. Thus, sodium ammonium hydrogen phosphate



yields sodium metaphosphate, $NaPO_3$, upon heating. (4) Salts also are prepared from reaction of a metal and a nonmetal.

Reactions of salts as such in solution, without decomposition of cation or anion, are dependent upon the presence of the cation and the anion of salt.

An *acid salt* is a salt in which all of the replaceable hydrogen of the acid has not been substituted by a radical or element. These salts, in ionizing, yield hydrogen ions and react like the acids (e.g., $NaHSO_4$, $KHCO_3$, Na_2HPO_4).

An *amphiprotic* (also called *amphoteric*) *salt* is a salt that may ionize in solution either as an acid or a base, and react either with bases or acids, according to the conditions.

A *basic salt* is a salt contains combined base as $Pb(OH)_2$ $Pb(C_2H_3O2)_2$, a basic acetate of lead. These salts may be regarded as formed from the basic hydroxides by partial replacement of hydroxyl (e.g., HO–Zn–Cl). They react like bases and, when soluble, ionize to yield hydroxyl ions.

A *complex salt* is a saline compound having the structure of a combination of two or more salts and that is regarded as the normal salt of a complex acid. Complex salts do not split into a mixture of the constituent salts in solution, but furnish a complex ion that contains one of the bases (e.g., potassium molybdophosphate and potassium platinochloride).

A *double salt* is a substance consisting of two simple salts that crystallize together in definite proportions and exist independently in solution (distinction from complex salts). The alums are representative double salts.

An *inner salt* is a member of a special class of internal salts in which an acid group and a neutral group coordinate with metals to form a cyclic complex. These salts occur widely in analytical chemistry, (where they are formed between metallic ions and organic reagents) in dyestuffs, in life processes (chlorophyll and hematin belong to this class of compounds), and in many other fields.

An *internal salt* is a compound in which the acidic or basic groups that react to produce the salt linkage (which may or may not entail the formation of water) are in the same molecule. This particular salt linkage may consist of a polar or a nonpolar bond.

A *mixed salt* is a salt of a polybasic acid in which the hydrogen atoms are replaced by different metallic atoms or positive radicals.

A *pseudo salt* is a compound that has some of the normal characteristics of a salt, but lacks certain others, notably the ionic lattice in the solid state and the property of ionizing completely in solution. The absence of these properties is due to the fact that the bonds between the metallic and nonmetallic radicals are covalent or semicovalent instead of polar. Because these salts do not ionize completely, they are also called *weak salts*.

SALT BATH. A molten mixture of sodium, potassium, barium, and calcium chlorides or nitrates to which sodium carbonate and sodium cyanide are sometimes added. Used for hardening and temperature of metals and for annealing both ferrous and nonferrous metals. Temperatures used may be as high as 1,315°C for hardening high-speed steels. Commercial mixtures are available for a variety of specifications.

SALT (NaCI). See **Sodium Chloride**.

SALTING OUT. Reduction in the water solubility of an organic solid or liquid by adding a salt (usually sodium chloride) to an aqueous solution of the substance. Ions of the dissolved salt attract and hold water molecules, thus making them less free to react with the solute. The result of this is to decrease the solubility of the solute molecules with consequent separation or precipitation. Colloidal suspensions of proteins, soaps, and similar substances are precipitated in this way.

SALTPETER. Potassium nitrate. Sodium nitrate is often called Chile saltpeter, and calcium nitrate is sometimes called Norway saltpeter.

SAMARIUM. [CAS: 7440-19-9]. Chemical element symbol Sm, at. no. 62, at. wt. 150.35, fifth in the Lanthanide Series in the periodic table, mp 1,073°C, bp 1,791°C, density 7.520 g/cm^3 (20°C). Elemental samarium has a rhombohedral crystal structure at 25°C. The pure metallic samarium is silver-gray in color, retaining a luster in dry air, but only moderately stable in moist air, with formation of an adherent oxide. When pure, the metal is soft and malleable, but must be worked and fabricated under an inert gas atmosphere. Finely divided samarium as well as chips from working are

pyrophoric and ignite spontaneously in air, burning at 150–180°C. There are seven natural isotopes of samarium ^{144}Sm, ^{147}Sm through ^{150}Sm, ^{152}Sm, and ^{154}Sm. Eleven artificial isotopes have been identified. The natural ^{147}Sm isotope is weakly radioactive with a half-life of 2.5×10^{11} years. The samarium isotope mixture is the second highest (after gadolinium) of all elements in terms of its thermal-neutron-absorption cross-section (5,800 barns at 0.025 eV). The cross-section of ^{149}Sm is about 40,000 barns. Samarium ranks 62nd in abundance of the elements in the earth's crust, exceeding tantalum, mercury, bismuth, and the precious metals, excepting silver. The element was first identified by Lecoq de Boisbaudran in 1879. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^5 5s^2 5p^6 5d^1 6s^2$$

Ionic radius Sm^{2+} 1.11 Å, Sm^{3+} 0.964 Å. First ionization potential 5.6 eV; second 11.1 eV. Other important physical properties of samarium are given under **Rare-Earth Elements and Metals**.

The principal sources of samarium are monazite (4.5% Sm_2O_3) and bastnasite (0.5% Sm_2O_3). Current demands for the element are met by the coproduction with europium and gadolinium from these minerals. The residues of uranium mining (Canada) also contain about 4.5% Sm_2O_3. Unlike the other light rare-earth metals, the salts and oxide of samarium do not reduce to metal using barium, calcium, or lithium, nor can electrolytic processes be used. The most effective reducing agent is lanthanum, which is mixed with Sm_2O_3 and heated under vacuum in a tantalum crucible. The samarium metal volatilizes and is condensed as powder or sponge on coiled tantalum or copper condenser plates. Subsequently, the samarium must be remelted under an argon or inert atmosphere before it is cast into graphite or tantalum molds.

Samarium has been alloyed with gadolinium and aluminum to produce nuclear reactor hardware that will absorb neutrons for short periods. The use of samarium in intermetallics, cermets, and other chemical forms for use in nuclear applications holds promise. Small quantities of Sm_2O_3 are used in optical-glass filters and to encase lanthanum borate glass rods, which then are drawn into fine fibers for fiberoptics applications. The element has been used as a coding agent for inks used in data handling systems. Small amounts also have been used for activating phosphate-type phosphors. The addition of samarium oxide produces a strong narrow emission in the near-infrared spectral region. The most significant use of samarium is in the permanent-magnet alloys $SmCo_5$ and Sm_2Co_{17}. The strength of these magnets Second to that of $Nd_2Fe_{14}B$ by only a small margin. But, because of costs the utilization of the $SmCo_5$–Sm_2Co_{17} alloys is much less than that of the Nd–based permanent magnets. The Sm–base permanent magnets have a much higher magnetic ordering temperature and are used in high temperature greater than 250°F (or 120°C) applications. See also **Cobalt**.

SANDSTONE. Sand grains cemented by such substances as silica, carbonate of lime or iron oxide, so as to form a solid rock is called sandstone. It occurs usually in beds of varying thickness, depending upon the conditions under which the original sediments were laid down. Because it is normally well-jointed and easy to work, sandstone has been much used for building purposes. Unfortunately, however, as most sandstones are quite porous, the weathering action of the atmospheric agencies may have a very deleterious effect upon them.

SANGER, FREDERICK (1918–). An English biochemist who won the Nobel prize for chemistry in 1958. His research was on protein structure. He identified the amino acid sequence of the protein insulin. His PhD. was awarded from Cambridge University.

SAPONIFICATION. A special case of hydrolysis in which an ester is converted into an alcohol and a salt of the appropriate acid by reaction with an alkali. Though the operation has numerous applications throughout the chemical industry, it is noteworthy because some 80% of standard soap is prepared by this method. The esters may be of mono- or polybasic acids and mono- or polyhydric alcohols, the physical conditions under which the reaction occurs being suitably varied to secure an adequate rate. The alkali most commonly used is sodium hydroxide, because of cost and water solubility, but other appropriate alkaline materials are suitable.

Since the preparation of soap is typical of a fairly complex reaction, chemically, and since it is common, it serves as a useful example of the saponification operation. The complication, of course, occurs because the usual esters used for soap are the glycerol esters of fatty acids, saturated and unsaturated. Thus the saponification of stearin (glycerol tristearate) is commonly shown as follows:

$$\begin{array}{l} C_{17}H_{35}COO\text{—}CH_2 \\ \qquad\qquad\quad | \\ C_{17}H_{35}COO\text{—}CH + 3NaOH \rightarrow \\ \qquad\qquad\quad | \\ C_{17}H_{35}COO\text{—}CH_2 \end{array}$$

$$\begin{array}{r} 3C_{17}H_{35}COONa + HO\text{—}CH_2 \\ | \quad \\ HO\text{—}CH \\ | \quad \\ HO\text{—}CH_2 \end{array}$$

Actually, the saponification appears to progress stepwise, the first hydrolytic reaction taking place as follows:

$$\begin{array}{l} C_{17}H_{35}COO\text{—}CH_2 \\ \qquad\qquad\quad | \\ C_{17}H_{35}COO\text{—}CH + NaOH \rightarrow \\ \qquad\qquad\quad | \\ C_{17}H_{35}COO\text{—}CH_2 \end{array}$$

$$\begin{array}{l} C_{17}H_{35}COO\text{—}CH_2 \\ \qquad\qquad\quad | \\ C_{17}H_{35}COO\text{—}CH + C_{17}H_{35}COONa \\ \qquad\qquad\quad | \\ \qquad\quad HO\text{—}CH_2 \end{array}$$

The diglyceride formed is subsequently split to the monoglyceride, which finally is converted to glycerol, if sufficient alkali is present. Thus, the reaction is a bimolecular one rather than quadrimolecular, as is commonly indicated. In actual practice, the fats used are complex glycerides of a number of saturated and unsaturated acids, rather than the stearin shown here.

Technologically, the saponification operation varies in degree of difficulty depending on the ester. The reaction rate differs for different esters, for one thing, bu another determining factor is the contact area possible between the alkali and the ester. In the case mentioned above, the fat at the start is insoluble and immiscible in water, so that reaction in a nonagitated vessel would be very slow, occurring only at the limited interface.

Though saponification is the dominant reaction when the techniques described above are used, in many instances side reactions may occur which may profoundly modify the products. Oxidation, of course, is one of the more obvious things to guard against, since many times the esters being treated are unsaturated. Both isomerization and polymerization, however, may occur under the alkaline conditions obtaining, the unconjugated polyethenoid acids becoming conjugated during treatment. This especially appears to be true in the case of highly unsaturated compounds. However, by properly controlling reactants and conditions, saponification remains a very flexible and useful industrial and laboratory operation possible of wide application and at low cost.

SAPONIFICATION NUMBER. See **Vegetable Oils (Edible)**.

SATURATED COMPOUND. See **Organic Chemistry**.

SATURATION. 1. The state in which all available valence bonds of an atom (especially carbon) are attached to other atoms. The straight-chain paraffins are typical saturated compounds.

2. The state of a solution when it holds the maximum equilibrium quantity of dissolved matter at a given temperature.

SAYBOLT UNIVERSAL VISCOSITY. The efflux time in seconds (SUS) of 60 mL of sample flowing through a calibrated Universal orifice in a Saybolt viscometer under specified conditions.

See also **Viscosity**; and **Viscometer (or Viscosimeter)**.

SCALE. 1. A calcareous deposit in water tubes of steam boilers resulting from deposition of mineral compounds present in the water, e.g., calcium carbonate.

2. A type of paraffin or petroleum was from which all but a few percent of oil has been removed by hydraulic pressing and subsequent processing.

3. A graduated standard of measurement in which the units (degrees) are defined in relation to some property of what is measured, e.g., temperature scale, Brix scale, and Baume scale.

4. The markings indication such units as on a thermometer or graduate.

5. A weighing device that may be of the beam type in which weights (poises) and lever systems are used, or the direct-reading spring type in which the gravitational pull of the object being weighed is counterbalanced by a known constant spring force.

SCANDIUM. [CAS: 7440-20-2]. Chemical element, symbol Sc, at. no. 21, at. wt. 44.956, periodic table group 3, is a member of the rare earth group of elements along with yttrium and the lanthanides, mp 1540°C, bp 2850°C, density 2.989 g/cm^3 (alpha form), 3.73 g/cm^3 (beta form). The alpha form is close-packed hexagonal and beta is the face-centered cubic allotrope. Scandium is a relatively soft metal with a silvery luster. The metal is stable in air. Scandium combines readily with acids and at elevated temperatures with oxygen, halogens, and chalcogenides. ^{45}Sc occurs in nature and is not radioactive. Nine radioactive isotopes have been identified ^{40}Sc through ^{44}Sc and ^{46}Sc through ^{51}Sc, all with relatively short half-lives, ranging from a fraction of a second up to 84 days. Scandium occurs widely throughout nature, but in reasonably concentrated forms only in a few uncommon minerals. Abundance in the Earth's crust is estimated at approximately $5–6 \times 10^{-4}$%, ranking it ahead of such elements as antimony, bismuth, silver, and gold. It is estimated that a cubic mile of seawater contains about 375 pounds of the element. Scandium was predicted by Mendeleev in 1869, at which time he called it *ekaboron* and foretold accurately a number of its properties. A small amount of scandium oxide was extracted from euxenite and gadolinite by Nilson in 1879, a material that Nilson called *scandia*. In the same year, Cleve isolated a greater quantity of the oxide, from which several compounds were prepared and favorably compared with Mendeleev's predictions for ekaboron. Ionic radius Sc^{3+} 0.745. First ionization potential, 6.54 eV; second, 12.80 eV; third, 24.76 eV. Other physical properties are given under **Chemical Elements**.

Scandium occurs in some ores with the Rare Earth Series elements. It is easily separated from the Lanthanides, as well as yttrium, by taking advantage of the greater solubility of its thiocyanate in ether. The three recognized scandium minerals are thortveilite, a silicate; and sterrettite and kolbeckite, both phosphates. Wiikite and bazzite, complex niobates and silicates, are known to contain more than 1% scandium. The recovery of scandium from uranium and tungsten from mining tailings, however is the major source of the element. Scandium has not been found without the other Rare earth elements. The element usually is separated from ore extracts and concentrates by precipitation as the oxalate. Scandium metal with a purity of 99.9% has been produced.

In water solutions, the scandium ion has a triple positive charge. Studies show, however, that the simple Sc^{3+} ion seldom exists. Rather, the form is highly polymerized and hydrolyzed—with hydroxy-bonded structures. In forming compounds, scandium parallels aluminum, yttrium, gallium, indium, and tellurium. Several carbides of scandium have been reported, the most stable carbide being ScC, including scandium clusters in fullerene cages.

Like the hydroxides of the Rare earth, scandium hydroxide, $Sc(OH)_3$, is precipitated by addition of alkalies to solutions of scandium salts; however, the latter is precipitated at pH 4.9, while the former require pH 6.3 or more, a property which is utilized in one method of separation. Upon heating the hydroxide (or certain oxyacid salts), scandium oxide, Sc_2O_3 is produced. Scandium hydroxide is less acidic than aluminum hydroxide, requiring boiling KOH solution to form the complex potassium compound, $K_2[Sc(OH)_5 \cdot H_2O] \cdot 3H_2O$.

All four trihalides of scandium are known. The trifluoride is very slightly soluble in H_2O, and is precipitated from scandium nitrate, $Sc(NO_3)_3$, solutions by hydrofluoric acid. It dissolves in alkali fluorides to yield the complex ion $[ScF_6]^{3-}$. The chloride is formed in solution by treating the hydroxide or oxide with HCl, yielding hydrated crystals on concentration, which give hydroxychlorides on heating. The bromide is also prepared from the oxide or hydroxide and hydrobromic acid, or in anhydrous form from the oxide, carbon, and bromine, on heating. The iodide is also prepared by the latter method.

The thiocyanate is prepared in solution by adding ammonium thiocyanate, NH_4SCN to HCl solutions of the chloride. Both basic and double carbonates are known. The former is precipitated from Sc^{3+} solutions by adding carbonate solutions, and is probably $Sc(OH)CO_3 \cdot H_2O$. The latter are obtained by the use of an excess of the soluble carbonate. Normal, basic, and double sulfates are known. The first exists in several degrees of hydration; the second is obtained as $Sc(OH)SO_4 \cdot 2H_2O$, by treating the normal sulfate tetrahydrate with the hydroxide. The alkali double sulfates and alums are obtained by treating the sulfate solution with an excess of the alkali (or ammonium) sulfate solution.

The nitrate is readily obtained by action of dilute HNO_3 on the hydroxide. In aqueous solution, the anhydrous nitrate yields a monobasic nitrate on heating.

To date, the applications for scandium and its compounds have been limited, mainly because of its high cost. The main uses of scandium are in sporting goods equipment and in lighting, including automotive headlights. In former application scandium is added to improve the strength of aluminum, while in the latter ScI_3 is used in metal halide arc lamps to increase the intensity and to improve the color rendition to match that of natural sunlight. Minor applications include: scandium substitution for yttrium in yttrium garnets for electronic uses, analytical standards, semiconductor applications, welding wire, and metallurgical research.

SCANNING TUNNELING MICROSCOPE. This microscopic technique (STM), invented by Gerd K. Binnig and Heinrich Rohrer (IBM Research Laboratory, Zurich, Switzerland) in 1981, generates topographic images of surfaces with atomic resolution. With the STM, scientists have obtained previously unseen images of gold, silicon, nickel, oxygen, and carbon atoms. STM views can reveal flaws and contaminants in atomic surface structure. Detailed views of three-dimensional atomic "landscapes" are improving and will continue to improve the knowledge of surface physics and chemistry and thus be of exceptional value in technical fields as varied as metallurgy, magnetism, semiconductor technology, and biology. Before development of the STM technique, scientists had been puzzled about the exact surface structure of silicon, the basic material from which computer chips are made. Many models of the silicon surface have been constructed. The STM has enabled researchers to sort out prior assumptions and hypotheses. In connection with gold, the STM has revealed a surface structure created by the spontaneous formation of ribbon-like facets, features that previously had not been distinguished with such clarity. The renowned physicist, Wolfgang Pauli, many years ago observed, "The surface was invented by the devil," with reference to the fact that the surface of a solid is its boundary or interface with the environment outside and beyond the solid. Whereas atoms within a solid interact with other atoms within the solid, those atoms on the surface can interact only with those

atoms directly underneath and those atoms in the environment beyond the surface. Thus, surface atoms behave with different rules.

Instrumental means for investigating the atomic pattern of surfaces have included electron microscopy and later (1950s), the field-ion microscope (invented by Edwin W. Müller). These techniques continue, but are generously abetted by the STM. In 1984, the inventors of the STM received the Hewlett-Packard Europhysics Prize for outstanding achievements in solid state physics and the King Faisal International Prize in Science. In 1986, Binnig and Rohrer shared in the Nobel Prize in Physics.

Expanded Applications of STM

Since its introduction for practical uses in the early 1980s, the scanning tunneling microscope has found scores of applications that were not contemplated at the outset of STM technology. These applications include the manufacture of optical grating masters, the manufacture of recording thin-film magnetic recording heads, the manufacture of compact disk stampers, and the repair of costly masks used for integrated circuit manufacture—just to mention a few examples of practical usage in the electronics field. STM can be operated under water and other fluids, permitting the examination of biological materials in a more natural setting. The versatility of the STM is demonstrated by the appearance of hundreds of technical papers in the literature over a 1-year period. The STM can achieve lateral resolution of 1 to 2 angstroms and, in the vertical dimension, better than 0.05 angstrom. To overcome the relatively few limitations of STM, the technology has spawned several other microscopic techniques, including the atomic force microscope, the friction force microscope, the magnetic force microscope, the electrostatic force microscope, the attractive mode force microscope, the scanning thermal microscope, the optical absorption microscope, the scanning ion-conductance microscope, the scanning near-field optical microscope, the scanning acoustic microscope, and the molecular dipstick microscope—all resulting from the character of innovative thinking that scientists have come to apply to the application of new forms of energy to microscopy, once wholly dependent upon materials interactions with visible light. STM has played an invaluable role, not only in the development of new materials, but in understanding how surface atoms differ from the permanently embedded atoms of a material.

STM Fundamentals

As put forth in their excellent 1985 paper (reference listed), Binnig and Rohrer credit *electron tunneling* as the phenomenon that underlies the operation of the STM. As indicated by Fig. 1, an electron cloud occupies the space between the surface of the sample and the needle tip used. The cloud is a consequence of the *indeterminacy*[1] of the electron's location (a result of its wavelike properties). Because the electron is "smeared out" so to speak, there is a probability that it can lie beyond the surface boundary of a conductor. The density of the electron cloud decreases exponentially with distance. A voltage-induced flow of electrons through the cloud thus is extremely sensitive to the distance between the surface and the tip. As the STM tip is swept across the surface, a feedback mechanism senses the flow (the *tunneling current*) and holds constant the height of the tip above the surface atoms. In this way, the tip follows the contours of the surface. The motion of the tip is read and processed by computer and displayed on a screen or plotter. By sweeping the tip through a pattern of parallel lines, a high-resolution, three-dimensional image of the surface is obtained.

Views of the STM are shown in Figs. 2 and 3. Binnig and Rohrer describe the STM as having two stages, suspended from springs, that operate within a cylindrical steel frame. The microscope mechanism is contained by the innermost stage. Vibration is a severe problem, requiring special preventive measures. To obtain images with high resolution (Fig. 4) of surface structures, obviously the microscope must be protected from even very small vibrations as may be caused by sound and footsteps and other disturbances within the laboratory. To subdue vibration, copper plates are attached to the bottom of the stainless-steel frame and magnets are attached to the bottom of the inner and outer stages. Any disturbance causes the copper plates to move up and down in the field generated by the magnets. The movement induces eddy currents in the plates. Interaction of the eddy currents with the magnetic field retards the motion of the plates and thus the motion of the microscope stages. Where investigations require vacuum conditions, a steel cover is placed over the outer frame of the microscope.

The microscopic device incorporates a sample and a scanning needle. Piezoelectric materials (expand or contract with applied voltage) make it

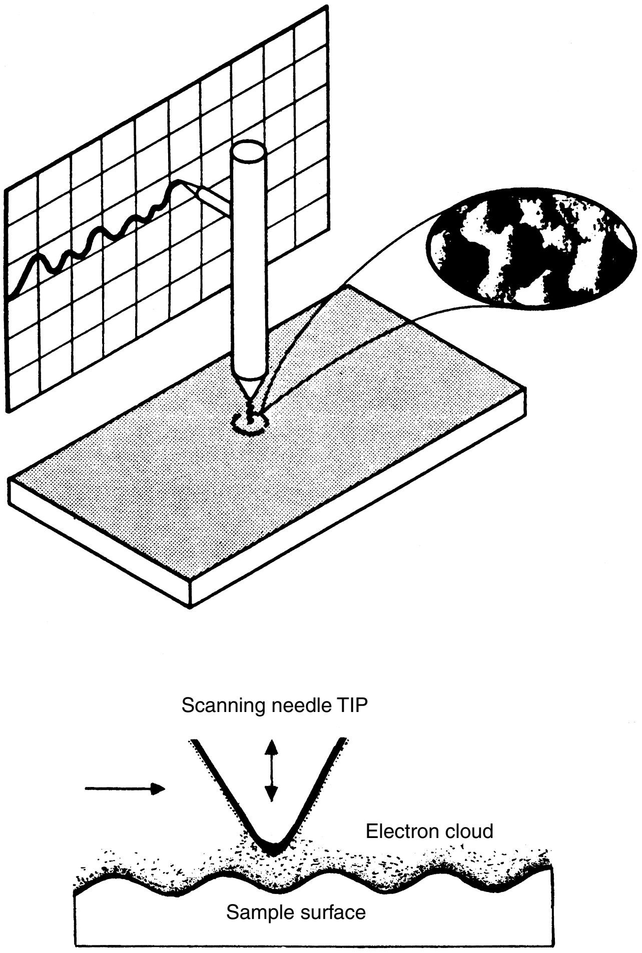

Fig. 1. As the probe tip of the STM is scanned across the microscopic "hills and valleys" of a surface, the vertical position of the probe is precisely adjusted to maintain a constant tip-to-surface distance. This is accomplished by keeping the tunneling current constant. Consequently, the probe follows the surface contour as it moves, yielding a 2-dimensional, enlarged representation of the surface contour for each such scan. A full 3-dimensional image is obtained by assembling an entire sequence of scans. (*IBM Corporation*)

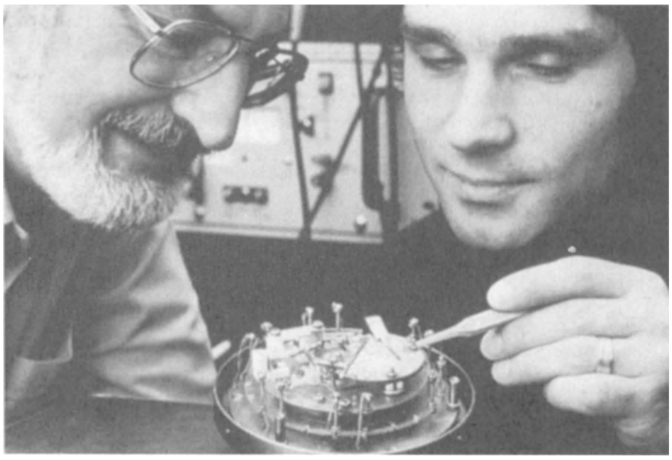

Fig. 2. Inventors Rohrer (left) and Binnig (right) shown adjusting the sample in the chamber of an early (1981) version of the scanning tunneling microscope. Later (1986), these scientists shared in the Nobel Prize in Physics for developing the STM instrument and technique. (*IBM Corporation*)

[1] The roots of atomic structure extend back over 50 years, to the development of the concept of quantum mechanics and experiments in 1927 by Davisson and Germer, the researchers who confirmed the wave nature of the electron. The first experimental verification of tunneling was made about three decades ago by Ivar Giaever.

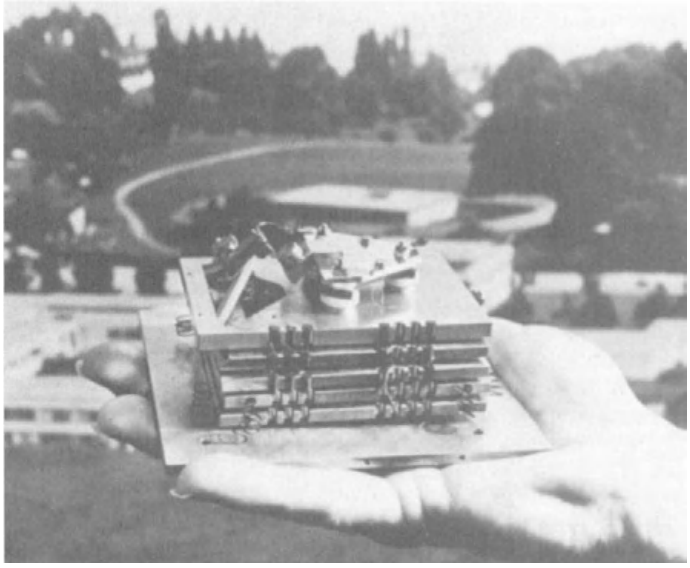

Fig. 3. Miniaturized version of the scanning tunneling microscope. The STM has become a very important tool for materials research and, in particular, to gaining new knowledge of computer chips. STMs are being used or are under construction by some fifty research groups worldwide in a broad range of physical, chemical, biological, and materials studies. (*IBM Corporation*)

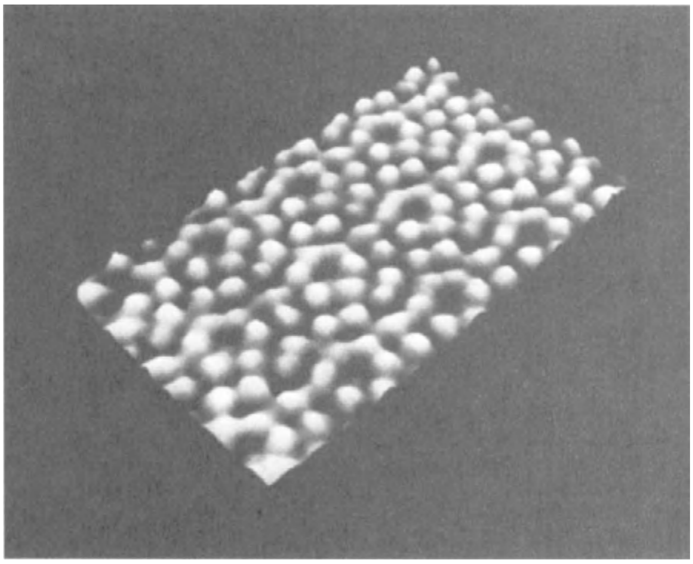

Fig. 4. Magnified millions of times are surface atoms of silicon. The image is computer-generated from data produced by a scanning tunneling microscope. (*IBM Corporation*)

possible for the device to resolve features that are about a hundredth the size of an atom. A piezoelectric drive positions the sample on a horizontal metal plate and a piezoelectric tripod then sweeps the scanning needle over the surface of the sample, simultaneously achieving high stability and precision. See also Figs. 5 through 8.

Not only does the STM portray atomic topography, but it also reveals atomic composition. The inventors observe that the tunneling current depends both on the tunnel distance and the electronic structure of the surface and on the fact that each atomic element has an electronic structure unique to itself. The ability of the STM to resolve both topography and electronic structure assures wide use of the technique in numerous fields. Unlike other imaging techniques, the STM does not alter or partially destroy the sample. The STM already has demonstrated its utility in biology even though lateral resolutions of only 10 angstroms can be achieved. In this instance, the relatively poor resolving power of the microscope is more than compensated for by its ability to provide a direct and nondestructive method of viewing biological samples. Researchers

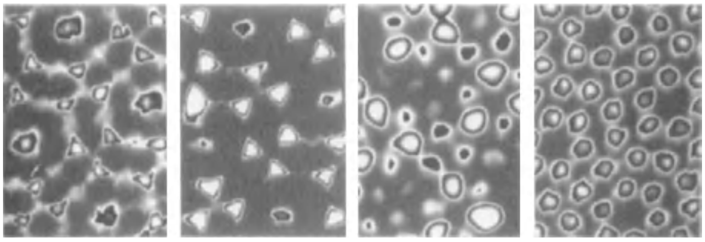

Fig. 5. Looking successively deeper into the atomic structure of silicon. Sequence shows surface magnified some ten million times, to a depth of about nine angstroms (36 billionths of an inch). Shown from left to right are the geometric positions of the atoms and three different classes of electronic bonds. (**a**) shows the position of the top atoms; (**b**) the dangling bonds that reach up from those atoms; (**c**) the dangling bonds that reach up from other atoms in the second layer in the surface; and (**d**) bonds (called “back bonds”) that reach out sideways from the atoms in the second layer in the surface. (*IBM Corporation*)

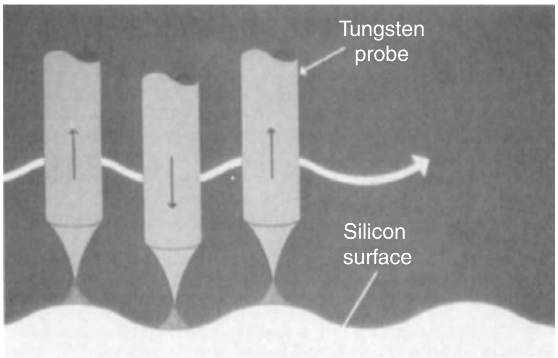

Fig. 6. As probe is scanned across silicon surface, its height above the surface is adjusted to keep the tunneling current constant. The monitoring of those height changes provides the desired topographic information. (*IBM Corporation*)

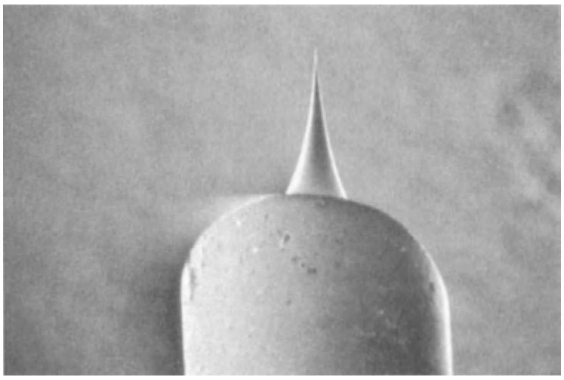

Fig. 7. Tungsten probe tip for scanning tunneling microscope as seen by a scanning electron microscope. Such probes, produced by field-ion microscopy, can be constructed with tips only one atom in width. (*IBM Corporation*)

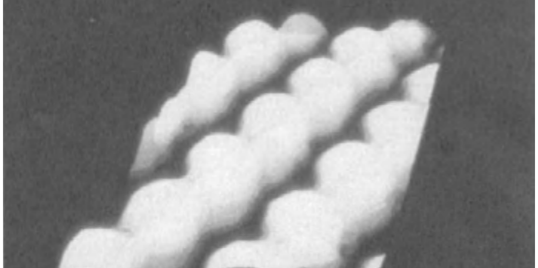

Fig. 8. Scanning tunneling microscope image of gallium arsenide (GaAs). Atoms to the left of each row are gallium; others are arsenic. (*IBM Corporation*)

at the IBM Zurich Research Laboratory and the Swiss Federal Institute of Technology have scanned the surface of DNA and observed a series of zigzags which correspond to its helical structure. Researchers at the Autonomous University of Madrid have made detailed examinations of viruses, notably phi 29 which measures $40 \times 300 \times 200$ angstroms. It is currently visualized that the STM also will be very useful for testing electronic circuits, particularly as further reductions in size are achieved.

SCAPOLITE. The mineral scapolite is a silicate of calcium and aluminum that contains also some potassium, sodium, and chlorine. The name identifies all intermediate members of a series with the following end members: Marialite $3Na(AlSi^3)O^8 \cdot NaCl$, Meinoite $3Ca(Al^2Si^2)O^8 \cdot CaCO_3$. Its tetragonal crystals are coarse and thick, often very large. It occurs also in massive forms. It has a distinct prismatic cleavage; subconchoidal fracture; is brittle; hardness, 5.5–6; specific gravity, marialite, 2.5–2.62, meionite, 2.72–2.78; luster, vitreous to rather dull, color, white to gray, red, green, blue, or yellow; translucent to opaque, rarely transparent.

Scapolite is found in the metamorphic rocks, particularly those rich in calcium; also in contact metamorphic deposits in limestones. It has been found in basic igneous rocks, probably as a secondary mineral. Notable localities are Lake Baikal, Siberia; Arendal, Norway; and Madagascar. In the United States, it is found in Massachusetts, New York, and New Jersey. Greenville, in the Province of Quebec, Canada is an important locality. Superb transparent yellow gem crystals have recently been found in Brazil and Tanzania. Wernerite (scapolite) was named in honor of A.O. Werner, a famous German mineralogist (1749–1817).

SCAVENGING. 1. The use of an unspecific precipitate to remove from solution by adsorption or coprecipitation a large fraction of one or more undesirable radionuclides. Voluminous gelatinous precipitates are usually used as scavengers, e.g., $Fe(OH)_3$. 2. The removal of impurities from molten metal by addition of substances to form slags, or other compounds that can readily be removed. 3. The removal of unwanted gases from systems, e.g., of products of combustion from an internal combustion engine, or residual gases from an evacuated tube.

SCHEELE, C. W. (1742–1786). One of the outstanding early chemical thinkers and experimenters, Scheele was a Swedish scientist who discovered a number of previously unknown substances, among which are tartaric acid, chlorine, manganese salts, arsine, and copper arsenite (Scheele's green). He also noted the oxidation states of various metals, observed the nature of oxygen two years before Priestley's discovery, and discovered the chemical action of light on silver compounds, thus laying the foundation of photochemistry and photography. Scheelite, or natural calcium tungstate, is named after him.

See also **Scheelite**.

SCHEELITE. The mineral scheelite is calcium tungstate, $CaWO_4$, with molybdenum substituting for tungsten up to 25% in the molybdian scheelite variety. It is a tetragonal with an octahedral habit although also at times tabular, and may occur massive. It displays an octahedral cleavage; is brittle; hardness, 4.5–5; specific gravity, 6.1; luster, vitreous; color, white to yellowish, reddish, greenish and brownish; white streak; transparent to translucent. Scheelite is found in pegmatite and ore veins associated with granites, also as a contact metamorphic mineral. It is known from the Czech Republic and Slovakia, Saxony, Italy, Alsace, Finland; Cumberland and Cornwall in England; and Mexico. Crystals of exceptional length (6–10 inches; 15–25 centimeters) are found at various localities in Korea and Japan; and in the United States, in Connecticut, Colorado, South Dakota, Arizona, Nevada, and California. The Swedish chemist, Karl Wilhelm Scheele, discovered tungsten in this mineral, which later was named for him.

The mineral fluoresces vivid bluish white to white; or yellowish white with increasing molybdenum content under exposure to short-wave ultraviolet light.

SCHIST. The schists form a great group of metamorphic rocks chiefly notable for the preponderance of the lamellar minerals such as the micas, chlorite, talc, hornblende, graphite, etc. Quartz often occurs in drawn out grains to such an extent that a quartz schist is produced. Most schists have in all probability been derived from clays and muds which have passed through a series of metamorphic processes involving the production of shales, slates and phyllites as intermediate steps. Certain schists have been derived from fine-grained igneous rocks such as lavas and tuffs. Most schists are mica schists, but graphite and chlorite schists are common. Schists are named for the prominent or perhaps unusual mineral constituent, as garnet schist, tourmaline schist, glaucophane schist, etc. The word schist is derived from the Greek meaning to split, with reference to the easy separation of these rocks in a direction parallel to that in which the platy minerals lie.

SCHMIDLIN KETENE SYNTHESIS. Formation of ketene by thermal decomposition of acetone over electrically heated wire at 500–750 degrees by a reaction involving radical formation with generation of methane and carbon monoxide.

SCHMIDT REACTION. Acid catalyzed addition of hydrazonic acid to carboxylic acids, aldehydes, and ketones to give amines, nitriles, and amides, respectively.

SCHORIGIN (or Shorygin) REACTION. Organometallic reactions of the Grignard type, employing sodium in place of magnesium; the reaction of alkyl sodium compounds with carbon dioxide to give monobasic acids is sometimes known as the Wanklyn reaction.

SCHOTTEN-BAUMANN REACTION. Acylation of alcohols with acyl halides in aqueous alkaline solution.

SCHWEITZER'S REAGENT. A solution of copper hydroxide in strong ammonia used in analytical chemistry as a test for wool. It dissolves cotton, silk, and linen.

SCLEROMETER. An apparatus for determining the hardness of a material by measuring the pressure on a standard point that is required to scratch the material. A scleroscope is a similar apparatus, which measures hardness by determining the rebound of a standard ball dropped on the subject material from a fixed height.

SCOLECITE. This mineral is a zeolite, a hydrous calcium-aluminum silicate, $CaAl_2Si_3O_{10} \cdot 3H_2O$. It occurs in slender monoclinic prisms and in fibrous and nodular masses. Hardness is 5; specific gravity, 2.27; luster vitreous to silky; transparent to translucent. When heated, some specimens of scolecite curl up like worms; hence its name, derived from the Greek meaning a worm. This mineral occurs with other zeolites, at Baden, Switzerland; Iceland; Greenland; the Deccan region of India; and in the United States at Golden, Colorado, and Paterson, New Jersey. Single crystals up to 12 inches (30 centimeters) in length have recently been found in a single large cavity in the basaltic trap rocks near Nasik, India.

SCORODITE. This hydrated arsenate of ferric iron and aluminum $(Fe_3+, Mg_3+)AsO_4 \cdot 2H_2O$, crystallizing in the orthorhombic system, is the iron-rich isomorphous end member of a complete series extending to the aluminum-rich mineral Mansfieldite. Crystals usually occur as drusy crusts. Also occurs as massive, compact, and earthy material. Hardness of 3.5–4, with specific gravity of 3.278. Vitreous to subadamantine luster, of pale green to liver-brown color.

Scorodite occurs as a secondary alteration mineral in the oxidized zone of metallic arsenic-containing veins. The mineral also may be a product of deposition from certain hot springs. World localities of note include Siberia; Laurium, Greece; Carinthia; Cornwall, England; and Nevada, Utah in the United States. Currently being deposited by hot springs at Yellowstone National Park in Wyoming.

SEABOARD PROCESS. Method of removing hydrogen sulfide from a gas by adsorption in sodium carbonate solution. Sodium bicarbonate and sodium hydrosulfide are formed. Blowing air through the solution, hydrogen sulfide is released and carried off, and the sodium carbonate is regenerated.

SEABORG, GLENN T. (1912–1999). An American atomic scientist, and one of the first scientists to produce a transuranium element. He received is A. B. degree at the University of California, Los Angeles in 1934, and his doctorate at the University of California, Berkeley in 1937. As a graduate student in the 1930s doing wet chemistry research for his advisor Gilbert Newton Lewis, Seaborg devoured the text *Applied Radiochemistry* by Otto Hahn, of the Kaiser Wilhelm Institute for Chemistry in Berlin. For several years, Seaborg conducted important research in artificial radioactivity using the Lawrence cyclotron at Cal Berkeley. He was excited to learn from others that nuclear fission was possible, but also chagrined, as his own research might have led him to the same discovery. In 1939 he became an instructor in chemistry at UC Berkeley.

In the same year in which he produced plutonium, 1941, he also discovered that the isotope U^{235} undergoes fission under appropriate conditions. He therefore was responsible for two different approaches to the development of nuclear weapons. At this time he was transferred to the Manhattan Project and was part of Enrico Fermi's team, which achieved the first nuclear chain reaction in 1942.

In 1951 along with Edwin McMillan he received the Nobel prize in chemistry for the creation of the first transuranium elements. He created plutonium, americium, curium, berkelium, and californium at Berkeley.

The element seaborgium was named for him in honor of his accomplishments. It was so named while he was still alive, which proved extremely controversial. For the remainder of his life, Seaborg was the only person in the world who could write his address in chemical elements: Seaborgium, Lawrencium, Berkelium, Californium, Americium (Glenn Seaborg, Lawrence Berkeley National Laboratory, Berkeley, California, United States of America).

SEABORGIUM. See **Chemical Elements**.

SEALANTS. Any organic substance that is soft enough to pour or extrude and is capable of subsequent hardening to form a permanent bond with the substrate. Most sealants are synthetic polymers (silicones, urethanes, acrylics, polychloroprene) that are semisolid before application and later become elastomeric.

Performance Characterists

Movement Capabilities. The movement capability of a sealant is the amount of displacement the sealant can endure in extension or compression without failing. In general, sealants with lower modulus of elasticity can handle higher movements.

Sealants can be broadly divided into classes according to the amount of movement they can successfully handle. High performance sealants such as silicones, urethanes, and polysulfides can typically handle movements of 25% or higher. Medium performance sealants such as some acrylics can handle movements of 10–25%. Low performance sealants such as butyls, putties, and caulks accommodate movements under 10%.

Modulus. The measure of the stress of a sealant at a specific strain is referred to as the modulus of elasticity, sometimes called the *secant modulus*. This important sealant property describes the force exerted by a sealant as it is stressed. Because a primary function of sealants is to adhere to the substrates it is in contact with, the forces generated by a joint opening or closing are transmitted by the sealant to the substrate–sealant bond line. For this reason, it is important to know the modulus of the sealant and also the strength of the substrate.

Durability. A primary factor in sealant durability is its ability to resist decay from environmental elements. For most typical applications this includes extremes of high and low temperature, water, oxidation, and sunlight.

Sealant Types and Formulations

Silicones. Commercially available silicone sealants are typically one of three curing types: moisture-reactive (curing) sealants, moisture-releasing (latex) sealants, and addition-curing sealants. Of these three types, moisture-curing silicones make up the vast majority of silicone sealants sold.

The formulation of moisture-curing silicones includes a silicone polymer, filler, a moisture-reactive cross-linker, and sometimes a catalyst. A newer class of silicone sealants are known as the silicone latex sealants. These sealants are silicone-in-water emulsions that cure by evaporation of the emulsifying water. Addition-curing silicones in general are two-part systems that cure by the platinum-catalyzed reaction of a silicone hydride with typically a vinyl group attached to silicon. Because no by-products are generated by the cure, there are few volatiles and no shrink in thick sections.

Urethanes. The basis for urethane chemistry is the reaction of an isocyanate group with a component containing an active hydrogen. The first step in formulating a urethane sealant is to prepare what is commonly called the prepolymer, typically by reaction of a hydroxy-terminated polyether with a stoichiometric amount of a diisocyanate.

Although polyethers are the main building blocks of the prepolymer, other materials such as polyesters, polythioethers, and polybutadienes are also used. Most urethanes use blends of polymers to achieve desired properties. Urethane sealants have good inherent adhesion to most substrates, but silane adhesion promoters are often used to improve this adhesion.

See also **Urethane**; and **Urethane Polymers**.

Polysulfides. Polysulfide sealants were the first high performance synthetic elastomeric sealants produced in the United States. The basic polymers are mercaptan-terminated (HS–R–SH), with molecular weights ranging from 1000 to ca 8000. Curing occurs through the mercaptan groups by oxidation and results in an S–S linkage. In addition to the terminal SH groups, pendent SH groups are located along the polymer chain and contribute to cross-linking. Polysulfide polymers provide inherent resistance to f1uel and quite good resistance to alkali. In contrast to the silicone polymers, they have low gas permeability. Different curing agents have different effects on the properties of the polysulfide sealant. Therefore, the choice of curing agent depends on the sealant application. Adhesion promoting silanes are often added to improve adhesion to various substrates. As is the case with urethane sealants, silanes with a dual-reactive nature are typically used.

Acrylics. There are two principal classes of acrylic sealants: latex acrylics and solvent-release acrylics. High molecular weight latex acrylic polymers are prepared by emulsion polymerization of alkyl esters of acrylic acid. The emulsion polymers are compounded into sealants by adding fillers, plasticizers, freeze–thaw stabilizers, thickeners, and adhesion promoters. As is true of the silicone latex sealants, the acrylic latex sealants are easy to apply and clean with water.

Another class of acrylic sealants are the solvent-releasing acrylics. Acrylic monomers are polymerized in a solvent. The natural adhesion of most of the solvent-releasing acrylics produces some of the best unprimed adhesion in the sealant industry. However, slow, continual cure generally produces large compression sets and limits their use to low movement applications. Also, the relatively high amounts of solvent and traces of acrylic monomer in these formulations limits their use to outdoor applications, usually in construction.

Butyls. Butyl-based materials are sold in the form of preformed tapes, thermoplastic hot melts, and one-part solvent-releasing sealants. Butyl polymers are made by the copolymerization of 97–98 mol % isobutylene with 2–3% isoprene. Another butyl-based polymer, polyisobutylene, is produced by the polymerization of isobutylene. Formulations of butyl-based sealants also include plasticizer, filler, and tackifier resins. Polybutenes are common plasticizers for butyl sealants. Solvents, such as mineral spirits, are used for the one-part solvent-releasing formulations. As the solvent leaves the typical one-part butyl, the sealant hardens and loses its elastomeric ability. This limits the use of solvents to low movement applications where durability is not of high concern.

Manufacture and Processing

Almost all sealants contain a mixture of a powdered filler incorporated into a viscous liquid, which results in a viscous liquid sealant having a paste-like consistency. Processing conditions can have a dramatic effect on sealant rheology, cure time, and physical properties. Typical processing variables are mixer speed (rpm), time, temperature, and vacuum. Order of ingredient addition is also important.

Health and Safety Factors

Most sealants use mineral-based fillers, which may contain small amounts of crystalline silica. Crystalline silica is a known cause of silicosis, a debilitating disease of the lung. Some but not all sealants use flammable ingredients, but for those that do, proper inserting and grounding are needed to prevent potential explosions. In general, sealants should be used in areas that have good ventilation. A careful review of the material safety data sheet is fundamental before use of any sealant.

Uses

Each class of sealants has certain attributes inherent to the polymer on which it is based. These attributes often define the sealant's applications and limitations. Future developments are likely to feature the production of more silicone sealants that do not pick up dirt, more latex acrylic sealants that have high performance properties. Urethanes that have improved uv stability, and high performance polysulfides that are made in the United States.

SEASON CRACKING. Spontaneous cracking of brass and other metals on standing. Intergranular cracks result from the action of residual internal stresses from cold-working operations aided by surface corrosion. Cold-worked high-zinc brasses sometimes fail during storage in ordinary atmosphere. Ammonia salts and other specific reagents greatly accelerate cracking in brasses subject to this defect. Many other metals, including stainless steels, are subject to cracking under certain conditions of stress and corrosion.

SEAWATER (Desalination). See **Desalination**.

SEAWATER (Elements in). See **Chemical Elements**.

SEDIMENTATION. The settling out by gravity of solid particles suspended in a liquid, the rate of settling being defined by Stoke's law. See also **Stoke's Law**. This method is used industrially in water purification. It is also an analytical procedure for separation of solids of different particle size, as well as for molecular weight determination. The sedimentation of large molecules in a strong centrifugal field permits determination of both average molecular weights and the distribution of molecular weights in certain systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250,000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary that progressively moves toward the bottom of the cell. An optical system is provided for viewing this boundary, and a study as a function of the time of centrifuging yields the rate of sedimentation for the single component, or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. The result of this work is the distribution of molecular weights in the sample, which is attainable by few other methods.

SEGER CONE. A series of substances having different fusion temperatures might serve roughly to measure the temperature of high-temperature regions such as furnaces, since, with a series of substances having progressively increasing fusing temperatures, the temperature naturally lies between the fusion temperature of the last substance fused, and that of the next not yet fused. A series of artificially prepared mixtures, mostly of the oxides such as clays, lime, feldspar, have been designed to form a series of "Seger cones." There are 60 mixtures covering a temperature range from 590 to 2,000°C.

SELECTION RULES (Energy Levels). It was found early in the study of atomic spectra that radiative transitions between certain pairs of energy levels seldom or never occur. A set of rules which are expressed in terms of the differences of the quantum numbers of the two states involved allow a prediction of allowed transitions and forbidden transitions. The conditions for allowed transitions are:

$$\Delta L(\text{orbital angular momentum}) = \pm 1$$
$$\Delta J(\text{total angular momentum}) = 0 \text{ or } \pm 1$$
$$\Delta M(\text{magnetic orientation}) = 0 \text{ or } \pm 1$$

The selection rules are not rigorously obeyed. In atoms that do not exhibit Russell-Saunders coupling, the quantum numbers L and S are not defined. Even in atoms that do have this type of coupling, forbidden transitions are merely of lower probability than allowed ones, and they may occur from a state from which no transitions are allowed by the rules, if conditions are such that collisions of the second kind do not remove the atom from the initial state before it radiates (e.g., at extremely low pressures).

Similar selection rules hold for molecular spectra. In fact, let ψ_i and ψ_j be wave functions for two levels in any quantum mechanical system. Then if P is the appropriate operator, a transition between levels i and j is permitted if the matrix element

$$\int \psi_i^* P \psi_j d\tau$$

does not vanish. Here ψ_i^* is the complex conjugate of ψ_i, $d\tau$ is a volume element including all of the variables involved in the two wave functions, and the operator may refer to electric or magnetic dipole

radiation, quadrupole radiation, polarizability, etc. If the integral vanishes, the transition is forbidden. Frequently, symmetry properties and group theory may be used to determine whether the matrix element does or does not vanish. This is very helpful since evaluation of the integral itself may be difficult or impossible.

SELECTION RULES (Nuclear). A set of statements that serves to classify transitions of a given type (emission or absorption of radiation, beta decay, and so forth) in terms of the spin and parity (I and π) quantum numbers of the initial and final states of the systems involved in the transitions, in such a way that transitions of a given order of inherent probability (after making allowance for the influence of varying energy, charge and size of system, and so forth) are grouped together. The group having highest probability of taking place per unit time is said to consist of allowed transitions; all others are called forbidden transitions. Table 1 lists the selection rules for radiative transitions: each entry gives the character (E = electric, M = magnetic) and the multipole order (1 for dipole, 2 for quadrupole, 3 for octopole, ...) of the predominant radiation mechanism for the indicated spin change ΔI and parity change $\Delta\pi$; the entry "none" means that radiative transitions are strictly forbidden.

TABLE 1. SELECTIVE RULES FOR RADIATIVE TRANSITIONS

	ΔI						
$\Delta\pi$	0 $I = 0$	0 $I \neq 0$	1	2	3	4	5
No	None	$M1$	$M1$	$E2$	$M3$	$E4$	$M5$
Yes	None	$E1$	$E1$	$M2$	$E3$	$M4$	$E5$

Fermi selection rules and Gamow-Teller (GT) selection rules are alternative sets of rules for allowed beta transitions; both are currently believed to be valid, so that a transition allowed according to either set is actually allowed.

Table 2 lists the selection rules for beta decay: the entry A means that for the indicated spin and parity change the transition is allowed; I, means that it is first forbidden; II, second forbidden ...

TABLE 2. SELECTION RULES FOR BETA DECAY

	ΔI						
$\Delta\pi$	0	1	2	3	4	5	6
No	A	A	II	II	IV	IV	VI
Yes	I	I	I	III	III	V	V

SELENIUM. [CAS: 7782-49-2]. Chemical element, symbol Se, at no. 34, at. wt. 78.96, periodic table group 16, mp 217°C, bp 685°C, density 4.82 g/cm^3 (solid), 4.86 (single crystal). Selenium has a large number of allotropes, some of which have not been fully investigated. On heating selenium above its melting point and cooling it, a red vitreous mass is formed, probably a mixture of allotropes. A red, amorphous allotrope is precipitated by SO_2 from selenous acid solutions. On heating at above 150°C, the red vitreous form changes to a gray hexagonal form, the stable form at ordinary temperatures, with metallic properties, one of which is photo-conductivity. By evaporation of a CS_2 solution of the red vitreous form below 72°C, a red α-monoclinic form is obtained; evaporation above 72°C gives β-monoclinic selenium. Black hexagonal selenium, believed to have a ring structure, is produced by heating amorphous selenium to near its melting point. Unlike sulfur, liquid selenium apparently has only one form.

There are six natural occurring isotopes: ^{74}Se, ^{76}Se through ^{78}Se, ^{80}Se, and ^{82}Se, and seven known radioactive isotopes ^{72}Se, ^{73}Se, ^{75}Se, ^{79}Se, ^{81}Se, ^{83}Se, and ^{84}Se. With exception of ^{79}Se which has a half-life of something less than 6×10^4 years, the half-lives of the other isotopes are comparatively short, measured in minutes, hours, or days. In terms of abundance, selenium ranks 34th among the elements occurring in the earth's crust. It is estimated that a cubic mile of seawater contains about 14 tons (3 metric tons per cubic kilometer) of selenium. First ionization potential 9.75 eV; second 21.3 eV; third, 33.9 eV; fourth, 42.72 eV; fifth, 72.8 eV. Oxidation potentials $H_2Se(aq) \longrightarrow Se + 2H^+ + 2e^-$, 0.36 V; $Se + 3H_2O \longrightarrow H_2SeO_3 + 4H^+ + 4e^-$, −.740 V; $H_2SeO_3 + H_2O \longrightarrow SeO_4{}^{2-} + 4H^+ + 2e^-$, −1.15 V; $Se^{2-} \longrightarrow Se + 2e^-$, 0.78 V; $Se + 6OH^- \longrightarrow SeO_3{}^{2-} + 3H_2O + 4e^-$, 0.36 V; $SeO_3{}^{2-} + 2OH^- \longrightarrow SeO_4{}^{2-} + H_2O + 2e^-$, −0.03 V. Other important physical properties of selenium are given under **Chemical Elements**.

Selenium was first identified by Berzelius in 1817. The element is found associated with volcanic activity, as for example in cavities of Vesuvian lavas and in the volcanic tuff of Wyoming (about 150 parts per million).

Selenium occurs as selenide in many sulfide ores, especially those of copper, silver, lead, and iron, and is obtained as a by-product from the anode mud of copper refineries. The mud is (1) fused with sodium nitrate and silica, or (2) oxidized with HNO_3, and the H_2O extract is then treated with HCl and SO_2, whereupon free selenium is separated.

Uses

Selenium is widely used in photoelectric cells. The element alters its electrical resistance upon exposure to light. The response is proportional to the square root of incident energy. Selenium cells are most sensitive in the red portion of the spectrum. Although an external emf must be applied, the resistance is low and amplification is easy. In the selenium photovoltaic cell configuration, a thin film of vitreous or metallic selenium is coated onto a metal surface. Then, a transparent film of another metal, often platinum, is placed over the selenium. A cell of this type generates its own emf, with a decrease in internal resistance with increasing irradiation. The response essentially is proportional to incident energy. The cells are not importantly sensitive to small temperature changes.

Advantage of the unipolar conduction characteristic of selenium is taken in arc rectifiers. In a typical unit, a nickel or nickel-plated steel or an aluminum disk with a thin layer of selenium applied to one side is used. Selenium also is added to copper alloys and to stainless steel to increase machinability. Advantages claimed for selenium copper are high machinability, combined with hot-working properties and high electrical conductivity. As a decolorizer in glass, selenium counteracts green shades arising from ferrous ingredients. Sodium selenite is used in the production of red enamels and in the manufacture of clear red glass. Addition of from 1 to 3% selenium to vulcanized rubber increases abrasion resistance. The element also is used in photographic and printing reproduction chemicals.

Selenium is also used as an additive to lead-antimony battery grid metal and as a vulcanizing agent to improve temperature and abrasion resistance of rubber.

Chemistry and Compounds

Due to its $4s^24p^4$ electron configuration, selenium, like sulfur, forms many divalent compounds with two covalent bonds and two lone pairs, and d hybridization is quite common, to form compounds with Se oxidation states of 4+ and 6+.

While selenium dioxide, [CAS: 7446-08-4], SeO_2, can be produced by direct reaction of the element with oxygen activated by passage through HNO_3, the compound is easily made by heating selenious acid, H_2SeO_3. Selenium dioxide sublimes at 315–317°C, and is readily reduced by SO_2 to elemental selenium. Selenium trioxide, SeO_3, is not prepared from the dioxide by oxidation, although selenium does react with oxygen to form SeO_3 and SeO_2 in an electric discharge. Preferred method of preparing SeO_3 is by refluxing potassium selenate with sulfur trioxide. The reverse reaction, hydration of SeO_3 to selenic acid, [CAS: 7783-08-6], H_2SeO_4, occurs easily. Selenous acid, H_2SeO_3, produced by hydration of SeO_2, is a stronger oxidizing agent than sulfurous acid as judged by its quantitative oxidation of iodide ion in acid solution, but is a weaker acid (ionization constants 2.4×10^{-3} and 4.8×10^{-9} at 25°C). It forms salts, the selenites, many of which, especially those of the heavy metals, are reduced to selenides by hydrazine. Many of the selenites, e.g., those of nickel, mercury, and ferric ion, are very slightly soluble in H_2O. Selenous acid is readily oxidized by halogens in the presence of silver ion or 30% H_2O_2 to selenic acid, H_2SeO_4. Selenic acid is as strong an acid as H_2SO_4, and it is more readily reduced, reacting with hydrobromic acid and hydriodic acid to form selenous acid or (at high concentration) elemental selenium. Like sulfate ion, $SO_4{}^{2-}$, $SeO_4{}^{2-}$ is tetrahedral in crystals.

Hydrogen selenide, [CAS: 7783-07-5], H_2Se, is a stronger acid than H_2S (ionization constants of H_2Se, 1.88×10^{-4} and about 10^{-10}) and is less readily obtained from selenides than H_2S from sulfides (the selenides of aluminum, iron and magnesium, Al_2Se_3, FeSe, and MgSe, require heating

with H_2O or dilute acids). In general, the metal selenides are prepared by direct combination of the elements. Those of transition groups 3–8, 1 and 2 and main groups 3 and 4 exhibit many instances of well-defined compounds, berthollide compounds, and substitutional solid solutions. Thus, four intermediate phases are found in the palladium-selenium system, Pd_4Se, $Pd_{2.8}Se$, $Pd_{1.1}Se$, and $PdSe_2$.

Selenium hexafluoride, SeF_6, the only clearly defined hexahalide, is formed by reaction of fluorine with molten selenium. It is more reactive than the corresponding sulfur compound, SF_6, undergoing slow hydrolysis. Selenium forms tetrahalides with fluorine, chlorine, and bromine, and dihalides with chlorine and bromine. However, other halides can be found in complexes, e.g., treatment of the pyridine complex of SeF_4 in ether solution with HBr yields $(py)_2SeBr_6$. Selenium tetrafluoride also forms complexes with metal fluorides, giving $MSeF_5$ complexes with the alkali metals.

Selenium forms several oxyhalides, e.g., $SeOF_2$, $SeOCl_2$, and $SeOBr_2$, the first two being liquids and the last a crystalline solid, mp 41.6°C. Selenium also forms tetraselenium tetranitride, Se_4N_4.

Selenocyanates, M^I SeCN, corresponding to the thiocyanates, are prepared by addition of selenium to soluble cyanides. They are similar to the thiocyanates except that HSeCN immediately decomposes in acid to selenium and hydrogen cyanide. The heavy metal selenocyanates are less soluble than the corresponding thiocyanates.

Selenium forms "thio"-type compounds, such as $SeSO_3$ by reaction of selenium and sulfur trioxide, $SeSO_3{}^{2-}$ (selenosulfates) by reaction of selenium and sulfites, SeS^{2-} (selenosulfides) by reaction of selenium with sulfides, as well as diselenides, $Se_2{}^{2-}$, and polyselenides, $Se_x{}^{2-}$.

Carbon diselenide is an evil-smelling liquid, and COSe and CSSe are also known.

Biological Role of Selenium

Some very interesting examples of the effect of soils on the nutritional quality of plants are associated with selenium. The element has not been found to be required by plants, but it is required in very small amounts by warm-blooded animals and probably by humans. However, selenium in larger quantities can be very toxic to animals and humans.

In large areas of the world, the soils contain very little selenium in forms that can be taken up by plants. Crops produced in these areas are, therefore, very low in selenium. A selenium deficiency in livestock is a serious problem. A deficiency causes a form of muscular dystrophy in younger animals and poor reproductive qualities in the adult animals. For prevention, sodium selenate or sodium selenite, sometimes augmented with vitamin E, is added in proper proportions to feedstuffs. Some areas, including the Plains and Rocky Mountain states in the United States have soils that are rich in available selenium. In regions like these, selenium toxicity is a problem. The situation is particularly serious in Arizona, California, Montana, Nevada, New Mexico, and South Dakota.

An interesting feature of selenium is that it occurs naturally in several compounds and these vary greatly in their toxicity and in their value in preventing selenium-deficiency diseases. In its elemental form, selenium is essentially insoluble and biologically inactive. Inorganic selenates or selenites and some of the selenoamino acids in plants are very active biologically, whereas some of their metabolites that are excreted by animals are not biologically active. In well-drained alkaline soils, selenium tends to be oxidized to selenates and these are readily taken up by plants, even to levels that may be toxic to the animals that eat them. In acid and neutral soils, selenium tends to form selenites and these are insoluble and unavailable to plants. Selenium deficiency in livestock is most often found in areas with acid soils and especially soils formed from rocks low in selenium.

In 1934, the mysterious livestock maladies on certain farms and ranches of the Plains and Rocky Mountain states were discovered to be due to plants with so much selenium that they were poisoning grazing animals. Affected animals had sore feet and lost some of their hair; many died. Over the next 20 years, researchers found that the high levels of selenium occurred only in soils derived from certain geological formations of high selenium content. They also found that a group of plants, called *selenium accumulators*, had an extraordinary ability to extract selenium from the soil. These accumulators were mainly shrubs or weeds native to semiarid and desert range lands. They usually contained about 50 parts per million (ppm) or more of selenium, whereas range grasses and field crops growing nearby contained less than 5 ppm selenium. These findings helped ranchers to avoid the most dangerous areas when grazing livestock.

In 1957, selenium was found to be essential in preventing liver degeneration of laboratory rats. Since then, research workers have found that certain selenium compounds, either added to the diet or injected into the animal, would prevent some serious disease of lambs, calves, and chicks. That selenium is an essential nutrient element for birds and animals has been established.

In most diets used in livestock production, from 0.04 to 0.10 ppm of selenium protects the animal from deficiency diseases. If the diet is very high in vitamin E, the required level of selenium may be lower.

In terms of human dietary requirements, much of the wheat for breadmaking in the United States is produced in selenium-adequate sections of the country. Bread is generally a good source of dietary selenium.

Selenomethionine decomposes lipid peroxides and inhibits *in vivo* lipid peroxidation in tissues of vitamin-E-deficient chicks. Selenocystine catalyzes the decomposition of organic hydroperoxides. Selenoproteins show a high degree of inhibition of lipid peroxidation in livers of sheep, chickens, and rats. Thus, some forms of selenium exhibit *in vivo* antioxidant behavior.

Health and Safety Factors

Commercial elemental selenium along with the stable metallic selenides are considered relatively nontoxic. However, other selenium compounds which include the reactive selenides; the gaseous, volatile, and soluble compounds; and particularly hydrogen selenide, the halides, oxides, and the organics are highly toxic and must be handled with care. Selenium can enter the body through inhalation, ingestion, or absorption through the skin where it accumulates primarily in the liver and kidney. Symptoms of selenium poisoning include bronchial irritation, gastrointestinal distress, nasopharyngeal irritation, and garlic on the breath.

Selenium plays a dual role in a living organism, depending on the compound and the amount adsorbed. Controlled small doses of some compounds are used in medicine and as diet supplements, for example, ca 0.1 ppm of diet dry matter for livestock. Larger amounts can be toxic.

SEMICARBAZONES. The products of the reaction between an aldehyde or a ketone with semicarbazide are termed *semicarbazones*.

$$\underset{\text{(acetaldehyde)}}{CH_3 \cdot CHO} + \underset{\text{(semicarbazide)}}{NH_2 \cdot CO \cdot NHNH_2} \longrightarrow \underset{\text{(acetaldehyde semicarbazone)}}{CH_3 \cdot CH{:}N \cdot NH \cdot CONH_2} + H_2O$$

$$\underset{\text{(acetone)}}{(CH_3)_2CO} + NH_2 \cdot CO \cdot NH \cdot NH_2 \longrightarrow \underset{\text{(acetone semicarbazone)}}{(CH_3)_2C{:}N \cdot NH \cdot CO \cdot NH_2} + H_2O$$

SEMICONDUCTORS. Materials and devices known as *semiconductors* have been the backbone of the electronics industry for many years. Semiconductors did not enter the industry in a major way, however, until several years after the vacuum tube (valve) had been well established. In terms of perspective, it is interesting to note that at least one semiconductor device predated the vacuum tube in the early days of radio communication. This was the then familiar galena crystal and accompanying whisker used in early crystal set radio receivers.

With the continuing attention to developing reliable and efficient vacuum tubes, which occurred over a long time span, interest in semiconductors stagnated—with the exception of the emerging radar technology of the World War II era. Massachusetts Institute of Technology's Radiation Laboratory became active in the investigation of crystal rectifiers and engaged in exploratory studies and in the development of very pure semiconducting materials, notably silicon and germanium. Several other research institutions during this same period became interested in the theoretical aspects of solid state and semiconductors, including the energy levels of solids and the charged carrier transport in silicon and a few other materials. Out of this early phase of semiconductor technology came, in 1947, the invention of the transistor (contraction for transfer resistor). Inventors Shockley, Bardeen, and Brattain (Bell Laboratories) received the Nobel Prize in physics in 1956 for their accomplishment.

The transistor had a tremendous impact, constituting the birth of modern electronics. The transistor led to the development of almost innumerable semiconductor device configurations and ultimately to the phasing out of the vacuum tube, except for rather special and limited applications.

Innovations to fabricate semiconductors with improved performance and smaller size (microelectronics) for many years has been a continuing process without apparent end. As of the very late 1980s, the enhancement of semiconductors continues apace. Circuit integration has gone through several major phases—from IC (integrated circuit) to LCI (large-scale integration) to VLSI (very large-scale integration) to VHSIC (very high-speed integrated circuits) to ULSI (ultralarge-scale integration)—to the point where it is difficult to find appropriate adjectives to describe developments in ICs.

With few exceptions, it is only within recent years that serious concern has been expressed by experts in what the physical limits on size and performance may be. Fortunately, thus far the advancements in fabrication (chip-making processes), such as electron beam and molecular beam lithography, have allayed these concerns in the short term. Although some interest in nonsilicon materials has always been present, there has been a recent reawakening of interest in the use of gallium, indium, arsenic, phosphorus, and antimony—this interest intensifying because of the opportunities such elements offer over silicon. Although silicon which for years has been the basis for volume-produced devices, is not seriously threatened at this juncture, some authorities feel that, in the long term, the emphasis on silicon will be heavily shared with these other materials.

Even with the aforementioned materials, the microelectronics and optoelectronics industries have relied almost exclusively on *inorganic* materials. This is expected to change. Some authorities now forecast that in the early 2000s, there will be a major shift, namely, to *molecular electronics*. Even today, considerable attention for the long term is being paid to the *organic* solid state. The richness of the variety of organic molecular materials available offers enormous potential compared with the relative paucity of structures achievable with inorganic compounds, even when due allowance is made for the exciting developments in inorganic quantum well semiconductors. A hint of what may be achieved along these lines is given by the progress thus far made in liquid crystals, piezoelectric and photoconducting polymers. This implies, of course, that organics no longer will be confined to their traditional applications in electronics, such as for insulation, adhesion, or encapsulation.

Molecular electronics currently is defined as the use of organic molecular materials to perform an active function in the processing of information and its transmission and storage. An alternative definition has been suggested, namely, the achievement of *switching* on a molecular scale. As observed by G.G. Roberts (University of Oxford), "It is interesting to note that only a modest diminution in the size of electronic circuit components is required before the scale of individual molecules is reached; in fact many existing circuit elements could already be accommodated within the area occupied by a leukemia virus."

Some investigators forecast that during the first quarter of the 21st Century, molecular electronics will lead to *supermolecular electronics* where signal transport and control will be effected by nanometer-scale assemblies.

Numerous applications of contemporary semiconductors are described throughout this encyclopedia. See also **Molecular and Supermolecular Electronics**.

Nature of Semiconductors

From the standpoint of their use in electronics, semiconductors are distinguished from other classes of materials by their characteristic electrical conductivityσ. The electrical conductivities of materials vary by many orders of magnitude, and consequently can be classified as: (1) the perfectly conducting superconductors; (2) the highly conducting metals ($\sigma \approx 10^6$ mho/centimeter); (3) the somewhat less conducting semimetals ($\sigma \approx 10^4$ mho/centimeter); (4) the semiconductors covering a wide range of conductivities ($10^3 \gtrsim \sigma \gtrsim 10^{-7}$ mho/centimeter); and (5) the insulators, also covering a wide range ($10^{-10} \gtrsim \sigma \gtrsim 10^{-20}$ mho/centimeter).

These low-conductivity materials are characterized by the great sensitivity of their electrical conductivities to sample purity, crystal perfection, and external parameters, such as temperature, pressure, and frequency of the applied electric field. For example, the addition of less than 0.01% of a particular type of impurity can increase the electrical conductivity of a typical semiconductor like silicon or germanium by six or seven orders of magnitude. In contrast, the addition of impurities to typical metals and semimetals tends to decrease the electrical conductivity, but this decrease is usually small. Furthermore, the conductivity of semiconductors and insulators characteristically decreases by many orders of magnitude as the temperature is lowered from room temperature to 1 K. On the other hand, the conductivity of metals and semimetals characteristically increases in going to low temperatures, and the relative magnitude of this increase is much smaller than are the characteristic changes for semiconductors. The principal conduction mechanism in metals, semimetals, and semiconductors is electronic, whereas both electrons and the heavier charged ions may participate in the conduction processes of insulators.

Classification

It is customary to classify a semiconductor according to the sign of the majority of its charged carriers, so that a semiconductor with an excess of negatively charged carriers is termed *n*-type. A semiconductor with an excess of positively charged carriers is called *p*-type, while a material with no excess of charged carriers is considered to be perfectly compensated. Many of the important semiconductor devices depend upon fabricating a sharp discontinuity between the *n*- and *p*- type materials, the discontinuity being called a *p*-*n* junction.

Other Characteristics

Even though most semiconductors exhibit a metallic luster when inspected visually, this does not provide a reliable criterion for their classification, since the electrical conductivity of all materials is frequency dependent. Visual inspection tends to be sensitive to the conductivity properties at visible frequencies ($\sim 10^{15}$ Hz). Although materials with a high optical reflectivity tend also to exhibit high D.C. conductivity, these two properties are not necessarily correlated in semiconductors and metals. An example of a metal without metallic luster is ReO_3 (rhenium trioxide), a semitransparent reddish solid. On the other hand, most of the common semiconductors do exhibit metallic luster primarily because electronic excitation across their fundamental energy gaps can be achieved at infrared frequencies. At low frequencies, the principal conduction mechanism is free carrier conduction, which is important in metals and is present to some extent in semiconductors that contain impurities or are found at elevated temperatures. In contrast, interband transitions dominate the conduction process at very high frequencies. Interband transitions contribute to the conductivity by about the same order of magnitude in semiconductors, metals, and insulators.

Since the D.C. conductivity due to free carriers is characteristically low in semiconductors and insulators, the generation of free carriers by exposure to light at infrared, visible, and ultraviolet frequencies can lead to a large increase in the D.C. conductivity. This photoconductive effect, which is not observed in metals or semimetals, can be enormous in low-conductivity semiconductors (an increase in the D.C. conductivity of CdS (cadmium sulfide) by 8 orders of magnitude is observed). The effects of ultraviolet light, for example have been used successfully in reprogramming EPROM (electrically programmable read-only memory) devices, exposure to UV light causing trapped charges to leak off.

Because of the extreme sensitivity of semiconductors to impurities, temperature, pressure, light exposure, and certain other factors, these

materials can be exploited in the fabrication of useful devices, such as the crystal diode, the transistor, integrated circuits, photodetectors, and light switches.

Flow of Current in Semiconductors

The flow of electric current depends upon the acceleration of charges by an externally applied electric field. Only those charges that resist collisions or scattering events are effective in the conduction process. Because of collisions, charged particles in a solid are not accelerated indefinitely by the applied field, but rather, after every scattering event, the velocity of a charged particle tends to be randomized. Thus the acceleration process must start anew after each scattering event and charged particles achieve only a finite velocity along the electric field **E**, the average value of the velocity being denoted by v_D, the drift velocity. The effectiveness of the charge transport by a particular charged particle is expressed by the mobility μ, which is defined as $\mu = v_D/E$. The mobility of a particle with charge e and mass m can be related directly to the mean time between scattering events (also called the relaxation time) by the expressed $\mu = e\tau/m$. The electrical conductivity s depends upon the mobility of the charged carriers as well as on their concentration n, and is simply written as $\sigma = ne\mu$, where e is the charge of the carriers. The advantage of expressing the conductivity in this form is the explicit separation into a factor n that is highly sensitive to external parameters, such as temperature, pressure, optical excitation, irradiation, and into another factor μ, which depends characteristically on scattering mechanisms and on the electronic structure of the semiconductor.

The classical theory for electronic conduction in solids was developed by Drude in 1900. This theory has since been reinterpreted to explain why all contributions to the conductivity are made by electrons which can be excited into unoccupied states (Pauli principle) and why electrons moving through a perfectly periodic lattice are not scattered (wave-particle duality in quantum mechanics). Because of the wavelike character of an electron in quantum mechanics, the electron is subject to diffraction by the periodic array, yielding diffraction maxima in certain crystalline directions and diffraction minima in other directions. Although the periodic lattice does not scatter the electrons, it nevertheless modifies the mobility of the electrons. The cyclotron resonance technique is used in making detailed investigations in this field.

The origin of the energy barrier[1] for carrier generation is directly connected with the energy levels for electrons in a solid. Considering electrons in a solid from a tight-binding point of view, the discrete energy levels of the free atom broaden in the solid to form energy bands. For materials that are well described by the tight-binding approximation, the width of the energy bands is sufficiently small so that an energy gap is formed between the energy bands; in the forbidden energy gap there are no bound states. Of particular importance to the conduction properties of a solid is the fact that *all* of the available states in each band would be filled if each atom were to contribute exactly two electrons, thereby causing every solid with an odd number of electrons per atom to be metallic; while solids with an even number of electrons per atom would be insulating or semiconducting. The occurrence of energy bandgaps is also a consequence of the weak binding approximation, whereby the periodic potential itself is responsible for creating bandgaps through the mixing of states separated by a reciprocal lattice vector. See also **Solid-State Physics**.

For semiconductors, the excitation energy lies in the range 0.1 to about 2 eV. Thermal fluctuations are sufficient to excite a small, but significant, fraction of electrons from the occupied levels (the valence band) into the unoccupied levels (the conduction band). Both the excited electrons and the empty states in the valence band (aptly called *holes*) may move under the influence of an electric field, providing a means for conduction of current. (A hole acts like an electron with a positive charge.) Such electron-hole pairs may be produced not only by thermal energy, but also by incident light, providing photo-effects.

Crystallographic defects, in general, are also electronic defects. In metals, they provide scattering centers for electrons, increasing the resistance to charge flow. The resistance wire in many electric heaters, in fact, consists of an ordinary metal, such as iron, with additional alloying elements, such as nickel or chromium, providing scattering centers for electrons. In semiconductors and insulators, alloying elements and defects provide an even greater variety of effects, since they can change the electron-hole concentrations drastically in addition to providing scattering centers. The semiconductor industry has been built on the alloying of silicon, and a few other elements, including germanium, with *selected impurities* in carefully controlled concentration and geometry. Some of the other emerging semiconductor materials are described later.

[1] The sets of discrete but closely adjacent energy levels, equal in number to the number of atoms, that arise from each of the quantum states of the atoms of substance when the atoms condense to a solid from a nondegenerate gaseous condition, make up the energy band (also called the Bloch band). For a semiconductor, the highest energy level is the conduction band, containing only the excess electrons resulting from crystal impurities. The next highest level is the valence band, and it is usually completely filled with electrons. In between these bands is the forbidden band, which is wider for an insulating material than for a semiconductor and which vanishes in a conducting material.

Doping

This is a process for purposely adding impurities to a semiconductor (or production of a deviation from stoichiometric composition in order to achieve a desired characteristic). Doped material thus is no longer intrinsic but is impure and called extrinsic. If a trivalent impurity is introduced into silicon or germanium, *holes* are created and the material is said to be p-type. Introduction of a pentavalent element into silicon or germanium, on the other hand, creates *free electrons* and the material is said to be n-type. Because of thermal effects, free electrons and holes are always being produced in silicon and germanium (intrinsic generation of electron-hole pairs). Consequently, there will be some electrons in p-type material and some holes in the n-type material. These carriers are referred to as *minority carriers*. Electrons in n-type material and holes in p-type material are termed *majority carriers*.

The process of placing impurities in the near-surface region of solids is accomplished by a procedure known as *implanting*. A commonly used implanting procedure is to accelerate impurity ions in an electrostatic field with the energy sufficient to impinge with the desired force on the solid target. Known as *ion implantation*, this carefully controlled and reproducible procedure has been widely used to dope semiconductors to create *p-n* junction formations. A certain amount of damage, however, occurs in the semiconductor material in some cases. The surface may become amorphous, or because the implanted dopants may not reach substitutional spots in the crystal lattice the ions may not become electrically active. Thus, it is necessary to anneal the solid for electrical activation of the implanted ions as well as to remove any damage.

Semiconductor Device Configurations

Representative of semiconductor devices is the diode, a two-terminal device which has the property of permitting current to flow with practically no resistance in one direction and offering nearly infinite resistance to current flow in the opposite direction. Applications of the diode are numerous, as in gating circuits used in digital computers.

A widely used semiconductor diode is the *p-n junction diode*. Imagine a crystal (single) of silicon doped so half the material is p-type and the other half is n-type. The internal boundary between the two extrinsic regions is a *p-n junction*, and the resulting device is a *diode*. See Fig. 1. Three possible configurations of the p-n junction are shown in Fig. 2. The energy diagrams for these three configurations are also shown in Fig. 2. Similar diagrams can be generated for holes. When the diode is unbiased, no net flow of electrons takes place across the junction. Assuming that some electrons on the n-side have sufficient energy to overcome the potential hill, electrons on the p-side (minority carriers) "slide down" the hill, making the net current flow zero. For the reverse biased example, the potential hill is raised and only the few minority carriers from the p-side slide down. This results in a minute reverse saturation current. When the diode is forward biased, the potential hill is lowered. This enables electrons to climb over the hill and current flow occurs. The same considerations apply to holes. In fact, the total diode current is equal to the sum of the electrons and holes flowing across the junction.

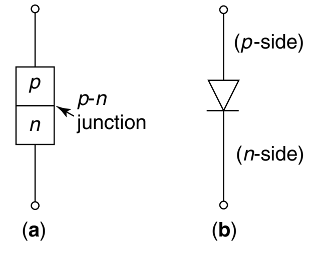

Fig. 1. (**a**) Configuration of *p-n* junction diode. (**b**) electrical symbol

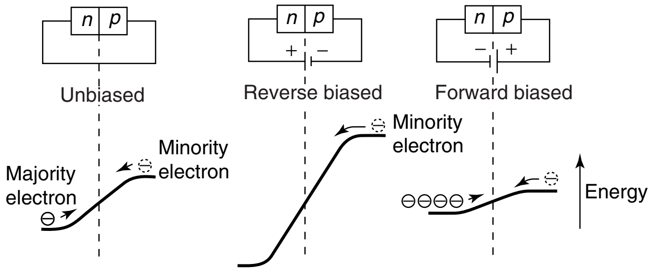

Fig. 2. Three possible configurations of a *p-n* junction diode

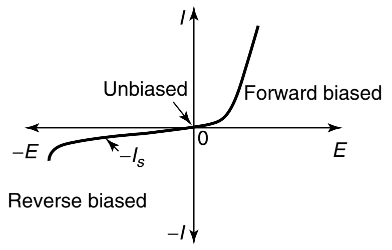

Fig. 3. Characteristic curve of a semiconductor diode

The characteristic curve of a semiconductor diode is shown in Fig. 3. An equation for this curve, called the *rectifier equation*, is expressed as:

$$I = I_s(e^{-11600E/T} - 1)$$

where I = diode current, amperes
I_s = reverse saturated current (temperature dependent), amperes
E = diode biasing voltage (+E for forward bias;—E for reverse bias), volts
T = absolute temperature (0°C + 273°), degrees Kelvin

At room temperature (300 K) and $E > 0.1$ volt,

$$I \cong I_s^{39E}$$

Where E is more negative than 0.1 volt,

$$I \cong -I_s$$

An example of a simple rectifier employing a *p-n* junction diode is given in Fig. 4. During the positive half-cycle (0° to 180°) of the A.C. sinusoidal waveform v_s, the diode is forward-biased and conducts. The voltage v_L across load resistance R_L is, therefore, nearly identical to that of v_s for the positive half-cycle. For the negative half-cycle (180° to 360°), the diode is reverse biased and does not conduct. No current flows in R_L, and $v_L = 0$ during the negative half-cycle. Because the diode conducts for only one-half cycle, the circuit of Fig. 4 is called a *half-wave rectifier*. The waveform of v_L is only unidirectional. To obtain steady D.C., like that from a battery, a filter is required. An example of an elementary filter is a large-valued capacitor placed across the load resistor.

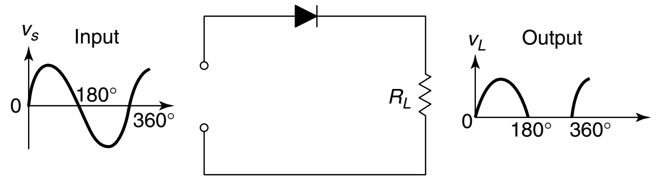

Fig. 4. Simple rectifier employing a *p-n* junction diode

The circuit of Fig. 4 can also be used as a detector of amplitude-modulated (AM) radio waves. Fig. 5(a) illustrates the components of an AM wave. If this is applied to the input of Fig. 4, the wave is rectified and the output appears as shown in Fig. 5(b). Placing a small-valued capacitor across R_L filters out the carrier frequency and the desired modulating signal is obtained, as shown in Fig. 5(c).

A bipolar transistor on a single silicon crystal is diagrammed in Fig. 6.

Metal Oxide Semiconductors

The metal oxide semiconductor field effect transistor (MOSFET) is representative of another class of semiconductors. In *n*-MOS device, two islands of *n*-type silicon are created in a *p*-type silicon substrate. A thin layer of nonconducting SiO_2 lies on top of the silicon substrate. Direct connections on a *source* and *drain* are made to the two islands, while a metal *gate* is coupled to the silicon substrate by capacitance. Usually the source and substrate are electrically connected and held at a potential of zero volts. The drain is held at a positive voltage. In this condition, no current flows into the MOS device. When a positive potential is applied to the gate, the electric field attracts a majority of electrons to the thin layer at the surface of the crystal under the gate. Since this region is normally *p*-type, the surface becomes “inverted” creating a continuous *n*-type channel between source and drain, thus allowing large currents to flow. This creates a current amplification as in a bipolar transistor. An advantage of MOSFET over bipolar transistors is that they require no isolation islands and thus can be packed more closely on a silicon chip.

Complementary MOS devices (CMOS) have been widely used in recent years. See Fig. 7. The CMOS is made up of a *n*-MOS and a *p*-MOS. A main advantage of the CMOS is its low power consumption.

Other Materials for Semiconductors

Although silicon (and germanium at one time) is the unquestioned principal semiconductor material to date, silicon does have limitations. For example, it is not easy to integrate electronic and photonic devices in the same microchip. Silicon has a relatively narrow range of temperature tolerance, is susceptible to radiation damage and has "slow" electrons compared with some other materials. Elements in Periodic Table Groups III and IV (now officially called Groups 13 and 15) have fast electrons. For example, the differences between electrons in gallium arsenide and silicon stem basically from the differing chemical characteristics. Electrons in gallium arsenide at low electric fields behave like very light particles which can move easily through the vibrating (and obstructing) crystal lattice of atoms. In contrast, the electrons in silicon behave like heavy particles that move sluggishly under the influence of an applied voltage. The result is significantly faster operating times in microchip operation. See Fig. 8. Fast electrons translate into fast switches. Such switches, when multiplied by thousands or even hundreds of thousands, comprise the basic building blocks of a digital integrated circuit (commonly called a microchip). As pointed out by Allyn, Flahive, and Wemple (1986), there are two classes of speed: (1) Maximum speed achievable, no matter how much "push" is provided by the applied voltage. This is known as *saturated voltage*. Gallium arsenide materials have an advantage in saturated voltage over silicon of 1.5; and with indium—gallium arsenide compounds, the advantage reaches 2.5. (2) The second speed relates to the ease with which electrons can be brought up to full speed (*low-field electron mobility*). Higher mobility in the Groups 13–15 (III–V) semiconductors means that the electrons reach full speed at lower operating voltages. These speed advantages are particularly important in terms of interdevice wiring, which tends to dominate the speed of high-density microchips. Major emphasis on these newer semiconductor materials is directed on the Schottky gate field effect transistor. See Fig. 9.

In the 1950s and 1960s, considerable investigation was made of amorphous *chalcogenide glasses* for possible use in semiconductor devices. The glasses are named for the chalcogens (Group 16, formerly Group VI in the Periodic Table). Early in their consideration, these materials created a considerable controversy among solid-state physicists. Claims were made

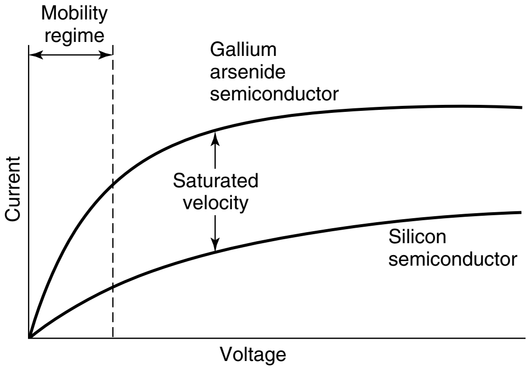

Fig. 8. Current-voltage characteristics of two hypothetical devices of identical physical size. The gallium arsenide curve rises faster and reaches peak velocity faster than the silicon. This means that the group III–V (13–15) electrons produce significantly faster operating times in microchips. (*AT&T Technology*)

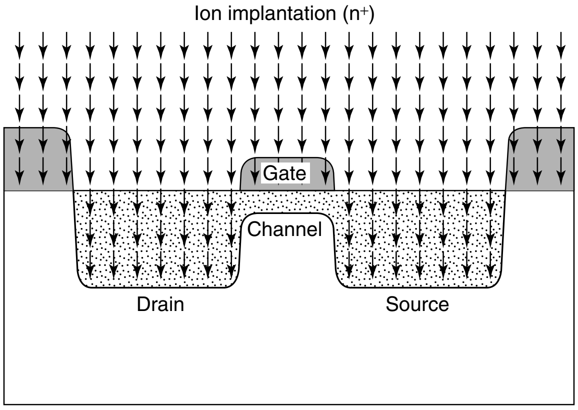

Fig. 9. A Schottky barrier gate used in the metal-semiconductor field-effect transistor (MESFET) in AT&T gallium arsenide microchips. The tiny gate is only one micrometer wide (1/25,400 inch). The gate electrode is deposited before the ion-implantation process so that the gate material will "shade" the channel under it from the "ion rain" that doses the exposed material. (*AT&T Technology*)

and challenged as regards their possible impact on further revolutionizing the semiconductor industry. However, it has been shown that chalcogenide glasses can "switch," but some scientists observe that almost any material will switch under the right conditions. Compositions proposed for memory switches are exemplified by $Te_{81}Ge_{15}Sb_2S_2$, and for non-memory switch materials, $Te_40As_{35}Si_{18}Ge_7$. It has also been shown that transitions occur in these glasses when they are exposed to intense light and thus possible photographic uses have been proposed.

Semiconductors used in solar cells are described under **Solar Energy**.

Gallium Arsenide Power Sources

GaAs was first synthesized in 1929 by V.M. Goldschmidt. Its semiconducting properties were not studied until 1952 by H. Welker. The first GaAs p-n junction used for power generation at microwave frequencies was the tunnel diode. Later, GaAs varactor diodes were used in harmonic frequency multipliers and parametric amplifiers at microwave and mm-wave frequencies because of the inherent higher cut-off frequencies possible with gallium arsenide. In 1963, J.B. Gunn discovered the negative resistance property of GaAs, after which GaAs diodes and field effect transistors (FETs) were developed.

The idea for using diodes for generation and amplification of power at microwave frequencies was suggested by A. Uhlir, Jr. Frequency multipliers have been used for power generation since 1958. These devices depend on the nonlinear reactance or resistance characteristics of semiconductor diodes. Generally, there are three types of multiplier diodes—step recovery diodes, variable resistance multiplier diodes, and variable capacitance multiplier diodes.

T.B. Ramachandran (Microwave Device Technology Corporation) notes that there are two inherent major disadvantages for current GaAs FET power devices:

1. The devices are surface oriented. Since the active region is close to the surface, the surface effects tend to affect the device performance. This may be seen in the noise performance of GaAs FETS close to the carrier.
2. To increase the power output, the breakdown voltage must be increased. Active channel doping has to be decreased in order to increase the breakdown voltage. This reduction in doping density decreases the maximum current density, and this tends to reduce the total power output.

J.B. Gunn (International Business Machines) noticed in 1963 the current instabilities in GaAs at high electric fields. Known as the Gunn effect, or the transferred electron effect, Gunn diodes have been used as a low-cost source for microwaves since 1968. These components are comparatively easy to manufacture and hence the cost is low. GaAs Gunn diodes are used from C-band (4 GHz) through W band (100 GHz).

W.T. Read (AT&T Bell Laboratories) first reported microwave oscillations in silicon p-n junctions in 1965. During the interim, much research has

gone into developing impact ionization avalanche transit time (IMPATT) diodes for a variety of applications.

RESEARCH AND DEVELOPMENT TRENDS

Quantum-Effect Devices. There is a limit on the components of ordinary integrated circuits because "smallness" of size can interfere with their functionality. Such problems may be overcome through the use of quantum-effect semiconductor devices.

It was predicted by a number of authorities that, before the year 2000, the physical laws that govern the behavior of circuit components would impede the ultimate shrinkage of the chip. As early as 1982, P.K. Chatterjee stressed how close the end point on downscaling components might be. Estimates of minimum feature size as of the early 1990s ranged between 100 and 500 billionths of a meter. As observed by R.T. Bate (Texas Instruments Incorporated), "The same solution that some of the very phenomena that impose size limits on ordinary circuits could be exploited in a new generation of vastly more efficient devices. The functional bases for these devices are quantum-mechanical effects that carry semiconductor technology into a realm of physics where subatomic particles behave like waves and pass through formerly impenetrable barriers. With the so-called quantum semiconductor device, I believe it will be possible to put the circuitry of a supercomputer on a single chip."

Doped silicon, doped and undoped gallium arsenide, and aluminum gallium arsenide have been used as the basis for quantum devices. Of course, size reduction of these proportions pose difficult production tasks. In addition to shrinking size, quantum devices can be expected to be faster and more efficient. A prototype quantum chip, with features one-hundredth of the size of an ordinary chip may appear as shown in Fig. 10. An operational semiconductor device based upon the quantum effect should appear prior to the year 2000. Aggressive research currently is being carried out by AT&T Bell Laboratories, IBM Corporation, the Massachusetts Institute of Technology, Hughes Research Laboratories, Texas Instruments Corporation, the University of Cambridge, Philips Research Laboratory, and the University of Glasgow, among others. As stressed by R.T. Bate, "The commitment of so many research teams to a problematic technology attests to the tremendous potential of these devices and to the faith that they will take the lead in the next semiconductor revolution. The costs and risks involved must be borne in order to revitalize a rapidly maturing electronics industry; the results can only benefit a society that has learned to depend on integrated circuits in many ways."

Atom Switch. By employing the technique of the Scanning Tunneling Microscope, D.M. Eigler and a research team at the IBM Almaden Research Division, San Jose, California, have improvised an "atom switch." Through careful movement of a single xenon atom between the microscope's tip or a nickel surface, the researchers have altered the amount of tunneling current between tip and sample. When the xenon rests on the surface, this is tantamount to the switch's off position. The switch is turned on by applying a 64-millisecond (0.8 V pulse) to the tip. This causes the xenon to jump to the tip, thus increasing the tunneling current by a factor of about seven. As of the present, no practical applications of this switching action are planned because the apparatus involved is bulky and costly. Some scientists believe that the principle ultimately may be useful for information storage systems. Other scientists have observed that, if storing a bit in a cluster of 1000 atoms ever becomes practical, a machine could be developed that would store the contents of the U.S. Library of Congress on a silicon disk only 12 inches (30 cm) wide. For more detail, see Yam reference listed.

Dynamical Phenomena at Metal and Semiconductor Surfaces. This topic has been investigated in recent years through the use of ultrafast measuring techniques involving lasers and nonlinear optics. As reported by J. Bokor (AT&T Bell Laboratories), "Understanding of the rates and mechanisms for relaxation of optical excitation of the surface itself as well as those of adsorbates on the surface is providing new insight into surface chemistry, surface phase transitions, and surface recombination of charge carriers in semiconductors." The combination of lasers and nonlinear optical techniques is now being brought to bear on the next frontier in surface physics, namely surface dynamics. Ultrafast lasers allow for the study of picosecond and femtosecond processes directly in the time domain, circumventing the ambiguities attendant on linewidth measurements for the determination of lifetimes. One may anticipate continued growth in the diversity of applications of these techniques to the understanding of the complexities of surface dynamics. See Fig. 11.

Amorphous Silicon. According to P.G. LeComber (University of Dundee), the most important difference between crystalline silicon and an amorphous semiconductor is that in the latter there is a continuous distribution of localized states within the forbidden energy gap. Another important difference concerns the mobility of the electrons or holes. LeComber observes, "In an amorphous material the periodicity of the lattice only extends over a few atomic spacings. Under these conditions, the electron transport may no longer be considered as band motion with occasional scattering, as in crystalline theory. In this case, the electron motion is essentially a diffusive process that can be considered to be similar to the Brownian motion of small particles in liquids. Properties of particular importance in the application of amorphous silicon films include:

- Thin films (about 1 micrometer thick).
- Low deposition temperature.
- Large area growth on many substrates, such as glass, metals, and flexible plastics.
- Mechanically very hard.
- Chemically very stable.
- Inert material.
- Extremely photoconductive.
- Room temperature electrical conductivity can be controlled over ten orders of magnitude by doping for both n-type and p-type material.
- Ease of sequentially producing p-type and n-type material by switching from one gas mixture to another.
- Easy to pattern arrays of devices using conventional photolithographic techniques developed for crystalline silicon.

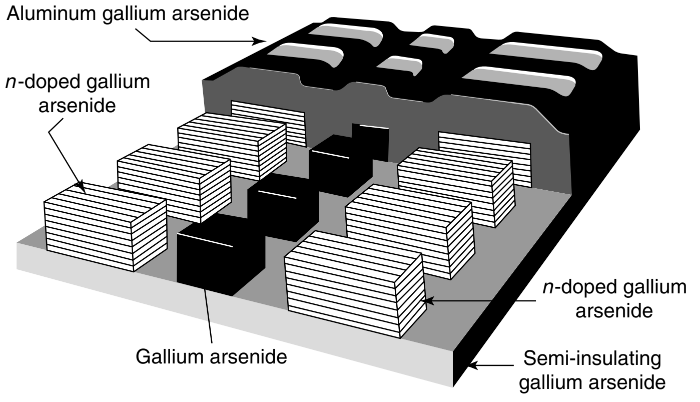

Fig. 10. Quantum chip consisting of four materials. Final product is about $\frac{1}{100}$th size of conventional chip. Current flows from one negatively doped (n-doped) gallium arsenide block to another by way of a layer of aluminum gallium arsenide, a gallium arsenide cube, and thence to an other aluminum gallium arsenide layer. Current conductivity of a quantum device is extremely sensitivity and thus capable of exacting control. (*This idealized model is suggested by R.T. Bate in the scholarly reference cited*)

Hybrid Ferromagnetic-Semiconductor Structures. G.A. Prinz and researchers at the Materials Science and Technology Division of the Naval Research Laboratory, Washington, DC, have been studying hybrid ferromagnetic-semiconductor materials through the use of modern thin-film techniques. Thus far, the team has researched and demonstrated combinations of Fe/Ge, Fe/GaAs, Fe/ZnSe, and Co/GaAs. The researchers observe, "Ultrahigh-vacuum growth techniques are being used to grow single-crystal films of magnetic materials. These growth procedures, carried out in the same molecular beam epitaxy systems commonly used for the growth of semiconductor films, have yielded a variety of new materials and structures that may prove useful for integrated electronics and integrated optical device applications."

Useful characteristics of hybrid ferromagnetic-semiconductor structures include:

1. Produce significant changes in the electrical and optical properties.
2. Coupling of devices to a radiation field, particularly in the microwave range.
3. Such devices provide a source of spin-polarized carriers.

Details of this research can be found in the Prinz reference listed.

Microclusters. These may be defined as small aggregates of atoms that make up a distinct phase of matter. The chemistry of clusters is highly reactive and selective. Their principle area of future application is catalysis. However, clusters also hold some promise for electronic applications. As observed by M.A. Duncan and D.H. Rouvray (University of Georgia), "Thin films of clusters possessing desirable electronic qualities could be of great interest in microelectronics. It is possible to envision applications in optical memories, image processing and superconductivity. Given the potential for construction of parts from networks of clusters, it may eventually be possible to make electronic devices on a molecular scale. Ultimately a machine might be designed that could serve as a link between solid-state electronics and biological systems, such as systems of neurons. Such a link might convey data from a television camera to the brain of a blind person."

SEMIPERMEABLE MEMBRANE (or Semipermeable Diaphragm). A membrane or septum through which one (or more) of the substances composing a mixture or solution may pass, but not all.

In osmotic pressure determinations, semipermeable membranes permit the passage of a solvent but not of certain colloidal or dissolved substances. Many natural membranes are semipermeable, e.g., cell walls; other membranes may be made artificially, e.g., by precipitating copper cyanoferrate(II) in the interstices of a porous cup, the cup serving as a frame to give the membrane stability.

Semipermeable membranes are also used in the separation of gases. See Fig. 1. When a semipermeable membrane is placed in a gas mixture, being impermeable to gas 2 and allowing gas 1 to pass, the force exerted on it will equal the area times the partial pressure of gas 2 only. While there are no ideal semipermeable membranes for gases, there exist in practice reasonable approximations to them, such as incandescent platinum or palladium sheets, which can be penetrated by hydrogen but not by other gases. A film of water also acts as a semipermeable membrane for gases, since it is pervious to NH_3 or SO_2 because of their solubility in water, but gases which are not easily soluble are held back.

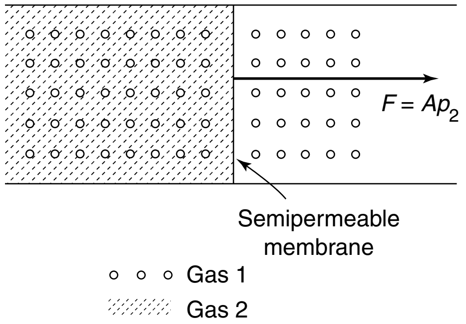

Fig. 1. Separation of gases by semipermeable membrane

SEPIOLITE. The mineral sepiolite or meerschaum is soft, white, light in weight, and occurs in clay-like nodular masses. It is a complex, hydrous magnesium silicate corresponding to the formula $Mg_4Si_6O_{15}(OH)_2 \cdot 6H_2O$. It crystallizes in the orthorhombic system; hardness, 2–2.5; specific gravity, 2; color, white, grayish white, sometimes a yellowish- or bluish-green; opaque. It is capable of floating on water, hence the name meerschaum or sea foam. It occurs in Asia Minor associated with serpentine and magnesite,

and may be derived from the latter. Other deposits are in the Czech Republic and Slovakia, Morocco, and Spain; and in the United States in Pennsylvania and New Mexico. The name meerschaum is from the German. Sepiolite is from the Greek, meaning cuttlefish, referring to the similarity of the bone of that animal to the light, porous sepiolite. The material is used in the manufacture of smoking pipes.

SEQUENTIAL ANALYSIS. The analysis of material derived by a sequential method of sampling, that is to say, it is the data, not the analysis, which are sequential.

In sequential sampling the members are drawn one by one (or in groups) in order, and the results of the drawing at any stage decide whether sampling is to continue. The sample size is thus not fixed in advance but depends on the actual results and varies from one sample to another. The sampling terminates according to predetermined rules which are decided by the degree of precision required.

SEQUESTERING AGENTS. See **Chelates and Chelation**.

SERANDITE. The mineral serandite is a hydrated manganese-sodium silicate corresponding to the formula $Mn_2NaSi_3O_8(OH)$, crystallizing in the triclinic system, of pseudo-monoclinic character. Color, rose-red, pink; transparent; brittle, and uneven fracture. Prominent basal and prismatic cleavage; vitreous to pearly luster. Crystals thick tabular or prismatic, and as intergrown aggregates. Occurs as superb crystals in a carbonatite zone in a host body of nepheline-syenite in association with analcime, aegerine, and other rare minerals at Mt. St. Hilaire, Quebec, Canada. Its only other known world occurrence is on the Island of Rouma, Los Islands, Guinea.

SERPENTINE. This is a group name for minerals encompassing two principal polymorphic forms: *chrysotile* and *antigorite*. This monoclinic mineral of hydrous magnesium silicate composition $Mg_3Si_2O_5(OH)_4$ is essentially a product of metamorphic alteration of ultrabasic rocks rich in olivine, pyroxene, and amphibole. Serpentine crystals are unknown except as pseudomorphic replacements of other minerals, e.g., after clinochlore crystals at the Tilly Foster Mine, Brewster, New York, Antigorite occurs as platy masses; *chrysotile* as silky fibers. Most massive serpentine rocks are composed essentially of antigorite. The hardness is 2–5, specific gravity ranges from 2.2 (fibrous varieties) to 2.65 (massive varieties). Color usually mottled green. The name *serpentine* stems from the mottled character, somewhat resembling the skin of a serpent. There is a greasy to wax-like luster in massive material; silky in fibrous material. The minerals are translucent.

Chrysotile fibers are the source of commercial asbestos, although fibrous amphiboles also contribute to similar usage. Asbestos is economically valuable for its incombustibility and low conductivity of heat, thus as fireproofing and insulating material. See also **Asbestos**.

Chrysotile deposits of economic value are found in Quebec, Canada, in the former U.S.S.R., and in South Africa. Minor occurrences are found in the United States in Vermont, New York, New Jersey, and Arizona. *Verd antique* marble (serpentine marble) is quarried extensively near West Rutland, Vermont.

SESAME SEED OIL. See **Vegetable Oils (Edible)**.

SET (Permanent). When a solid has been strained beyond the elastic limit and the deforming stress is completely removed, in general the strain does not decrease ultimately to zero but to some nonvanishing value, known as a permanent set.

SEWAGE SLUDGE (Energy Source). See **Wastes as Energy Sources**; **Sludge**.

SHALE. A fine-grained sedimentary rock whose original constituents were clays or muds. It is characterized by thin laminae breaking with an irregular curving fracture, often splintery, and parallel to the often indistinguishable bedding planes.

SHELL. 1. In physical chemistry, this term is applied to any of the several sets of, or orbits of, the electrons in an atom as they revolve around the nucleus. They constitute a number of principal quantum path representing successively higher energy levels. There may be from one to seven shells, depending on the atomic number of the element and corresponding to the seven periods of the periodic table. The shells are usually designated by number, though letter symbols have been used, i.e., K, L, M, N, O, P, Q. The laws of physics limit the number of electrons in the various shells as follows: two in the first (K), eight in the second (L), 18 in the third (M), and 32 in the fourth (N). With the exception of hydrogen and helium, each shell contains two or more orbital, each of which is capable of holding a maximum of two electrons.

See also **Orbitals**; **Quantum Number**; and **Pauli Exclusion Principle**.

2. The hard integument of mollusks and crustaceans, consisting mostly of calcium carbonate, chitin, etc.

3. The brittle covering of avian eggs, chiefly calcium carbonate, lime, etc. The formation of proper shell structures in certain species of birds is said to be adversely affected by DDT and similar insecticidal contaminants of their food.

4. The shells of nuts are cellulosic in character. Some contain industrially useful oils.

SHELL (Atomic). See **Chemical Elements**.

SHELLAC. A secretion or excretion of the lac insect, *Coccus lacca*, found in the forests of Assam and Siam. Freed from wood it is called "seed lac." It is soluble in alkaline solutions such as ammonia, sodium borate, sodium carbonate and sodium hydroxide, and also in various organic chemicals. When dissolved in acetone or alcohol, shellac yields the familiar shellac varnish of superior gloss and hardness. Orange shellac is bleached with sodium hypochlorite solution to form white shellac. See also **Paints and Coatings**.

SHERARDIZING. The process for applying an adherent protective coating of zinc to steel parts by heating at 700°F (371°C) in contact with zinc dust in a rotating-drum container.

SHIFT REACTION (Water Gas). See **Coal**; **Substitute Natural Gas (SNG)**.

SIDERITE. This mineral is a carbonate of iron, $FeCO_3$. It is hexagonal with rhombohedral crystals, and also occurs in various massive forms. It has a rhombohedral cleavage; uneven fracture; is brittle; hardness, 3.75–4.25; specific gravity, 3.96; luster, vitreous to pearly; color, gray, yellowish- or greenish-gray, green, reddish-brown and brown. Siderite is found as concretionary masses in the sedimentary rocks; as a replacement mineral from the action of iron solutions upon limestones; and in metalliferous veins as a gangue mineral. It is relatively common. Siderite is found in Austria, Saxony, the Czech Republic and Slovakia, France, England, Italy, Greenland, Australia, Brazil and Bolivia. In the United States important localities are in Connecticut, Pennsylvania, New Jersey, Ohio, and Washington. It is an iron ore. The mineral was at one time called chalybite.

SILICATES (Soluble). The most common and commercially used soluble silicates are those of sodium and potassium. Soluble silicates are systems containing varying proportions of an alkali metal or quaternary ammonium ion and silica. The soluble silicates can be produced over a wide range of stoichiometric and nonstoichiometric composition and are distinguished by the ratio of *silica* to *alkali*. This ratio is generally expressed as the *weight percent ratio* of silica to alkali-metal oxide (SiO_2/M_2O). Particularly with lithium and quaternary ammonium silicates, the molar ratio is used.

Sodium silicates find wide application in many types of detergents and cleaning compounds and have been used for many years as adhesives and cements. Both sodium and potassium silicates are important bonding agents in a large variety of ceramic cement and refractory applications, notably because of their heat stability and resistance to chemicals. Alkali-metal silicate bonds are used in high-temperature ceramic products in the fabrication of electrical components. Soluble silicates find wide application for pelletizing, granulating, and briquetting finely divided particles, such as clays, fertilizers, and ores. Sodium silicates also are used as bonding materials for foundry mold and core compositions. Because of their adherence properties, soluble sodium and potassium silicates are widely

used as coatings. Frequently, sodium silicates are used to protect against water-line corrosion in tanks. The ability to form sols and gels is an interesting and very useful characteristic of soluble silicates. Silica gels are used in a major way as desiccants and as carriers for the production of petroleum-cracking catalysts, as well as raw materials in the manufacture of zeolites. Activated sols are used in water clarification.

Generally, sodium and potassium silicates are made by fusion of pure sand with alkali-metal carbonate or alkali-metal sulfate and carbon. This operation is carried out in large open-hearth furnaces heated to a temperature range of 1300–1500°C. The resulting glasses may be used in this form, or dissolved in water to produce silicate solutions. Sodium and potassium silicate solutions also can be made by dissolving sand in sodium or potassium hydroxide solution at elevated temperatures and pressures. Lithium silicate glasses, although insoluble in water, can be made by dissolving silica gel in, or mixing silica sols with lithium hydroxide solutions. Anhydrous sodium metasilicate is made from the anhydrous melt. This salt crystallizes rapidly from its aqueous solution at temperatures in the range of 80–85°C.

The most important property of sodium and potassium silicate glasses and hydrated amorphous powders is their solubility in water. The dissolution of vitreous alkali is a two-stage process. In an ion-exchange process between the alkali-metal ions in the glass and the hydrogen ions in the aqueous phase, the aqueous phase becomes alkaline, due to the excess of hydroxyl ions produced while a protective layer of silanol groups is formed in the surface of the glass. In the second phase, a nucleophilic depolymerization similar to the base-catalyzed depolymerization of silicate micelles in water takes place.

When sodium silicate solutions of intermediate ratios are concentrated to a thick gum, they become very sticky and tacky. This property is important to many of the adhesive applications. It is related to high cohesion and low surface tension rather than primarily to viscosity.

The stability of soluble silicate solutions depends strongly on pH and concentration. The addition of acids and acid-forming compounds gives rise to the formation of silica gels. Soluble alkali-metal silicate solutions are not compatible with most organic water-miscible solvents. The addition of alcohols and ketones causes phase separation into liquid layers. A few organic systems, however, particularly polyols, such as glycols, glycerins, sugars, and polyethylene glycols, are compatible and miscible with alkali-metal silicate solutions. See also **Adhesives**; and **Glass**.

SILICIC. 1. Containing or pertaining to silicon. 2. Containing silicic acid (ortho) H_4SiO_4; or silicic acid (meta) H_2SiO_3; or silicic acids of a higher degree of hydration (disilicic acids, trisilicic acids, etc.).

SILICIFICATION. An important geochemical process by which certain sedimentary rocks such as limestones and dolomites, or calcareous fossils are partially or entirely replaced by silica, SiO_2. See also **Chert**; and **Flint**.

SILICON. [CAS: 7440-21-3] Chemical element, symbol Si, at. no. 14, at. wt. 28.086, periodic table group 14, mp 1408–1,412°C, bp 2,355°C, density 2.242 g/cm^3 (solid crystalline, 20°C), 2.32 g/cm^3 (single crystal, 20°C). Elemental silicon has a face-centered cubic crystal structure (diamond structure). The existence of a hexagonal form of silicon with a wurtzite-type structure and with lattice parameters $a = 3.80$ Å and $c = 6.28$ Å was established in 1963 (Wentorf-Kasper). Claims to different parameters were made by Jennings-Richman (1976). These differences are discussed by Kasper-Wentorf (1977). Much new knowledge concerning the crystalline structures and phase transitions of silicon has been gained during the mid-1980s, notably from research under immensely high pressures and investigations involving the tunneling microscope, as described shortly.

The common form of silicon is a dark-gray, hard solid. It can be obtained as a brown microcrystalline powder, which is not an allotrope of the gray form. Both forms are unaffected by air at ordinary temperatures, but when heated in air to high temperatures a protective layer of oxide is formed. Silicon reacts with nitrogen at high temperatures to form the nitride; with chlorine to form the chloride, with several metals to form silicides. Crystalline silicon is unattacked by HCl or HNO_3, or H_2SO_4, but is attacked by hydrofluoric acid to form silicon tetrafluoride gas. Silicon is soluble in NaOH solution forming sodium silicate and hydrogen gas. Silicon reacts with dry chlorine to form silicon tetrachloride.

There are three naturally occurring isotopes, ^{28}Si through ^{30}Si, and three radioactive isotopes have been identified, ^{27}Si, ^{31}Si, and ^{32}Si. The latter isotope has a half-life of approximately 700 years, while the half-lives of the other two are short, measured in terms of seconds and hours.

Lavoisier showed in 1787 that SiO_2 was not a single element and indicated that it was the oxide of a hitherto unknown element. In the early 1800s, Scheele, Davy, Gay-Lussac, and Thénard attempted to isolate the element, but were not successful. In 1871, Berzelius discovered silicon in a cast-iron melt and, in 1823, succeeded in isolating the element by reduction of potassium fluorosilicate with potassium. Small laboratory amounts were produced by H.E. Sainte-Claire Deville in 1854 and by C. Winkler in 1864. It was not until 1900 that the effective properties of silicon as a deoxidizing agent for steel production were observed. Shortly thereafter, ferrosilicon alloys, using quartzite, coke, and iron pellets, were produced in electric refining furnaces of the type already in use for making calcium carbide. With this technique, it was possible to produce silicon of about 98% purity. It remained for the rigid purity requirements of semiconductors many years later before silicon of higher purities was produced.

Silicon is ranked second in the order of chemical elements appearing in the earth's crust, an average of 27.72% occurring in igneous rocks. In terms of seawater, it is estimated that a cubic mile of seawater contains about 15,000 tons of silicon (3240 metric tons per cubic kilometer). In terms of abundance throughout the universe, silicon is ranked seventh. First ionization potential 8.149 eV; second, 16.27 eV; third, 33.30 eV; fourth, 44.95 eV. Oxidation potentials $Si + 2H_2O \longrightarrow SiO_2 + 4H^+ + 4e^-$, 0.86 V; $Si + 6OH^- \longrightarrow SiO_3{}^{2-} + 3H_2O + 4e^-$, 1.73 V.

Other important physical properties of silicon are given under **Chemical Elements**.

Because of its chemical reactivity, silicon does not occur in elemental form in nature. The element is present in igneous rocks and clays as alumino-silicate; as the oxide SiO_2 in quartz, sand. (Fig. 1), flint, and the gems amethyst, jasper, chalcedony, agate, onyx, tridymite, opal, crystobalite; as silicates in zircon (zirconium silicate, $ZrSiO_4$), in willemite (zinc silicate, Zn_2SiO_4), in wollastinite (calcium silicate, $CaSiO_3$), in serpentine (magnesium silicate, $Mg_3Si_2O_7$). Impure (up to 98% Si) silicon is obtained from the oxide (1) by igniting with aluminum powder, or (2) by reduction with carbon in an electric furnace. See also **Cancrinite**.

Silicon Production for Alloys: production of raw steel requires about 1.6–1.7 kilograms of silicon per metric ton of steel. The silicon is used in the form of ferrosilicon, which contains about 20% silicon. It is estimated that about 3 million metric tons of ferrosilicon are consumed annually in steelmaking. The 20%-silicon-content ferrosilicon can be made in a conventional blast furnace. Ferrosilicons with higher silicon contents (45, 75, 90, and 98%) must be produced in electric furnaces. The raw materials are pure quartzites. The presence of impurities, such as Al_2O_3 and CaO, interfere with the melting process because of the formation of dross. The reducing agent used is chemical coke. For the very high concentrations of silicon

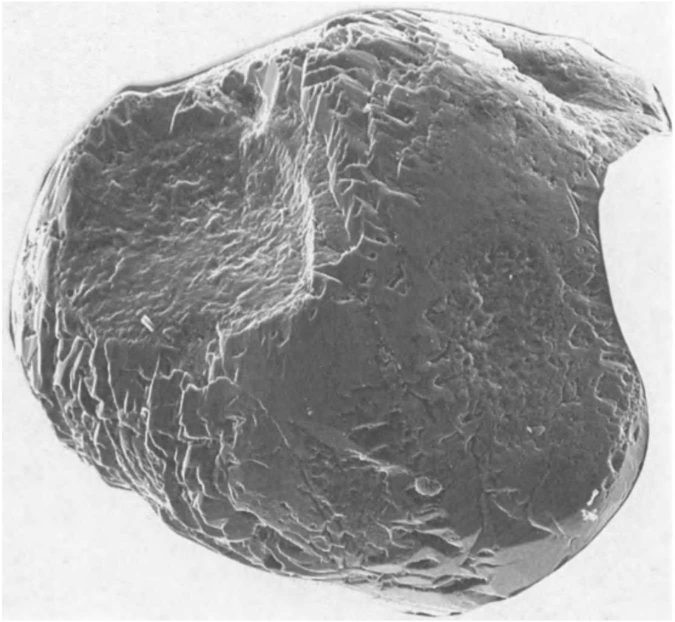

Fig. 1. Grain of sand, originally magnified 100×

(90–98%), ash-free petroleum coke or charcoal are used. Iron is added in the form of small pellets or chips in the production of the 45–75%-silicon alloys.

For certain metal alloys, a calcium silicon alloy is required. This alloy also is used as a steel deoxidizer and is favored because it forms a low-melting-point calcium silicate product. A representative composition of the alloy is: 30–33% Ca, 60–64% Si, 3–5% Fe, 1–2% Al, 0.3–0.6% C, and less than 0.15% S and P.

Silicon is used in the primary and secondary aluminum industry. The purity of silicon for metallurgical purposes ranges from 96.7 to 98.5% silicon; 0.10 to 0.75% aluminum; 0.03 to 0.04% calcium; with the remainder being principally iron.

Silicon Carbide

This compound is an important industrial abrasive, having a hardness of 9.5 on the Mohs scale. In this compound, each silicon atom is surrounded tetrahedrally by four carbon atoms, and similarly, each carbon atom is surrounded by four silicon atoms. Silicon carbide is made by reducing pure quartz (glass-sand) with petroleum coke in an electric-resistance type furnace, known as the Acheson process. The product is hexagonal crystals ranging from light-green to black. It is used as a ceramic raw material for dross-repellent linings as well as for many abrasive applications.

Silicon carbide also has been recognized for many years because of its having a unique set of electronic material advantages over silicon and gallium arsenide. Not only can SiC withstand higher device operating temperatures (approximately 650°C compared with silicon's 150°C), but SiC devices can operate with ten times the voltage capability and three times the thermal conductance capability. And, they are mechanically much more robust than traditional semiconductors.

The foregoing characteristics enable the configuration of a whole new family of high-power microwave and high-temperature electronics that can withstand high radiation for military and commercial systems.

Only recently has it been possible to produce uniform, centimeter-sized crystals. A high-purity vapor transport growth process has been developed (Westinghouse) to produce 1.5-inch (3.8-cm) device-grade SiC crystals and wafers. These comprised the building blocks for a demonstration of microwave transistors in the early 1990s. See Fig. 2.

Fig. 2. Researcher Dan Barrett (Westinghouse Science & Technology Center) checks the hot (2400°C) crystal growth furnace that he designed for physical vapor transport growth of single crystals of silicon carbide

Super- or Hyperpure Silicon

For semiconductor use, there can be only one atom of impurity for every 100,000 silicon atoms! The starting material for the manufacture of hyperpure silicon is silicon tetrachloride, $SiCl_4$, or trichlorosilane, $SiCl_3H$. Both of these materials can be reduced with hydrogen to yield a compact deposition of silicon on hot surfaces, ranging from 800–1,200°C. The starting compounds are purified of boron and phosphorus by fractional distillation and absorption techniques. The process hydrogen is purified by passing it through molecular sieves under high pressure, followed by absorption techniques at a low temperature (−190°C). With the highly purified starting ingredients an excess of hydrogen is circulated through heated quartz tubes. Or, the gas mixture may be blown into quartz bell jars, whereupon the silicon is deposited on filaments of tantalum or tungsten or on thin rods of hyperpure silicon, which may be heated by electrical resistance or radiofrequency energy. This process yields polycrystalline rods of silicon which range up to about one meter in length and 150 millimeters in diameter.

To be used in seimconductor devices, the polycrystalline silicon must be converted to single crystals of a defined, predetermined type of conductivity (*n* or *p* type). The crystals must be rigidly controlled as regards their resistivity, and possess the highest degree of crystallographic perfection. The two crystal-growing techniques used are: (1) crucible free vertical float zoning which removes all residual impurities, including phosphorus, arsenic, and oxygen, but boron is essentially irremovable by floating zoning, or (2) crucible pulling in which the crystals, particularly those of lower resistivity, are drawn out of a melt in a process known as the Czochralski technique. Both processes must be conducted under helium or argon, often under a vacuum of 10^{-5} torr.

Production of Ultrapure Silicon Crystal

In 1990, Westinghouse engineers reported the production of the purest crystal of silicon ever made—namely, four times purer than previously reported material. The crystal also is significantly larger, adding to its practicality in the manufacture of microelectronic circuits and devices.

The cylindrical structure, called a *boule*, weighs 22 pounds (10 kg) and is over a yard (meter) long, with a diameter of just over 3 inches (8 cm). Impurities are a few parts in 100 billion, compared with more than 10 parts in 100 billion previously reported for 1-inch (2.5-cm) diameter ultrapure crystals.

Crystal boules are sliced into wafers on which microelectronic circuits and power semiconductor devices are fabricated. An important use of the wafers is for infrared dectors for space, defense, and environmental applications.

Liquid-Solution Synthesis of Silicon Crystals

In late 1992, J.R. Heath (IBM Watson Research Laboratory) reported on a liquid-solution phase technique for preparing submicrometer-sized silicon single crystals. The synthesis is based on the reduction of $SiCl_4$ and $RSiCl_3$ ($R = H$, octyl) by sodium metal in a nonpolar organic solvent at high temperatures (385°C) and high pressure (above 100 atmospheres). For $R = H$, the synthesis produces hexagonal silicon single crystals ranging from 5 to 2000 nanometers. For $R =$ octyl, the synthesis also produces hexagonal-shaped silicon single crystals.

Light Emission from Silicon

Because of silicon's successes in the electronic components field, research has been going on to find a form of Si that will produce luminous radiation. Because of former failures, numbers of scientists have given up this research. However, independently in French and British laboratories during 1990, some success has been achieved. These researchers have found that, if one etches Si into structures so tiny that the electronic behavior of the material is transformed, full-color emission from what are termed "silicon quantum wires." A British researcher L. Canham (Royal Signals and Radar Establishment, Malvern, England) has observed that, to make silicon quantum wires, a process for sculpting silicon, known for some 30 years, is the basis. A silicon wafer is immersed in an acid electrochemical bath, which bores into the disk to produce extremely small so-called "wormholes." The latter are etched chemically, enlarging them until they meet one another. The result is a columnar structure of silicon. The latter are about a micron high, and 50 of them, stacked end to end, would span an area about equivalent to a cross-section of a human hair and are only a few nanometers thick ($\frac{1}{15,000}$), smaller than a hair. The researchers have found that, when such a structure

is bathed in ultraviolet light, light emission occurs. The emitted wavelength is determined by the porosity of the Si layer.

J.P. Harbison (Bellcore, Redbank, New Jersey) observes, "This is not the moment of the breakthrough for light-emitting silicon, but it is the moment when a lot of people are realizing its potential."

Research on Silicon Structure and Surface Properties

The rather unusual properties of silicon have intrigued scientists for many years. It possesses the physical properties of a *metalloid* (exhibits properties of both a metal and nonmetal). In several ways, silicon resembles germanium and, to a lesser extent, it resembles arsenic and boron. Silicon is a semiconductor of electricity, the conductivity rising with temperature. Silicon, in pure form, is intrinsically a semiconductor. The presence of impurities in very minute amounts markedly increases its conductivity. By introducing elements of group 13 (such as boron), which have a deficiency of electrons, the *p*-type silicon results. Therein, electricity is conducted by migration of electron vacancies or holes. On the other hand, introduction of elements of group 15, such as arsenic or phosphorus, in which there is no deficiency of electrons, the *n*-type silicon results, in which extra electrons carry an increased current because of their migration. Scientists have not been satisfied with oversimplified explanations such as that just given. As a key material in the microelectronics field, where the processing of silicon into chips and other configurations for electronic components is essentially effected at the surface of the silicon, particular interest concerns those crystalline structural details that play a role in the electronic nature of the element. However, prior to the emergence of solid-state technology, scientists were puzzled by what appeared to be crystal structure and surface anomalies and, consequently, research dates back many years, with progress largely determined by the instrumentation available to investigators. The *tunneling microscope*, the invention of which is accredited to G.K. Binnig and H. Rohrer and partially to E.W. Müller (who also invented the field-ion microscope in the 1950s), has contributed much toward an understanding of the surface of the silicon crystal, an understanding which is expected to be translated ultimately in manufacturing improvements and better final properties of silicon-based electronic components. See also **Scanning Tunneling Microscope**.

The relatively recent availability of means to create extremely high pressures (see also **Diamond Anvil High Pressure Cell**) has made it possible to gain further insights into the character of silicon. It has been learned from such experimentation that at a pressure of 110 kilobars (about 1.6 million pounds per square inch), silicon enters *truly metallic* phases. At the pressure stated, silicon abruptly assumes a structure similar to the beta form of tin. At this pressure and at a temperature of 6 degrees Kelvin (six Celsius degrees above absolute zero) the metal becomes superconducting, that is, it offers no resistance to the passage of electrons. At a pressure of 130 kilobars, the beta-tin form of silicon transforms into what has been designated as the *primitive hexagonal* phase, a phase first discovered in 1984. This research was conducted by Cohen, Chang, and Dacorogna (University of California, Berkeley). Prior to this experiment, it was not thought that such a phase would exist in the crystal of any chemical element. The researchers entered into theoretical calculations after the experiment to better understand the properties of the primitive hexagonal phase. The calculations were lengthy and required a CRAY/X-MP computer. A major finding was that the bonds linking the atoms in each of the planes defined by the hexagons should be weaker than the bonds linking the atoms in adjacent planes. This indicates that the electronic charge distribution should be inhomogeneous along one dimension. This inhomogeneity is an indication of a good superconductor because, in effect, it provides corridors through which electrons can move.

In their investigation, the researchers turned back to the much earlier hypotheses of quantum mechanics, including the properties of phonons (in quantum mechanics, a phonon can be treated as a particle, one that interacts with electrons). A strong interaction improves the opportunities for superconductivity. However, where the coupling is too strong, the integrity of the lattice may collapse and a structural phase transition may occur. Testing for superconductivity at such high pressures will be difficult. The Berkeley group predicts that the superconducting temperature will rise to a value greater than 10 degrees as the pressure nears the value required for the transition from the simple hexagonal phase to the hexagonal closed-packed phase. If expectations are proved, silicon could be the best superconductor of all chemical elements. Translating this to practical application, of course, may or may not be feasible at some future date. See also **Superconductivity**.

Silicon Chemistry and Compounds

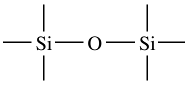
Like carbon, silicon forms chiefly covalent bonds, but its greater atomic radius enables it to form positive ions more readily. Unlike carbon and tin, silicon is not allotropic, having only one elemental form, the diamond structure in which each atom is surrounded tetrahedrally by four others to which it is covalently bonded. An apparently amorphous brown powder, produced by combustion of silane, SiH_4, has been found to be a microcrystalline variety of this covalently-bonded structure. Much research has been conducted during the 1970s and 1980s pertaining to the more exotic silicon compounds, such as the *disilenes*, and to silicon-mediated organic synthesis. These topics are discussed later in this article. The following several paragraphs are devoted to the large number of traditional silicon compounds whose constitution and characteristics have been well established over the years.

Silicon Dioxide, (SiO_2)

This compound exists in at least eleven distinct crystalline forms. Several of them are obtained by heating α-quartz, which has a number of transition points, to produce β-quartz, and to give various forms of tridymite and crystobalite. The unit of structure is the tetrahedron in which each silicon atom is covalently bonded to four oxygen atoms, and the variation is in the ways these tetrahedra are interconnected (by oxygen atoms) to form a three-dimensional system.

Silicon dioxide is converted by hydrofluoric acid into silicon tetrafluoride, SiF_4, a gas. SiF_4 can also be produced directly from the elements, as can the other tetrahalides, silicon tetrachloride, $SiCl_4$ (a liquid), silicon tetrabromide, $SiBr_4$ (a liquid), and silicon tetraiodide, SiI_4 (a solid). The silicon halides hydrolyze much more readily than the carbon halides, because the unoccupied silicon $3d$ orbitals are energetically not far above its $3s$ and $3p$ orbitals. This fact also permits the formation of the sp^3d^2 hybrid bonds of the fluorosilicate ion, $SiF_6{}^{2-}$, and additional compounds of the halides, e.g., $SiX_4 \cdot 2$ pyridine. Silicon also is intermediate between carbon and the higher members of main group 4 of the periodic table in forming a dichloride, $SiCl_3$, by strong heating of silicon with silicon tetrachloride.

Quartz and other forms of silica react very slightly with water to form monosilicic acid, $(SiO_2)_n + 2nH_2O \longrightarrow nSi(OH)_4$. As shown, this reaction is a depolymerization followed by a hydrolysis, and proceeds rapidly with hot alkalis or fused alkali metal carbonates, yielding soluble silicates containing the $SiO_4{}^{4-}$ and $(SiO_3{}^{2-})_n$ ions. The hydrolysis reaction is geologically important, because it is considered to be the starting point in the formation of the innumerable silicate minerals that occur so widely in nature, just as many of the silica minerals may have originated by the reverse reaction. Many of the more complex silicic acids are considered to form by polymerization of $Si(OH)_4$ molecules by sharing of OH ions between two silicon ions (octahedrally coordinated by six hydroxyl ions) followed by condensation with the loss of water to produce



linkages. The polymerization of silicic acid is carried out industrially to produce silica gel, a stable sol of colloidal particles. The various methods involve careful removal of H_2O, the catalytic effect of acid or alkali (or fluoride ion) and controlled pH. Many varieties of silica gel have been made, including the zerogels and aerogels, in which the aqueous phase is displaced by a gaseous one.

In 1992, Yeganeh-Haeri, Weidner, and Parise (Center for High Pressure Research, State University of New York, Stony Brook) used laser Brillouin spectroscopy to determine the adiabatic single-crystal elastic stiffness coefficients of silicon dioxide in the alpha-cristobalite structure. This SiO_2 polymorph, unlike other silicas and silicates, was found to exhibit a negative Poisson's ratio. Alpha-cristobalite contracts laterally when compressed and expands laterally when stretched. Tensorial analysis of the elastic coefficients showed that Poisson's ratio reached a maximum value of -0.5 in some directions, whereas averaged values for the single-phased aggregate yielded a Poisson's ratio of -0.16.

Silicon Dioxide as a Chemical Intermediate

In 1992, R.M. Laine (University of Michigan, Ann Arbor) announced the development of a process that transforms sand and other forms of silica into reactive silicates that can be used to synthesize unusual silicon-based chemicals, polymers, glasses, and ceramics. The Laine procedure produces pentacoordinate silicates directly from low-cost raw materials—silicon dioxide, ethylene glycol, and an alkali base. The mixture is approximately a 60:1 ratio of silica gel, fused silica (or sand) to metal hydroxide and ethylene

glycol. Heating the mixture slowly, the ethylene glycol and water (used to put the materials in solution) boils off. The resulting glycolatosilicates, unlike the hexa- and tetracoordinate forms, are reactive and offer potential for synthesizing a wide range of materials. Laine observes, “The new silicon chemistry could produce alternatives to many petrochemical-based products and could be competitive with or superior to present carbon-based materials.” Thus far, a number of materials have been produced by the process:

1. A clear polymer capable of conducting electric current when spread in a thin layer across a flat surface. Potential includes applications in batteries, heated windshields, and electrochromic windshields.
2. A fire retardant polymer that is easily impregnated into wood to “petrify” the material, making it stronger and nonflammable.
3. Liquid-crystal polymers stable to about 425°C (800°F), with potential for uses in watch displays and aerospace instrumentation.
4. Silicate glasses capable of withstanding high temperatures.

Silicates

The great number of naturally occurring silicates result, as just indicated, from the polymerization and dehydration of monosilicic acid to form, ultimately, such groups and ions as $(Si_2O_7)^{6-}$, $(Si_3O_9)^{6-}$, $(Si_4O_{12})^{8-}$, and $(Si_6O_{18})^{12-}$. Various cations, such as those of boron, B^{3+}, aluminum, Al^{3+}, etc., in the structure lie at the centers of anionic polyhedra having as anions the O^{2-} ions of neighboring SiO_4 tetrahedra, in which each Si O bond has an electrostatic bond strength of 1. Cations of lower charge density, on the other hand, like sodium, Na^+, potassium, K^+, calcium, Ca^{2+}, etc., are located interstitially. The great variety of the silicates is due to the considerable degree of isomorphism, exhibited not only by elements of the same group, but by elements of different groups, whereby they partly replace each other in the complex silicates, and by no means necessarily in stoichiometric proportions. Thus troosite may be represented by the formula $(Zn, Mn)_2SiO_4$, chrysolite by $6Mg_2SiO_4 \cdot Fe_2SiO_4$, and vermiculite by $(Mg, Fe)_3(AlSi)_4O_{10} \cdot (OH)_2 \cdot 4H_2O$, even the silicon in vermiculite being partly replaced (by aluminum). One plane of classification of the silicates is upon the basis of the linking of the SiO_4 tetrahedra:

A. *Discrete silicate radicals.*
   1. Single tetrahedral $(SiO_4{}^{4-})$, e.g., phenacite, Be_2SiO_4.
   2. Two tetrahedra $(Si_2O_7)^{6-}$, e.g., hardystonite, $Ca_2ZnSi_2O_7$.
   3. Three tetrahedra $(Si_3O_9)^{6-}$, e.g., benitoite, $BaTiSi_3O_9$.
   4. Four tetrahedra $(Si_4O_{12})^{18-}$, e.g., axinite, (Fe, Mn) $Ca_2Al_2BO_3$ Si_4O_{12}.
   5. Six tetrahedra $(Si_6O_{18})^{12-}$ e.g., beryl, $Be_3Al_2Si_6O_{18}$.

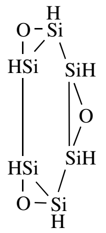
B. *Silicon-oxygen chains of indefinite length.*
   1. Single chains with one silicon atom to three oxygen atoms, e.g., diopside, $CaMg(SiO_3)_2$.
   2. Double chains (Si:O = 4:11), e.g., tremolite, $Ca_2Mg_5(Si_4O_{11})_2$ $(OH)_2$.

C. Silicon-oxygen sheets. (Si:O = 2:5), e.g., talc, $Mg_3(SiO_5)_2(OH)_2$.

D. *Silicon-oxygen spatial networks.*
   1. Composition SiO_2 (composed of interlinked SiO_4 tetrahedral), e.g., quartz, SiO_2.
   2. Composition $M_n(Si, Al)_nO_{2n}$, e.g., feldspar, KSi_3AlO_8. These are probably based upon silicon and aluminum tetrahedra, variously linked.

Silanes

The increasingly large number of silicon compounds produced by industrial processes may be systematized about the silanes and their substitution products, just as the silicates are about the SiO_4 tetrahedron. Silicon, like carbon, forms a number of hydrides, though their number is much more limited. The silane series, analogous to the paraffin hydrocarbons, has at least six members, silane (SiH_4), disilane ($H_3Si{-}SiH_3$), … hexasilane ($H_3Si{-}SiH_2{-}SiH_2{-}SiH_2{-}SiH_2{-}SiH_3$). They are increasingly unstable, hexasilane dissociating at room temperature. They are halogenated with free halogens to form substituted silanes, and catalytically with the hydrogen halides. The halosilanes react with NH_3 to form silylamines or silazanes and are hydrolyzed by water to form siloxanes. Prosiloxane, H_2SiO, polymerizes readily but disiloxane, $H_3Si{-}O{-}SiO_3$, and the higher siloxanes, although they polymerize, can readily be studied. They have properties like the ethers and other analogous carbon compounds. Hydrogen-containing siloxanes, such as $HO_2Si{-}SiO_2H$ are also known and polymerize readily. There are also ring siloxanes, such as siloxen, which has a polymerized structure of epoxy form (a powerful reducing agent)



Silyl and polysilyl radicals also combine with nitrogen, arsenic, and other main group 5 elements, as with sulfur and selenium.

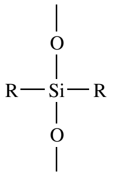
The silazanes are such compounds of silicon, nitrogen and hydrogen of the general formula $H_3Si(NHSiH_2)nNHSiH_3$, being called disilazane, trisilazane, etc., according to the number of silicon atoms present. (In disilazane, n in the above formula has a value of 0, in trisilazane it is 1, etc.)

The silthianes are sulfur compounds having the general formula $H_3Si(SSiH_2)_nSSiH_3$ which are called disilthiane, trisilthiane, etc., according to the number of silicon atoms present. They have the generic name *silthianes*. (In disilthiane, n in the above formula has a value of 0, in trisilthiane, a value of 1, etc.)

Silicones

These are semiorganic polymers with a quartz-like structure in which various organic groups are attached to the silicon atom. By varying the kind and number of organic groups, a variety of materials ranging from liquids through gels and elastomers to rigid solids (resins) can be produced.

The organosilicon compounds may be regarded as substituted silanes, although of course their preparation is not usually in this way. Thus, ethyl silicate, $Si(OC_2H_5)_4$, is prepared from silicon tetrachloride and ethyl alcohol, and tetraethyl silane, $Si(C_2H_5)_4$, is prepared from silicon tetrachloride and diethylzinc. The silicon-carbon bond, unlike the carbon-carbon bond, has about 12% of ionic character, varying somewhat with the atoms or groups attached to the two atoms. Other types of organosilicon compounds include the esters, the alkoxyhalosilanes, the higher tetra-alkylsilanes (prepared from silicon tetrachloride and Grignard reagents), the alkylsilanes (H partly replaced by R), the alkylhalosilanes, the alkylalkoxysilanes, the alkylsilylamines, some aryl compounds of the foregoing types, and many related derivatives of disilane and the polysilanes. Other types of compounds are those having silicon-carbon chains and the organosiloxane compounds, for which the name “silicones” is often used. These are essentially chains or networks of groups



joined by oxygen atoms attached to the silicon atoms as shown. There are many other groups of silicon compounds, as well as individual ones.

Aluminates

Many complex silico-aluminates or aluminosilicates are formed in nature. Of these, clay in more or less pure form (pure clay, kaolinite; kaolin, china clay, $H_4Si_2Al_2O_9$ or $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) is of great importance. Clay is formed by the weathering of igneous rocks, and is used in the manufacture of bricks, pottery, porcelain, Portland cement. Sodium aluminosilicate is used in water purification to remove dissolved calcium compounds.

Fluosilicate

Sodium fluosilicate, Na_2SiF_6, white solid slightly soluble; magnesium fluosilicate, $MgSiF_6$, white solid, soluble.

Sulfides

Silicon monosulfide, SiS, yellow solid, somewhat volatile, formed by heating to redness crystalline silicon in sulfur vapor, reactive with water;

silicon disulfide, SiS_2, white crystals, formed by heating amorphous silicon and sulfur, and then subliming, reactive with water.

Nitrides

Trisilicon tetranitride, Si_3N_4, by heating silicon oxide plus carbon to 1,500°C in a current of nitrogen gas.

Silicates

See also **Adhesives**.

Silicon-Silicon Double Bond

Of the chemical elements, Si is closest to carbon in terms of its chemical properties. Multiple bonds pervade carbon chemistry and thus it is no surprise that investigators, over a period of many years, have been seeking evidence of multiple bonding in silicon. As early as 1911, Kipping reported compounds exhibiting this bonding, but these substances were later shown to be polymers or cyclic oligomers. It was not until the 1960s that good evidence was reported for the existence of Si = C (silene), Si = Si (disilene), and Si = O (silanone) compounds. The full reality of such compounds, however, was not reported until 1981. At that time, a silene and a disilene, each of which is stable at room temperature, were reported by two separate groups. Brook, et al. reported on a silene; West, et al. reported on a disilene. It has since been concluded that many disilenes can be prepared, including compounds that are unexpectedly stable. Molecules containing Si = Si bonds can be synthesized by several routes. The key to stabilization of these compounds is to provide large substituents bonded to the Si atoms so that polymerization is blocked. It has been determined that disilenes react chemically by addition across the double bond, as do alkenes. Tetramesityldisilene, as reported by West, also undergoes a wide variety of addition reactions previously unestablished in organic chemistry. The result is several "new" and unusual types of molecules, the details of which are reported in the West paper listed under references.

Silicon-Mediated Organic Synthesis

As reported by Paquette (reference listed), since the late 1960s, organic chemists have used the chemical properties of tetracovalent silicon to achieve a variety of new synthetic transformations. Paquette (Ohio State University) summarizes, "In carbon-functional silanes, exceptional stabilization is provided to a carbocation center in the beta position when the carbon-silicon bond lies in plane. This phenomenon directs electrophilic attack to the silicon-substituted carbon in aryl-, vinyl-, and alkynylsilanes and to carbon-3 in allylsilanes. For different reasons, silicon also stabilizes a carbon-metal bond in the alpha position. Consequently, access to many silicon-containing organometallics is readily available. The exceptional strength of silicon-oxygen and silicon-fluorine bonds is yet another factor that controls the chemical reactivity of silicon reagents. In recent developments, preparative chemists have taken advantage of these properties in imaginative and useful ways." In the Paquette paper, these observations are developed in exceptional and illustrated detail.

Reactions of Elemental Silicon

In the late 1980s, E.A. Pugar and P.E.D. Morgan and a team of researchers at the Rockwell International Science Center, Thousand Oaks, California, conducted a thorough effort to understand "Low Temperature Direct Reactions Between Elemental Silicon and Liquid Ammonia or Amines for Ceramics and Chemical Intermediates." Details are given in reference cited.

Because of the important potential applications of silicon nitride, the use of low-cost starting materials, such as elemental silicon and liquid ammonia or amines, may be more effective than the existing chloride method. In earlier work, this process was found to form silicon di-imide ($Si(NH)_2$), but required purification steps to remove chloride.

Pugar and Morgan elucidate their research and include a summary of the work of other researchers over the years. The report concludes: "Through the use of modern sensitive probes, direct elemental silicon reactions with liquid ammonia, silicon-hydrazine and silicon-organic amines have been discovered. The reaction of elemental silicon with nitrogen-containing reagents, under rather benign conditions, can produce ceramic precursors and with further chemical treatments can produce fibers, films, and other commercial and industrial products."

Nomenclature of Silicon Compounds

The name of the compound SiH_4 is *silane*. Compounds having the general formula $H_3Si \cdot [SiH_2]_n \cdot SiH_3$ are called disilane, trisilane, etc., according to the number of silicon atoms present. Compounds of the general formula Si_nH_{2n+2} have the generic name *silanes*. Example: Trisilane, $H_3Si \cdot SiH_2 \cdot SiH_3$.

Compounds having the formula $H_3Si \cdot [NH \cdot SiH_2]_n \cdot NH \cdot SiH_3$ are called disilazane, trisilazane, etc., according to the number of silicon atoms present; they have the generic name *silazanes*. Example: Trisilazaine, $H_3Si \cdot NH \cdot SiH_2 \cdot NH \cdot SiH_3$.

Compounds having the formula $H_3Si \cdot [S \cdot SiH_2]_n \cdot S \cdot SiH_3$ are called disilthiane, trisilthiane, etc., according to the number of silicon atoms present; they have the generic name *silthianes*. Example: Trisilthiane, $H_3Si \cdot S \cdot SiH_2 \cdot S \cdot SiH_3$.

Compounds having the formula $H_3Si \cdot [O \cdot SiH_2]_nO \cdot SiH_3$ are called disiloxane, trisiloxane, etc., according to the number of silicon atoms present; they have the generic name *siloxanes*. Example: Trisiloxane, $H_3Si \cdot O \cdot SiH_2 \cdot O \cdot SiH_3$.

For designating the positions of substituents on compounds named as silanes, silazanes, silthianes, and siloxanes, each member of the fundamental chain is numbered from one terminal silicon atom to the other. When two or more possibilities for numbering occur, the same principles are followed as for carbon compounds. Examples:

1-Butyl-2,3-dichloro-2-pentyltrisilane
$Cl \cdot SiH_2 \cdot SiCl(C_5H_{11}) \cdot SiH_2 \cdot C_4H_9$
2-Methyl-3-pentyloxytrisilazane
$SiH_3 \cdot N(CH_3) \cdot SiH(OC_5H_{11})\cdot$
$H \cdot SiH_3$
1-Methoxytrisiloxane
$CH_3O \cdot SiH_2 \cdot O \cdot SiH_2 \cdot O \cdot SiH_3$

The names of representative radicals containing silicon are shown below. These illustrate the principles on which any further radical names should be formed.

Silicon, hydrogen	
silyl	H_3Si-
silylene	$H_3Si=$
silylidyne	$HSi\equiv$
disilanyl	$H_3Si \cdot SiH_2-$
trisilanyl	$H_3Si \cdot SiH_2SiH_2-$
disilanylene	$-SiH_2 \cdot SiH_2-$
trisilanylene	$-SiH_2 \cdot SiH_2 \cdot SiH_2-$
cyclohexasilanyl	$SiH_2 \cdot SiH_2 \cdot SiH_2$ | | $SiH_2 \cdot SiH_2 \cdot SiH_2$
Silicon, hydrogen, oxygen	
siloxy	$H_3Si \cdot O-$
disiloxanyl	$H_3Si \cdot O \cdot SiH_2-$
disilanoxy	$H_3Si \cdot SiH_2 \cdot O-$
disiloxanoxy	$H_3Si \cdot O \cdot SiH_2 \cdot O-$
Silicon, hydrogen, sulfur	
silylthio	$H_3Si \cdot S-$
disilanylthio	$H_3Si \cdot SiH_2 \cdot S-$
disilthianyl	$H_3Si \cdot S \cdot SiH_2-$
disilthianylthio	$H_3Si \cdot S \cdot SiH_2 \cdot S-$
Silicon, hydrogen, sulfur, oxygen	
disilthianoxy	$H_3Si \cdot S \cdot SiH_2 \cdot O-$
disiloxanylthio	$H_3Si \cdot O \cdot SiH_2 \cdot S-$
Silicon, hydrogen, nitrogen	
silylamino	$H_3Si \cdot NH-$
disilanylamino	$H_3Si \cdot SiH_2 \cdot NH-$
disilazanyl	$H_3Si \cdot NH \cdot SiH_2-$
disilazanylamino	$H_3Si \cdot NH \cdot SiH_2 \cdot NH-$
Silicon, hydrogen, nitrogen, oxygen	
disilazanoxy	$H_3Si \cdot NH \cdot SiH_2 \cdot O-$
disiloxanylamino	$H_3Si \cdot O \cdot SiH_2 \cdot NH-$

Compound radical names may be formed in the usual manner. Examples:

silyldisilanyl	$(H_2Si)_2SiH-$
disilyldisilanyl	$(H_3Si)_3Si-$
triphenylsilyl	$(C_6H_5)_3Si-$

Open-chain compounds which have the requirements for more than one of the structures already defined are named, if possible, in terms of silane, silazane, silthiane, or siloxane containing the largest number of silicon atoms. Examples:

3-Siloxytrisilthiane
$H_3Si \cdot S \cdot SiH \cdot SiH_3$
|
$O \cdot SiH_3$
1-Siloxy-3-(disilthianoxy)trisilthiane
$H_3Si \cdot S \cdot SiH \cdot S \cdot SiH_2 \cdot OSiH_3$
|
$O \cdot SiH_2 \cdot S \cdot SiH_3$

When there is a choice between two parent compounds possessing the same number of silicon atoms, the order of precedence is siloxanes, silthianes, silazanes, and silanes. Examples:

1-Silylthiodisiloxane
$SiH_3 \cdot O \cdot SiH_2 \cdot S \cdot SiH_3$
1-Silylaminodisilthiane
$SiH_3 \cdot S \cdot SiH_2 \cdot NH \cdot SiH_3$
1-Phenyl-3-silyldisiloxane
$SiH_3 \cdot SiH_2 \cdot O \cdot SiH_2 \cdot C_6H_5$

Cyclic silicon compounds having the formula $[SiH_2]_n$ are called cyclotrisilane, cyclotetrasilane, etc., according to the number of members in the ring; they have the generic name *cyclosilanes*. Example:

Cyclotrisilane $SiH_2{\cdot}SiH_2{\cdot}SiH_2$

Cyclic compounds having the formula $[SiH_2.\ NH]_n$ are called cyclodisilazane, cyclotrisilazane, etc., according to the number of silicon atoms in the ring. They have the generic name *cyclosilazanes*. Example:

Cyclotrisilazane
$HN{\cdot}SiH_2{\cdot}NH{\cdot}SiH_2{\cdot}NH{\cdot}\ \ SiH_2$

Cyclic compounds having the formula $[SiH_2{\cdot}\ S]_n$ have the generic name *cyclosilthianes* and are named similarly to the cyclosilazanes. Example:

Cyclotrisilthiane
$S{\cdot}SiH_2{\cdot}S{\cdot}SiH_2{\cdot}O{\cdot}\ \ SiH_2$

Cyclic compounds having the formula $[SiH_2{\cdot}\ O]_n$ have the generic name *cyclosiloxanes* and are named similarly to the cyclosilazanes. Example:

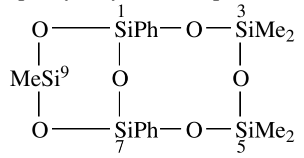
Cyclotrisiloxane
$O{\cdot}SiH_2{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}\ \ SiH_2$

Cyclosilanes, cyclosilazanes, cyclosilthianes, and cyclosiloxanes are numbered in the same way as carbon compounds of similar nature. Examples:

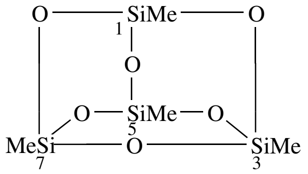
2-Methoxycyclotrisilazane
$HN{\cdot}SiH_2{\cdot}NH{\cdot}SiH_2{\cdot}NH{\cdot}SiH{\cdot}OCH_3$
2-Methoxycyclotrisilthiane
$S{\cdot}SiH_2{\cdot}S{\cdot}SiH_2{\cdot}S{\cdot}SiH{\cdot}OCH_3$
2-Methoxycyclotrisiloxane
$O{\cdot}SiH_2{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}SiH{\cdot}OCH_3$

Polycyclic siloxanes (polycyclic compounds whose members consist entirely of alternating silicon and oxygen atoms) are named as bicyclosiloxanes, tricyclosiloxanes, etc., or as spirosiloxanes, and are numbered according to methods in use for carbon compounds of similar nature. Polycyclic silthianes, silazanes, and silanes are treated similarly. Examples:

3,3,5,5,9,9-Hexamethyl-1,7-diphenylbicyclo[5,3,1]pentasiloxane

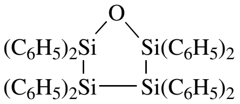


Tetramethyltricyclo[3,3,1,1]tetrasiloxane



The names of compounds containing silicon atoms as heteromembers (with or without other heteromembers) but not classifiable as (linear or cyclic) silanes, silazanes, silthianes or siloxanes are derived with the aid of the oxa-aza convention. Examples:

2,2,4,4,6,6-Hexamethyl-2,4,6-trisilaheptane
$(CH_3)_3Si{\cdot}CH_2{\cdot}Si(CH_3)_2{\cdot}CH_2{\cdot}Si(CH_3)_3$
2,4,6,8,-Tetraoxa-5-carbonsoilane
$SiH_3{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}CH_2{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}SiH_3$
Octaphenyloxacyclopentasilane

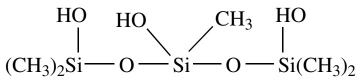


Hydroxy-derivatives in which the hydroxyl groups are attached to a silicon atom are named by adding the suffixes *ol, diol, triol*, etc., to the name of the parent compound. Examples:

Silanol	$H_3Si \cdot OH$
Silanediol	$H_2Si(OH)_2$
Silanetriol	$HSi(OH)_3$
Disilanehexaol	$(HO)_3Si \cdot Si(OH)_3$
Disiloxanol	$H_3Si \cdot O \cdot SiH_2 \cdot OH$
Cyclohexasilanol	$SiH_2 \cdot SiH_2 \cdot SiH \cdot OH$ / $SiH_2 \cdot SiH_2 \cdot SiH_2$

Polyhydroxy-derivatives in which hydroxyl group is attached to a silicon atom are named wherever possible in accordance with the principle of treating like things alike. Example:

1,13,5,5-Pentamethyltrisiloxane-1,3,5-triol



Otherwise they are named in accordance with the principle of the largest parent compound. Example:

2-Hydroxysilyltetrasilane-1,4-dio
$SiH_2 \cdot OH$
|
$HO \cdot SiH_2 \cdot SiH_2 \cdot SiH \cdot SiH_2 \cdot OH$

Substituents other than hydroxyl groups (functional atoms or groups and hydrocarbon radicals) attached to silicon are expressed by appropriate prefixes or suffixes. Examples:

Ethyldisilane
$CH_3 \cdot CH_2 \cdot SiH_2 \cdot SiH_3$
Hexachlorodisiloxane
$Cl_3Si \cdot O \cdot SiCl_3$
Dibutyldichlorosilane
$(CH_3 \cdot CH_2 \cdot CH_2 \cdot CH_2)_2SiCl_2$
Silylamine
$H_3Si \cdot NH_2$
Silanediamine
$H_2Si(NH_2)_2$
Silanetriamine
$HSi(NH_2)_3$
N-Methylsilylamine
$H_3Si \cdot NH \cdot CH_3$
N, *N*-Dimethylsilylamine
$H_3Si \cdot N(CH_3)_2$
N, *N*′-Dimethylsilanediamine
$H_2Si(NH \cdot CH_3)_2$
N, *N*′, *N*″-Trimethylsilanetriamine
$HSi(NH \cdot CH_3)_3$
Acetoxytrimethylsilane
$(CH_3)_3Si \cdot O \cdot OC \cdot CH_3$
Diacetoxydimethylsilane
$(CH_3)_2Si(O \cdot OC \cdot CH_3)_2$

Compounds containing carbon as well as silicon and in which there is a "reactive group" in the carbon-containing portion of the molecule not shared by a silicon atom are named in terms of the organic parent compound wherever feasible. Examples:

α-Trimethylsilylacetanilide
$(CH_3)_3Si \cdot CH_2 \cdot NH \cdot C_6H_5$
1-Trichlorosilylethanol
$Cl_3Si \cdot CH(OH) \cdot CH_3$
2-Trimethylsilylethanol
$(CH_3)_3Si \cdot CH_2 \cdot CH_2OH$
(Hydroxydimethylsilyl)methanol
$(CH_3)_2Si \cdot CH_2OH$
|
OH
α-(Hydroxydimethylsilyl)acetanilide
$(CH_3)_2Si \cdot CH2 \cdot CO \cdot NH \cdot C_6H_3$
|
OH
(Silylmethyl)amine
$H_3Si \cdot CH_2 \cdot NH_2$
But by rules 70.16 and 70.17:
(Methoxymethyl)silanol
$CH_3O \cdot CH_2 \cdot SiH_2 \cdot OH$
N-Methylsilylamine
$H_3Si \cdot NH \cdot CH_3$

Compounds in which metals are combined directly with silicon are, in general, named as derivatives of the metal. Example:

(Triphenylsilyl)lithium
$(C_6H_5)_3SiLi$

However, in exceptional cases, the metal may be named as a substituent. Example:

Sodium *p*-(sodiosilyl)benzoate
p-$NaO_2C \cdot C_6H_4 \cdot SiH_2Na$

Metallic salts of hydroxy-derivatives may be named in the customary manner. Example:

Sodium salt of triphenylsilanol
$(C_6H_5)_3Si \cdot ONa$

ESSENTIALLY NONCHEMICAL PROPERTIES OF SILICON

Were it not for the firm establishment of silicon as an indispensable material for modern electronics, the other exceptionally attractive properties of Si may have been overlooked for many years. Over the past few decades, electronics components manufacturers have mastered the skills required for manufacturing microminiature components, and this experience has given Si a head start for use in other subminiature structures. Si has been recognized as an outstanding material for making micromachined subminiature structures essentially just within the past decade, and it has become one of the key materials in the comparatively new field of *nanotechnology*.

As a mechanical material, silicon is stronger than steel, it does not show mechanical hysteresis, and it is highly sensitive to stress. This combination of properties qualifies Si as an excellent sensor for detecting acceleration, pressure, force, and other variables encountered in processing and manufacturing. One method of measuring fluid flow, for example, traditionally has depended upon sensing pressure differentials, as in the case of an orifice-type flowmeter. Thus, silicon sensors can be used. Silicon accelerometers can employ the same piezoresistive sensing technique used in pressure sensors.

In addition to sensors, Si can be used at the subminiature scale for the production of tiny pipe, nozzles, and valves required by automatic control systems. Thus, the weight and bulk of future control systems may be reduced by several orders of magnitude.

As of the early 1990s, engineers are working at the "edge" of a new kind of robotics—that is, subminiature handling devices that can master the handling requirements of the new nanomanufacturing technology. Such robots would be miniature, fully integrated silicon systems drawing heavily on the technologies of silicon-integrated electronics and micromachining. Semi-intelligent robots could be used in many manufacturing and control tasks. According to some researchers, such robots could have intelligence at the lowest possible system level, thus allowing them to function semiautonomously, with occasional input from a central control system.

Biological Applications of Silicon Technology

H.M. McConnell (Stanford University) and a team of researchers have developed a silicon-based device called a cytosensor (microphysiometer) that can be used to detect and monitor the response of cells to a variety of chemical substances, particularly ligands for specific plasma membrane receptors. As pointed out by McConnell, "The microphysiometer measures the rate of proton excretion from 10^4 to 10^6 cells. The instruments serves two distinct functions. In terms of detecting specific molecules, selected biological cells in this instrument serve as detectors and amplifiers. The microphysiometer can also investigate cell function and biochemistry. A major application of this instrument may prove to be screening for new receptor ligands. In this respect, the instrument appears to offer significant advantages over other techniques." More detail is given in the McConnell reference listed.

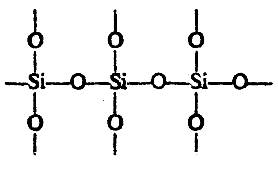
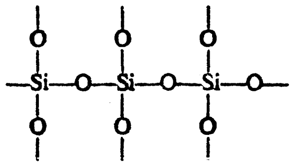
SILICON CHIP (Fabrication). See **Semiconductors**.

SILICONE RESINS. The chemistry of the silicones is based on the hydrides, or silanes, the halides, the esters, and the alkyls or aryls. The silicon oxides are composed of networks of alternate atoms of silicon and oxygen so arranged that each silicon atom is surrounded by four oxygen atoms and each oxygen atom is attached to two independent silicon atoms:



Such a network can be described as a series of spiral silicon-oxygen chains crosslinked with each other by oxygen bonds. If some of the oxygen atoms are replaced with organic substituents, a linear polymer will result:



Taking into consideration the stability of structures involving C−Si bonds, it is evident that the basic chain itself must be comparable in its stability to that of silica and the silicate minerals, and if the R substituents contain no carbon-to-carbon bonds, as for example with methyl groups, the combination should have excellent thermal stability and chemical resistance.

Among the most efficient of silicone monomers in early use as building blocks in the preparation of silicone resins are the halogen alkyl or aryl silanes. Compounds of the type represented by the formula R_2SiCl_2 are capable of undergoing hydrolysis to form long-chain polymers of varying consistencies and viscosities with a predetermined number of molecules of R_3SiCl as chain stoppers. If cross links are desired, tri-functional compounds such as $RSiCl_3$ can be used.

Many silicone resins have been prepared through the use of silazine monomers, that is, compounds with amino groups attached directly to silicon. Di-2-pyridyldichlorosilane has also been described as an intermediate in the preparation of oils, emulsifying agents and resins. Fluorinated aromatic rings are found in many silicone resins. The esterification of dimethylbis-(*p*-carboxylatophenyl)-silane with glycol or glycerol yields thermoplastic materials. Trimethyl-*p*-hydroxyphenylsilane is acceptable as a monomer in resin formation when compounded with hexamethylenetetramine. Trichlorosilane is often a constituent of cohydrolysis monomeric mixtures.

Emulsifying agents have been prepared from quaternary ammonium salts with silicon in the cation. There is a large number of alkyd-silicone resins.

Water-soluble metal salts of alkyltrisilanols are efficient in the reduction of surface tension. A silicone putty is made by compounding a benzene-soluble silicone polymer with silica powder and an inorganic filler.

Chlorinated alkyl or aryl groups are often found in polysiloxane resins. One of the chief advantages of this type of halogenated product lies in its reduced tendency to burn. Whereas diphenyloxosilane polymer burns readily in a flame, the introduction of one, two or three chlorines in each benzene ring progressively reduces this tendency. Physically, these resins appear in many different forms, from horny through sticky-resinous to rubber-like, depending on the conditions of combination and composition.

Some of the most important types of silicone resins, useful as coating preparations, are analogous to the alkyds. Glycerol, for instance, is allowed to react with trialkylethoxysilanes, by which reaction one or more hydroxyls of the glycerol are replaced by R_3SiO. Polysiloxane resins with terminal ethoxyl groups can be used. Synthesis of silicone resins with terminal halogen or hydroxyl is also possible, though generally the halogen disappears in hydrolysis of further processing.

Ethyl silicate (tetraethoxysilane) is often used without modification as a water-repellent material for concrete and masonry in general. All, or nearly all, the ethoxyl groups are hydrolyzed by the moisture of the air to form cross-linked water-repellent polymers. The material is applied in desirable thickness, dissolved in some volatile solvent which soon evaporates. Silicone resins which are partially condensed before application, or even fully condensed, can also be used here. In the latter case, hardness is achieved on evaporation of the solvent. Certain silicone resins are useful as hydrophobic agents for the impregnation of paper and fabrics.

The simplest silicone resins are formed by the almost simultaneous hydrolysis and condensation (by dehydration) of various mixtures of methylchlorosilanes. Ice water often suffices for the first step, but advanced condensation to resinous materials of satisfactory thermosetting properties generally comes about on heating. As far as solvents are concerned, water alone has its disadvantages in that the organic materials are so slightly soluble therein. Mixed solvents are commonly used, generally water with such compounds as dioxane, one of the amyl alcohols, dibutyl ether or even an aromatic hydrocarbon. Warm water hydrolysis of di-*t*-butyldiaminosilane forms noncrystallizable liquids or resinous products, and this resinification can be controlled. Among catalysts for these

condensations may be found ferric chloride, the hydroxyl ion, triethyl borate, stannic chloride and sulfuric acid.

A water-methylene dichloride mixture is satisfactory as a hydrolyzing agent on groups of compounds such as phenyltrichlorosilane, dimethyldichlorosilane and methyltrichlorosilane. The value of higher-boiling ethers lies in their ability to provide higher-boiling reaction systems.

Ferric chloride is sometimes an important constituent of the hydrolyzing mixture. The formation of gels during polymerization can be controlled. Patents are in existence covering the hydrolysis of chlorosilanes by pouring their solutions onto the surface of a swirling solution of the active electrolyte.

Alkaline hydrolysis of dialkyldialkoxysilanes can sometimes be used for the purpose of preparing silicone resins.

Triethyl orthoborate affects polymerization by dehydration, probably reacting with the water which it abstracts, to form boric acid and alcohol. This principle is commonly used. Antimony pentachloride is used on occasion and also sulfuric acid, but there is always danger that the latter will split off an alkyl or an aryl group. Sulfuric acid also sometimes induces equilibration. This *tendency* on the part of the acid *reacts* sometimes with the opposite effect.

Some polysiloxanes are curable with lead monoxide, with a consequent reduction in both curing time and temperature. High-frequency electrical energy vulcanizes in one case at least. Zirconium naphthenate imparts improved resistance to high temperatures. Barium salts are said to prevent "blooming." Sulfur dichloride is also used. Some resins are solidified by pressure vulcanization, using di-*t*-butyl peroxide. Improvements are to be found in lower condensation temperatures and shorter times of treatment.

Viscosity is often regulated by bubbling air through solutions of polysiloxanes or the liquid material itself. In this manner, alkyl side chains are oxidized and oxygen bridges set up between silicon atoms. Obviously, the greater the number of such cross links, other influences constant, the greater will be the viscosity.

Addition of glycerol, phthalic anhydride and "butylated melamine formaldehyde resins" is sometimes found to improve the thermosetting properties of silicone resins. Methylsilyl triacetate has the same effect in certain cases. Some silicone resins can be advantageously modified by the addition of polyvinyl acetyl resins or nitroparaffins.

A solution of cellulose nitrate in butyl acetate, diluted with toluene, can be plasticized with dibutyl phthalate and tetraethoxysilane. After application to glass, the lacquer cannot be stripped from the surface even after soaking in boiling water. It has been stated, however, that tetraethoxysilane sometimes decreases the tensile strength of a lacquer in spite of its effect in increasing adhesive properties. A uniformly lustrous appearance is imparted to compounds containing plasticized ethylcellulose, cellulose fibers and pigment, by applying liquid polymerized alkyl polysiloxanes with an average radical/silicon ratio of between 1185 and 2.20. Several resinous materials are known which contain sulfur connected to carbon but not directly to silicon.

Inorganic fillers include titanium dioxide, "Celite" and zinc oxide. Lithium or lead salts of acetic acid, stearic acid or phenol are sometimes used as fillers. Silica and alumina are also feasible. Trimethyl-β-hydroxyethylammonium bicarbonate has been used as a curing agent.

There are any number of review articles and patents covering the increase in serviceability of paints and varnishes which are admixed with silicone resins. Products suitable for use as plasticizers, paint vehicles, etc., are sometimes prepared from mixtures which include phthalic anhydride. Silicone paints, in general, show high adhesion and permit greater retention of color and tint. Of special importance here is the absence of color in the resin and the freedom from discoloration during baking and curing. At high temperatures, silicone varnishes show much higher electrical resistance than others. Paints admixed with silicone resins generally show increased resistance to alkalies and to the elevated temperatures involved in baking processes.

Treating spinnarets with silicon resins eliminates much of the plugging. Aluminum alkoxides are successful as hardening agents.

Copolymers of adipic acid, glycerol, and 1,3-diacetoxy-methyltetramethyldisiloxane, or similar compound, are sometimes used. The silicon adaptation of the alkyd resin possesses, in general, increased hardness and flexibility. In addition, there is greater stability at higher temperatures. Copolymers can also be prepared using amyldibutoxyboron. Antiknock properties are claimed for this type of product as well as increased heat resistance.

The most important development in the chemistry of silicone resins embodies the preparation of monomeric silanes with at least one alkenyl group attached to silicon. Hydrolyzable groups are also present, so that polymerization can take place in two ways—by the conventional hydrolytic processes followed by condensation and by addition polymerization on the double bond, usually through the catalytic activity of benzoyl peroxide or similar agent. Some of the products find use as textile finishes, lubricating oils, additives or molding compounds. Vinyl and allyl groups are most common, with an occasional methallyl.

Triethylsilyl acrylate can be induced to undergo hydrolysis of the ethoxyl radicals to a desired extent forming linear or cross linked polymers. Addition polymerization will also take place on the double bond of the acrylate radical. More stable monomers result from the use of allyl or vinyl groups instead of acrylates. The latter contain a silicon-oxygen-carbon linkage which is always more or less susceptible to hydrolysis.

Other copolymers of this type with vinyl acetate or vinyl butyral resins have been found satisfactory for use in the lamination of wood, glass and metals. Glass-resin adhesives are also known.

General resistance to external influences constitutes the most outstanding property of silicone resins. Ultimate failure and breakdown is probably attributable, more than do anything else, to eventual oxidation of the radicals.

Among the more recent developments in this field may be mentioned the use of certain silicone resins, particularly those containing vinyl groups, as adhesives. Others find value as woodsealing products. A silicone-glycol copolymer has been reported with curing properties, and alkyd resins are now modified with silicones. Combination epoxide-silicone resins have been investigated. A harder type of silicone resins sometimes results from the processing of monomers containing H or olefinic group attached to silicon. Dental impression materials are coming more to the front from this source as well. Finally, more attention is being devoted to studies of the relation between chemical structure and thermodynamic properties.

Resistance to γ-radiation is especially valuable. "Mouth-tissue-simulating molding compositions" for dentures are on the market. Optical lenses prepared from silicone resins are not affected by hot climates. Mold release agents are still the subject of research, as are resins with long storage capabilities. Coating bananas with silicone resins reduces the possibility of bruising. Heat-transfer compositions must have high molecular weights. In oil wells, a new use has come to the fore in the prevention of sand flow. Transparent resins are still in demand, some of which are porous.

Compounding silicone resins with phenyl formaldehyde or melamine polymers seems to produce good results. Sulfur in the resin makes a product suitable for use as fuel hose, gaskets and gas tanks. Phosphorus is found in silicone resin coatings but the product is liable to be toxic. Titanium is found in waterproof coatings. Tin compositions have low toxicity. Some resins of high viscosity contain Si–O–N units. Crosslinking, however, is not recommended. The tendency to become brittle is ever present although a few instances are known to be contrary.

Howard W. Post
Williamsville, New York

SILLIMANITE. The mineral sillimanite is an aluminum silicate, the formula Al_2SiO_5 being like that of andalusite and kyanite. It is orthorhombic, usually in slender prisms, but may be fibrous or massive. Its hardness is 6.5–7.5; specific gravity, 3.23–3.27; luster, vitreous to silky; color, various shades of gray, grayish-green, and grayish-brown; transparent to translucent. It occurs in granites and gneisses as tiny prisms and aggregates, and is often associated with andalusite, cordierite and corundum. Sillimanite has been found in Bavaria, the Czech Republic and Slovakia, France, India, the Malagasy Republic, Myanmar and Ceylon, the latter two localities furnishing transparent sapphire-blue gem stones. In the United States sillimanite has been found in Connecticut, New York, Pennsylvania, Delaware, North Carolina, and in California, where in Inyo County is the largest deposit in the world. This mineral was named in honor of Benjamin Silliman for many years professor of chemistry and natural science at Yale University. Sillimanite is used in the manufacture of spark plug "porcelains" and laboratory ware.

SILOXANES. See **Silicon**.

SILTHIANES. See **Silicon**.

SILVER. [CAS: 7440-22-4]. Chemical element, symbol Ag (from Latin *argentum*), at. no. 47, at. wt. 107.868 ± 0.003, periodic table group 11, mp 961.93°C, bp approximately 2,212°C, density 10.50 g/cm^3 (20°C). Elemental silver has a face-centered cubic crystal structure.

Silver is a white metal, softer than copper and harder than gold. When molten, silver is luminescent and occludes oxygen, but the oxygen is released upon solidification. As a conductor of heat and electricity, silver is superior to all other metals. Silver is soluble in HNO_3 containing a trace of nitrate; soluble in hot 80% H_2SO_4; insoluble in HCl or acetic acid; tarnished by H_2S, soluble sulfides and many sulfur-containing organic substances (e.g., proteins); not affected by air or H_2O at ordinary temperatures, but at 200°C, a slight film of silver oxide is formed; not affected by alkalis, either in solution or fused. There are two stable, naturally occurring isotopes, ^{107}Ag and ^{109}Ag. In addition, there are reported to be 25 less stable isotopes, ranging in half-life from 5 seconds to 253 days.

In terms of cosmic abundance, the estimate of Harold C. Urey (1952), using silicon as a base with a figure of 10,000, silver was assigned an abundance figure of 0.023. In terms of abundance in sea water, silver is ranked number 43 among the elements, with an estimated content of 1.5 tons per cubic mile (0.324 metric ton per cubic kilometer) of sea water.

Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^1$. First ionization potential is 7.574 eV; second, 21.4 eV; third, 35.9 eV. Oxidation potentials: $Ag \longrightarrow Ag^+ + e^-$, $E^0 = -0.7995$ V; $Ag^+ \longrightarrow Ag^{2+} + e^-$, -1.98 V; $2Ag^+OH^- \longrightarrow Ag_2O + H_2O + 2e^-$, -0.344 V; $Ag_2O + 2OH^- \longrightarrow 2AgO + H_2O + 2e^-$, -0.57 V; $2AgO + 2OH^- \longrightarrow Ag_2O_3 + H_2O + 2e^-$, -0.74 V. Other important physical properties of silver are given under **Chemical Elements**.

Occurrence and Processing

Silver is widely distributed throughout the world. It rarely occurs in native form, but is found in ore bodies as silver chloride, or more frequently, as simple and complex sulfides. In former years, simple silver and gold-silver ores were processed by amalgamation or cyanidation processes. The availability of ores amenable to treatment by these means has declined. Most silver is now obtained as a byproduct or coproduct from base metal ores, particularly those of copper, lead, and zinc. Although these ores are different in mineral complexity and grade, processing is similar.

All the ores are concentrated in complex mills by selective froth flotation to produce individual copper, zinc, lead, and, infrequently, silver concentrates. The copper and lead concentrates are smelted to produce lead and copper bullions from which silver is recovered by electrolytic or fine refining. The silver bearing zinc concentrates are commonly processed by leaching and electrolytic methods. Silver is ultimately recovered as a byproduct from zinc plant residues. Canada is a leading silver mining country. Other important sources of silver are Mexico, the United States, Peru, the former U.S.S.R., and Australia. See also **Mineralogy**.

A substantial portion of the total world silver supply is obtained from recycled scrap. Much of this scrap comes from photographic film, jewelry and the electrical field. The high value of the scrap dictates accurate sampling and careful feed preparation. Efficient and fast processing is required to minimize metal losses and a tie-up of high-value materials. The highly complex nature of plant feed, with respect to physical form, chemical composition, and grade, requires use of complex and highly flexible processing procedures.

Uses of Silver

Silver in the twentieth century can be classified an industrial commodity. For most of the 19th century, silver was a monetary metal. Industrial consumption of silver is principally in photographic film, electrical contacts, batteries and brazing alloys. Sterling silver and silver plated copper alloys are used extensively for tableware and for jewelry and other decorative art. Recently, the field of commemorative and collector arts has become a substantial market for silver alloys, particularly sterling silver.

The predominant place of silver salts as photographic receptors is not the result of any unusual primary sensitivity to illumination, but is due to the fact that they undergo an unusual secondary amplification process called "development." Silver salts, like the salts of many metals, when immersed in solutions of many reducing agents, are changed to metallic silver. The photographic system depends upon the fact that when certain mild reducing agents (called "photographic developers") are chosen, the rate of reduction is increased many fold if the silver salt crystals carry very small amounts of metallic silver at the developer-crystal interface. The effect produced by the original light exposure is amplified in the development process by a factor of 100 billion. Whereas new photographic or recording devices are being developed not involving silver, none yet approach the packing density of a fine-grained image possible using silver. Thus, it appears that silver will be used in photographic recording for many years to come.

Among the electrical uses for silver are electrical contacts, printed circuits, and batteries. By far, the primary use is in electrical contacts where the high electrical and thermal conductivities, as well as corrosion and oxidation resistances, of silver are major reasons for its selection. Although silver has a strong tendency to weld under heavy currents, this is counteracted by alloying or by adding nonmetallic substances (such as cadmium oxide) to the silver matrix. The use of silver-cadmium oxide and silver-tungsten materials in electrical contact applications is widespread. The alloys used to improve the wear resistance and to reduce the sticking tendency of silver include silver-gold, silver-copper, silver-palladium, and silver-platinum. More complex alloys include silver-copper-nickel, silver-magnesium-nickel, silver-gold-cadmium-copper, and silver-cadmium-copper-nickel. Silver-cadmium oxide alloys are unique materials and are prepared either by combining silver and cadmium oxide by powder metal techniques or by the internal oxidation of a silver-cadmium alloy. Electrical alloys, which are impossible to combine by conventional melting, lend themselves to powder metal fabrication. Such composite structures as silver-graphite, silver-iron, and silver-tungsten are good examples of these types of materials.

In silver batteries, the silver oxide-zinc secondary battery has found its place in applications where energy delivered per unit of weight and space is of prime importance. The major disadvantages lie in their high cost and relatively short life. Consequently, a large part of the silver battery market is concerned with defense and space components. See also **Batteries**.

Prior to World War II, consumption of silver in silverware and jewelry was the largest industrial use of silver. Competition from stainless steel in flatware and holloware has contributed to a decline in overall use. Most consumption of silver in silverware and jewelry is in the form of sterling silver, an alloy of silver with approximately 7.5 weight percent copper. Silver plate, which is silver electroplated on a base metal, varies widely in specification. The thickness, expressed for example in penny-weights of pure silver per gross of teaspoons can range from a low of 1 to as high as 200.

In the 1920s and 1930s, low-temperature silver-copper brazing alloys were found to be useful on copper and its alloys and iron and its alloys (including stainless steel). Silver and copper form a simple eutectic system with limited solid solubility. This system can absorb elements such as zinc, cadmium, tin, and indium. These additions lower its melting temperature. It also can absorb higher melting elements such as nickel or palladium. These raise its melting temperature, but may improve its wetting characteristics, corrosion resistance, and strength at elevated temperatures. Silver solders or brazing alloys have the ability of making joints far stronger and more durable than common soft-solder (such as lead-tin) alloys. They are used in most refrigeration systems to join copper tubing. Also, extensive use is found in the assembly of automotive parts, military components, aircraft assemblies, and other hard goods manufacture. The nominal composition of a popular brazing alloy, ASTM Classification BAg-1 is silver 45%, copper-15%, zinc-16%, cadmium-24%.

One silver alloy containing about 70% silver, 26% tin, 3% copper, and 1% zinc is unique in that it is used extensively by dentists in combination with mercury to fill cavities in teeth. The "amalgam" manufacturers supply dentists with the alloy in the form of powder (filed, or more recently, atomized). This is mixed with mercury, using from 8 to 5 parts of mercury to 5 of alloy, and the cavity is packed. In the cavity, a metallurgical reaction takes place in which the silver-tin compound in the alloy becomes a durable silver-tin-mercury compound.

Silver, its oxides, halides and other salts play important roles in chemistry. Silver is an excellent catalyst in oxidizing reactions such as in the production of formaldehyde from methanol and oxygen, ethylene oxide from ethylene and oxygen, and glyoxal from ethylene glycol and oxygen. Silver has oligodynamic properties, that is, the ability of minute amounts of silver in solution to kill bacteria. Modern technology has made use of this property in various ways, mainly as a means of purifying water.

Small amounts of silver are used annually in such diverse applications as a backing for mirrors, and in control rods for pressurized water nuclear reactors. Miscellaneous uses like this account for only a small fraction of total silver consumption.

Chemistry of Silver

Silver(I) oxide, [CAS: 20667-12-3], Ag_2O, is made by action of oxygen under pressure on silver at 300°C, or by precipitation of a silver salt with carbonate-free alkali metal hydroxide; it is covalent, each silver atom (in solid Ag_2O) having two collinear bonds and each oxygen atom four tetrahedral ones; two such interpenetrating lattices constitute the structure. Silver(I) oxide is the normal oxide of silver. Silver(II) oxide, AgO, is formed when ozone reacts with silver, and thus was once considered to be a peroxide. Silver(III) oxide, Ag_2O_3, has been obtained in impure state by anodic oxidation of silver.

All of the silver(I) halides of the four common halogens are well known. The fluoride may be prepared from the elements, the chloride by action of hydrogen chloride gas at 150°C, upon silver, and the bromide and iodide by ionic reactions in solution. The chloride, bromide, and iodide are essentially insoluble in H_2O, but the fluoride is soluble. There is also a subfluoride, Ag_2F, which may be prepared as a cathodic deposit by electrolysis of silver(I) fluoride AgF, or by evaporation of finely divided silver with silver(I) fluoride in dilute hydrofluoric acid. It is an anisotropically conducting solid and is considered to be made up in the solid state of two silver layers, metallic-bonded to each other, and ionic-covalent bonded to a single fluorine layer. It has reverse cadmium iodide structure. Silver subchloride, Ag_2Cl is made by reaction of Ag_2F and phosphorus trichloride. Silver(II) fluoride, AgF_2, made by action of fluorine upon a silver(I) halide, is a fluorinating agent or catalyst for fluorinations. The silver(I) halides vary markedly in ionicity, the values given by Pauling being AgF 70%, AgCl 30%, AgBr 23% and AgI 11%. This is reflected in their crystal structures and in their solubility in water (or rather, their relative insolubility). The first three have sodium chloride structure, AgI has wurtzite structure; AgF has a molal solubility of 14, and the pK_{sp} values of the others are 9.75, 12.27 and 16.08, respectively.

Silver differs markedly from copper in forming few oxy compounds. One of these is silver oxynitrate or silver(II, III) nitrate which has the empirical formula $AgO_{1.148}(NO_3)_{0.453}$, in which the average oxidation number of silver is 2.448. It is prepared by action of fluorine upon aqueous silver nitrate or is obtained as an anodic deposit by electrolysis of silver nitrate in dilute HNO_3.

Silver enters into complex formation with many ions and molecules. With halogens, the silver complexes are fewer than the copper ones. Silver chloride dissolves in HCl with the formation of such chloroargentate ions as $(AgCl_2)^-$, $(AgCl_3)^{2-}$, and possibly $(AgCl_4)^{3-}$. Complex ions with bromide, $(AgBr_2)^-$ and $(AgBr_3)^{2-}$ are more stable, as are those with iodide, than those with chloride. Complexes of the type Ag_2Cl^+, Ag_3Cl^{2+}, Ag_2Br^+, Ag_3Br^{2+}, Ag_4Br^{3+}, $Ag_2Br_6{}^{2-}$, Ag_2I^+, Ag_3I^{2+}, Ag_4I^{3+}, $Ag_2I_6{}^{4-}$, $Ag_2I_7{}^{5-}$ and $Ag_3I_8{}^{5-}$ are also known. With ammonia the ions $(Ag(NH_3)_2)^+$ and $(Ag(NH_3)_3)^+$ are definitely known and others may exist. Similar complexes are formed with amines and diamines. With cyanides, silver forms very stable complexes, the number of CN−ions in the complex depending somewhat upon the excess of cyanide, so that $(Ag(CN)_2)^-$, $(Ag(CN)_3)^{2-}$, and $(Ag(CN)_4)^{3-}$ are definitely known. With thiosulfates, silver forms various complexes. In dilute solution, $(Ag_2(S_2O_3)_2)^{2-}$ exists, while in high concentration of $S_2O_3{}^{2-}$ ion, the complex $(Ag_2(S_2O_3)_6)^{10-}$ has been identified. In HNO_3 solution Ag^+ is easily oxidized to Ag^{2+} by peroxydisulfate. From this solution complex compounds of dipositive silver can be prepared, which are stable because coordination radically alters the oxidation potential of Ag(I) to Ag(II). They include pyridine complexes such as $(Ag(py)_4) \times (NO_3)_2$. 8-Hydroxyquinoline complexes containing the ions $(Ag(oxin)_2)^{2+}$, and o-phenanthroline complexes containing the ion $(Ag(o\text{-}phen)_2)^{2+}$. Silver(III) is known in the square, planar complex $AgF_4{}^-$, which has been prepared as $KAgF_4$ by direct fluorination of a mixture of potassium chloride and silver chloride. Silver(III), like Cu(III), also occurs in tellurate and periodate complexes.

Other silver compounds include: Silver chromate [CAS: 7784-01-2] (Ag_2CrO_4), yellow to red to brown precipitate by reaction of silver nitrate solution and potassium chromate solution.

Silver dichromate ($Ag_2Cr_2O_7$), red precipitate by reaction of silver nitrate solution and potassium dichromate solution, changing to silver chromate upon boiling with H_2O.

Silver phosphate (Ag_3PO_4), [CAS: 7784-09-0] yellow precipitate, by reaction of silver nitrate solution and disodium hydrogen phosphate solution, soluble in HNO_3 and in NH_4OH, turns dark on exposure to light.

Silver sulfate [CAS: 10294-26-5] (Ag_2SO_4), white precipitate, by the action of silver nitrate solution and potassium sodium or ammonium sulfate solution or H_2SO_4, mp of silver sulfate 652°C.

Silver sulfide [CAS: 21548-73-2] (Ag_2S), black precipitate, by the reaction of silver nitrate solution and hydrogen sulfide.

Silver forms several compounds or complexes with proteins by the action of silver oxide with gelatin in alkali solution, or with albumin, or by suspension in casein solution and by other methods. Such silver-protein complexes containing from 19 to 23% of silver are known as "mild silver protein" and are used as antiseptic solutions. They are readily soluble in H_2O.

SIMPLE DISTILLATION. Distillation in which no appreciable rectification of the vapor occurs, i.e., the vapor formed from the liquid in the still is completely condensed in the distillate receiver and does not undergo change in composition due to partial condensation or contact with previously condensed vapor.

SIZING COMPOUND. 1. A material such as starch, gelatin, casein, gums, oils, waxes, asphalt emulsions, silicones, rosin, and water-soluble polymers applied to yarns, fabrics, paper, leather, and other products to improve or increase their stillness, strength, smoothness, or weight.

2. A material used to modify the cooked starch solutions applied to warp ends prior to weaving.

SKUTTERUDITE. This mineral includes an isomorphous series with *smaltite-chloanthite*, essentially cobalt/nickel arsenides, (Co, Ni) As_{2-3}, crystallizing in the isometric system. The usual habit is cubic, octahedral, or cubo-octahedral. The mineral also occurs in massive and granular forms. Skutterudite has a metallic luster; hardness of 5.5 to 6.0, a specific gravity of 6.5. The mineral is opaque with tin-white to silver-gray color. The nickel-rich material alters surficially to annabergite (green color); the cobalt-rich material to erythyrite (rose color). The streak is black. The mineral is an essential ore of cobalt and nickel.

Skutterudite is found in moderate-temperature veins, commonly associated with other cobalt/nickel minerals, e.g., cobaltite and nickeline. The mineral was named for its occurrence at Skutterud, Norway. Important ore sources are Norway, Bohemia, Saxony, Spain, France, and New South Wales, Australia. Notable occurrences are in Ontario, Canada, mainly Sudbury, South Lorrain, and Gowganda.

SLACK. 1. Descriptive of a soft paraffin was resulting from the incomplete pressing of the settlings from the petroleum distillate. Though it has some applications in this form, it is actually an intermediate product between the liquid distillate and the scale wax made by expressing more of the oil.

2. Specifically, to react calcium oxide (lime) with water to form calcium hydroxide (slaked or hydrated lime), the reaction is $CaO + H_2O \longrightarrow Ca(OH)_2 + \text{heat}$. The alternate spelling "slake" has the same meaning.

SLAG. Slag is a fused product occurring in connection with metallurgical and combustion processes. It is composed of the oxidized impurities in a metal, and of a fluxing substance, and of ash. In the steel industry, slag is the neutralized product of anhydrous compounds entering into the process. Slag is of great importance to the operator of a steel furnace or a cupola, in that, through the slag, impurities are separated and removed from the metal. By floating as a molten covering on the pool of metal, slag protects it from oxidation and serves to keep it clean. By controlling the character of slag, and continuous observation, the metallurgist insures that the metal is of the quality desired.

Molten ash is one of the products of combustion of coal in certain high-capacity boiler furnaces. It is also called slag. In some plants, the ash is removed from the furnace in this fluid form. Such furnaces are known as slag tap furnaces. Slag has some commercial value as ballast, coarse aggregate for concrete, road metal, etc.

SLATE. A fine-grained homogeneous sedimentary rock composed of clay or volcanic ash which has been metamorphosed (foliated) so as to develop a high degree of fissility or salty cleavage which is usually at a high angle to the planes of stratification. This high degree of fissility makes the better grades of slates an extremely useful roofing material which, however, has been somewhat replaced in recent years by synthetic and manufactured substitutes. The finest slates in the world come from Wales, Britain.

SLUDGE. When fresh sewage is admitted to settling tanks a certain amount of the solid matter in suspension will settle out, 50% more or less for sedimentation periods of an hour and a half or so. This collection of solids is known as fresh sludge. Such sludge will become actively putrescent in a short time and in modern treatment plants must be passed on from the sedimentation tank before this stage is reached. This may be done in two common ways. The fresh sludge may be passed through the slot in an Imhoff tank to the lower story or digestion chamber. Here, decomposition by anaerobic bacteria takes place with considerable liquefaction and reduction in volume. After the decomposition process has run its course (in 6–9 months) the resulting sludge is called "digested" sludge and is relatively inoffensive in character. It may be disposed of by drying on sludge drying beds and spreading on the land. It has little, if any, fertilizing value, being in the nature of humus. The sludge digestion chamber is operated on a periodic schedule of sludge withdrawals.

Alternatively, plain sedimentation basins with mechanical equipment for continuous collection of the fresh sludge may be used. The fresh sludge, so collected, is discharged into separate sludge digestion tanks which operate on the principle of the lower story of the Imhoff tank except that by means of higher and better temperature control the digestion cycle is much more rapid and efficient than for the Imhoff tank.

SMALLEY, RICHARD E. (1943–). An American who won the Nobel prize for chemistry along with Robert. F. Curl, Jr. and Sir Harold W. Kroto in 1996, the 100^{th} anniversary of Alfred Nobel's death. The trio won for the discovery of the C_{60} compound called buckminsterfullerene. He graduated from the University of Michigan and earned a Ph.D. from Princeton University.

See also **Buckminsterfullerene (Buckyballs)**.

SMART MATERIALS. From a technical and simple point of view, a smart material is a material that responds to its environment in a timely manner. To expand on this definition, a smart material is one that receives, transmits, or processes a stimulus and responds by producing a useful effect, which may include a signal that the material is acting upon it. Stimuli may include strain, stress, temperature, chemicals, an electric field, a magnetic field, hydrostatic pressures, different types of radiation, and other forms of stimuli. Transmission or processing of the stimulus may be in the form of an absorption of a photon, of a chemical reaction, of an integration of a series of events, of a translation or rotation of segments within the molecular structure, of a creation and motion of crystallographic defects or other localized conformations, of an alteration of localized stress and strain fields, and of others. The useful effects produced could be a change in color, index of refraction, stress or strain distribution, or volume. Also, incorporated within the definition of smart materials is the ability to be reversible.

Under the proper set of environments and circumstances all materials are smart and depict smart behavior at some point during their life cycle. Some examples of technically smart behaving materials are piezoelectric materials, electrostrictive materials, magnetostrictive materials, electrorheological materials, magnetorheological materials, thermoresponsive materials, pH-sensitive materials, uv-sensitive materials, smart polymers, smart gels (hydrogels), smart catalysts, and shape memory alloys.

Smart structures are structures that incorporate at least one smart material within itself and from the effort produced by the smart material causes an action.

Piezoelectric Materials

Piezoelectric materials are materials that exhibit a linear relationship between electric and mechanical variables. The direct piezoelectric effect can be described as the ability of materials to convert mechanical stress into an electric field; and the reverse, to convert an electric field into a mechanical stress. The use of the piezoelectric effect in sensors is based upon the latter property.

There are two principal types of materials that can function as piezoelectrics: the ceramics and polymers. The piezoelectric materials most widely used are the piezoceramics based upon the lead zirconate titanate, PZT. The advantages of these piezoceramics are that they have a high piezoelectric activity and they can be fabricated in many different shapes.

A newer class of materials called smart tagged composites has been developed for structural health monitoring applications. These composites consist of PZT-5A particles embedded into the matrix resin (unsaturated polyester) of the composite.

Electrostrictive Materials

Electrostrictive materials are materials that exhibit a quadratic relationship between mechanical stress and the square of the electric polarization. Electrostriction can occur in any material. Whenever an electric field is applied, the induced charges attract each other, thus, causing a compressive force. This attraction is independent of the sign of the electric field. Typical electrostrictive materials include such compounds as lead manganese niobate, lead titanate (PMN:PT), and lead lanthanium zirconate titanate (PLZT).

Magnetostrictive Materials

As materials show mechanical deformation induced by electric fields, the same type of material response can be observed when the stimulus is a magnetic field. Shape changes are the largest in ferromagnetic and ferrimagnetic solids. The repositioning of domain walls that occur when these solids are placed in a magnetic field leads to hysteresis between magnetization and an applied magnetic field.

Materials that have shown a response to magnetic stimuli have primarily been inorganic in chemical composition, alloys of iron, nickel, and cobalt doped with rare earths. However, there has been a great interest in the development of organic and organometallic magnets.

In comparing organic magnets with organometallic magnets there are several key differences between the two types. The first is that the organic-based magnets do not contain metal atoms. The second difference involves the fact that in organic-based magnets, the coupled spins residue entirely in the p orbitals; whereas in the organometallic-based magnets, they are either in the p or d orbitals, or a combination of the two.

Electrorheological Materials

Electrorheological materials are fluids whose viscous properties are modified by applying an electric field. There are many electrorheological fluids, which are usually a uniform dispersion or suspension of particles within a fluid. In an applied electric field the particles orient themselves in fiberlike structures (fibrils). When the electric field is off, the fibrils disorient themselves. The damping characteristics of the system can be changed (flexible to rigid). Electrorheological fluids are non-Newtonian fluids, that is, the relationship between shear stress and shear strain rate

is nonlinear. The changes in viscous properties of electrorheological fluids are obtained only at relatively high electric fields in the order of 1 kV/mm.

Magnetorheological Materials

Magnetorheological materials (fluids) are the magnetic equivalent of electrorheological fluids. In this case, the particles are either ferromagnetic or ferrimagnetic solids that are either dispersed or suspended within a liquid and the applied field is magnetic.

An adaptation of magnetorheological fluids is a series of elastomeric matrix composites embedded with magnetic particles such as iron. During the thermal cure of the elastomer, a strong magnetic field was applied to align the iron particles into chains. These chains of iron particles were locked into place within the composite through the cross-linked structure of the cured elastomer. The resistance of the composite to changes in modulus or deformation was controlled by an external magnetic field. When stimulated by a compressive force, the composite was 60% more resistant to deformation in a magnetic field.

Thermoresponsive Materials

Polymeric materials are unique because of the presence of a glass-transition temperature. At the glass-transition temperatures, the specific volume of the material and its rate of change changes, thus, affecting a multitude of physical properties.

Materials that typify thermoresponsive behavior are polyethylene–poly-(ethylene glycol) copolymers that are used to functionalize the surfaces of polyethylene films (smart surfaces). When the copolymer is immersed in water, the poly(ethylene glycol) functionalities at the surfaces have solvation behavior similar to poly(ethylene glycol) itself. The ability to design a smart surface in these cases is based on the observed behavior of inverse temperature-dependent solubility of poly(alkene oxide)s in water.

pH-Sensitive Materials

By far the most widely known classes of pH-sensitive materials are those classes of chemical compounds that include the acids, bases, and indicators. The most interesting of these are the indicators. These materials change colors as a function of pH and usually are totally reversible.

In addition to acting as a means of observing changes in pH in titrations and in chemical reactions, indicators have been used in the development of novel chemical indicating devices.

Other examples of pH-sensitive materials are the smart hydrogels and smart polymers.

Light-Sensitive Materials

There are several different types of material families that exhibit different kinds of responses to a light stimuli. One type comprises materials that exhibit electrochromism. This is a change in color as a function of an electrical field. Other types of behaviors include thermochromism (color change with heat), photochromic material (reversible light-sensitive materials), photographic materials (irreversible light-sensitive materials), and photostrictive materials (shape changes due to light usually caused by changes in electronic structure).

Smart Polymers

Even though smart polymers have been used in all types of applications and can exhibit all types of stimuli–response behaviors, the term, smart polymers, has been used as a separate category of smart materials. In medicine and biotechnology, smart polymer systems usually involve aqueous polymer solutions, interfaces, and hydrogels. These are polymeric systems that are capable of responding strongly to slight changes in the external medium; a first-order transition accompanied by a sharp decrease in the specific volume of the system. The presence of a poor solvent is one of the main conditions for this phenomenon in swollen polymer networks or linear polymers to occur. A poor solvent causes the forces of attraction between the polymer chain segments to overcome the repulsion forces associated with the extended volume, thus, leading to the collapse of the polymer chain.

Smart polymers can respond to environmental stimuli such as temperature, pH, ions, solvents, reactants, light or uv radiation stress, recognition, electric fields, and magnetic fields. These stimuli once acted upon, result in changes in phases, shape, optics, mechanics, electric fields, surface energies, recognition, reaction rates, and permeation rates. The polymers that fit into this category include the naturally occurring polymers, acrylic polymers and copolymers, and polymers based on combining acid monomers with basic monomers.

Smart Gels (Hydrogels)

Smart (intelligent) gels (or hydrogels) are not new. They are finally reaching commercialization after thirty years of research and development. The concept of smart gels is also more complex than the simple concept of solvent-swollen polymer networks. It is the behavior of the solvent-swollen polymer networks in conjunction with the material being able to respond to other types of stimuli; such as temperature, pH, and concentrations of solvents. An example of a smart gel chemical composition consists of an entangled network of two polymers; one is a poly(acrylic acid) (PAA), and the second, a tri-block copolymer containing poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO) in a PEO–PPO–PEO sequence. The PPA portion of the smart gel system is a bioadhesive and is pH responsive. The PPO segments are hydrophobic that help solubilize lipophilic substances in medical applications, and the PPO segments tend to aggregate, thus resulting in gelation at body temperatures.

Smart Catalysts

One class of smart catalysts is based on homogeneous rhodium-based poly(alkene oxide)s, in particular those with a poly(ethylene oxide) backbone. Traditionally chemical catalyzed reactions proceed in a manner in which the catalysts become more soluble and active as the temperature is raised. This can lead to exothermal runaways, thus, posing both safety and yield problems. The behavior of these smart catalysts is different from that of traditional catalysts. As the temperature increases, they become less soluble, thus precipitating out of solution and becoming inactive. As the reaction mixture cools down, a smart catalyst redissolves and becomes active again.

Smart Memory Alloys

Shape-memory alloys undergo thermomechanical changes as they pass from one phase to another. The crystalline structure of such alloys based on nickel and titanium enters the martensitic phase as the alloy is cooled below a critical temperature. In this stage, the alloy is easily manipulated through large strains with a little change in stress. As the temperature of the alloy is increased above the critical (transformation) temperature it changes into the austentic phase. In the austentic phase, the alloy regains its high strength and high modulus. It behaves like a “normal” metal. The alloy shrinks during the transformation from the martensitic to austentic phase.

The use of shape-memory alloys as actuators depends on their use in the plastic martensitic phase that has been constrained within the structural device. Shape-memory alloys (SMAs) can be divided into three functional groups; one-way SMAs, two-way SMAs, and magnetically controlled SMAs. The magnetically controlled SMAs show great potential as actuator materials for smart structures because they could provide rapid strokes with large amplitudes under precise control. The most extensively used conventional shape-memory alloys are the nickel–titanium- and copper-based alloys (see **Shape-Memory Alloys**).

Elastorestrictive Materials

This class of smart materials is the mechanical equivalent of electrostrictive and magnetostrictive materials. Elastorestrictive materials exhibit high hysteresis between strain and stress. This hysteresis can be caused by motion of ferroelastic domain walls. This behavior is more complicated and complex near a martensitic phase transformation.

Materials with Unusual Behaviors or Unusual Materials

Only a few materials fit into this category; they seldom can be categorized into one of the above material classes. Water fits into the category of materials with unusual behavior. Water is one of the few materials that expands upon freezing. It changes volume by approximately 8% transiting from the liquid to the solid state.

Fullerene and its derivatives can be included in the unusual material category. One interesting application of fullerenes as smart materials has been in the area of embedding fullerenes into sol–gel matrices for the purpose of enhancing optical limiting properties. A semiconducting material with a magnetic ordering at 16.1 K was produced from the reaction of the fullerene C_{60} with tetra(dimethylamino)ethylene.

SMECTIC LIQUID CRYSTALS. See **Liquid Crystals**.

SMELTING. The process of heating ores to a high temperature in the presence of a reducing agent, such as carbon (coke), and of a fluxing agent to remove the accompanying rock gangue is termed smelting. Iron ore is the most abundantly smelted ore. It contains about 20% gangue (clay and sand). The ore is heated in an air blast furnace with coke and limestone (fluxing agent) at a temperature above the melting point of iron and slag (fusion mixture of impurities and flux). The molten iron (the more dense material) and molten slag (the less dense material) are removed separately from the furnace. See also **Arsenic**; **Cadmium**; **Cobalt**; **Copper**; **Indium**; **Iron Metals, Alloys, and Steels**; **Lead**; **Silver**; and **Tin**.

SMITHSONITE. Smithsonite is zinc carbonate, $ZnCO_3$, a hexagonal mineral with a rhombohedral cleavage. It is a brittle mineral; hardness, 4–4.5; specific gravity, 4.3–4.5; luster, vitreous to dull; color, usually white, but may be colored yellowish or brownish or perhaps blue or green due to impurities. It is translucent to opaque. Smithsonite is a secondary mineral after sphalerite or may replace limestone or dolomite. It is sometimes called calamine (but true calamine is a zinc silicate) and often associated with it. Smithsonite occurs in Siberia, Greece, Rumania, Austria, Sardinia, Cumberland and Derbyshire, England; New South Wales, Australia; South West Africa, and Mexico. In the United States, it is found in Pennsylvania, Wisconsin, Missouri, Arkansas, and Utah. This mineral was named in honor of James Smithson, whose legacy founded the Smithsonian Institution at Washington, DC.

SMOG. A coined word denoting a persistent combination of smoke and fog occurring under appropriate meteorological conditions in large metropolitan or heavy industrial areas. The discomfort and danger of smog is increased by the action of sunlight on the combustion products in the air, especially sulfur dioxide, nitric oxide, and exhaust gases (photochemical smog). Strongly irritant and even toxic substances may be present e.g., peroxybenzoyl nitrate. Fatalities have resulted from exposure from exposure to particularly severe photochemical smogs.

See also **Pollution (Air)**.

SMOKE. A colloidal or microscopic dispersion of a solid in gas, and aerosol. (1) Coal smoke: A suspension of carbon particles in hydrocarbon gases or in air, generated by combustion. The larger particles can be removed by electrostatic precipitation in the stack (Cottrell). Dark color, nauseating odor.

See also **Cottrell, Frederick G. (1877–1948)**; **Pollution (Air)**; and **Smog**.

(2) Wood smoke: Light-colored particles of cellulose ash, pleasant aromatic odor. Smoke from special kinds of wood (e.g., hickory, maple) is used to cure ham, fish, etc., also to preserve crude rubber.

(3) Chemical smoke: Generated by chemical means for military purposes (concealment, signaling, etc.).

(4) Metallic smoke (fume): An emanation from heated metals or metallic ores, the particles being of specific geometric shapes. Such smoke is particularly damaging to vegetation in the neighborhood of zinc and tin smelters.

(5) Cigarette smoke: There is conclusive evidence that the tars occurring in cigarette smoke can lead to lung cancer; chief factors are age of individual at initiation of smoking, extent of inhalation, an amount smoked per day. Polonium, a radioactive element, is known to occur in cigarette smoke; more than 100 compounds have been identified including nicotine, cresol, carbon monoxide, pyridene, and benzopyrene, the latter a carcinogen.

SMOKELESS POWDER. Nitrocellulose containing about 13.1% nitrogen, produced by blending material of somewhat lower (12.6%) and slightly higher (13.2%) nitrogen content, converting to a dough with alcohol-ether mixture, extruding, cutting, and drying to a hard, horny product. Small amounts of stabilizers (amines) and plasticizers are usually present, as well as various modifying agents (nitrotoluene, nitroglycerin salts).

SNG. See **Substitute Natural Gas (SNG)**.

SOAPS. Chemically, a soap is defined as any salt of a fatty acid containing 8 or more carbon atoms. Structurally a soap consists of a hydrophilic (water compatible) carboxylic acid which is attached to a hydrophobic (water repellent) hydrocarbon. Soap molecules thus combine two types of behavior in one structure; part of the molecule is attracted to water and the other part is attracted to oil. This feature underlies the function of these materials as surface active agents, or surfactants. Soaps are one class of surfactants. The other classes generally are called detergents. See also **Colloid Systems** and **Detergents**.

All surfactants, including soaps, demonstrate a common physical property—when they dissolve they preferentially concentrate at solution surfaces. These surfaces are known as the *interfacial regions* or regions where one continuous phase, such as water, stops and another, such as oil, begins. By their presence at the interface, surfactants lower the total energy associated with maintaining that boundary and thereby stabilize it. Without surfactants, a mixture of oil and water will soon separate into two distinct phases where the total surface area across which water and oil contact each other will be minimal. Adding soap to the water reduces its surface tension—the energy needed to maintain contact between the oil and the water. The oil then can be broken into microscopic droplets, which are dispersed in the water. Creation of these droplets, however, is accompanied by a huge increase in the interfacial contact area between oil and water. The dispersion of the oil in water is only possible, and only can be maintained over a period of time, because the surfactant reduces the energy associated with the large surface over which oil and water are in contact with each other. This phenomenon is the basis for the cleansing action of soaps and other detergents. Stabilization of the interface between the water used to cleanse and oils and other water-insoluble soils facilitates the dispersion of these materials into the water.

Although soaps and synthetic detergents have similar physical properties, several factors distinguish between them. Soap is generally made from natural fats and oils (oleochemicals). Some important synthetic detergents are also derived from oleochemicals, but almost no ordinary soaps are produced from petrochemicals. Fats and oils are triglycerides which contain three fatty acids, the basic structural unit of soaps, chemically linked to a glycerine backbone. As the "soap" chemical structure basically exists in natural triglycerides, with relatively straightforward processing operations, soap can be obtained from fats and oils.

Another important distinguishing feature of soaps is that they form a curdy, insoluble compound in hard water due to interaction between the carboxylate soap structure and calcium and magnesium ions in the water. Synthetic detergents, which generally are based on sulfate or sulfonate chemical structures for the water-attracting portion of the molecule, have less affinity for these metals and thus work well in all types of water. In addition, since these synthetics maintain their surfactancy, they also function to disperse objectionable curd. For these reasons, the synthetic detergents have generally replaced soaps in heavy-duty cleaning (laundry, floors, woodwork). Soaps, however, remain popular for mild cleaning and particularly for personal cleansing.

Personal Cleansing Soap Products

The major soap-based products which one commonly encounters are soap bars. Two broad categories of bar soaps may be defined: *basic cleaning bars*, which are natural soaps without extra ingredients and comprise about 20% of the market; and bars with special ingredients to provide a benefit beyond fundamental cleansing. The latter category may be further subdivided into *deodorant soaps* and *skin care bars*. Generally most of these bars command a higher retail price than basic cleaning bars, with skin care bars priced above deodorant soaps.

Deodorant soaps add fragrances that are partially substantive to the skin and that mask body odors, and antimicrobial agents. The antimicrobials, such as *Triclocarban*®, are deposited on the skin and inhibit bacterial growth and associated malodors.

Skin care bars are formulated with ingredients for which specific skin benefits are claimed. Consumers generally recognize and are concerned that personal cleansing products can dry the skin, leaving it feeling rough, itchy, and tight, and looking powdery and scaly. To counter these effects, particularly during the dry winter months, they may elect to use a cleansing bar containing a moisturizer, as well as increasing their use of body oils and hand and body lotions. Skin care claims for these products are based on the inclusion of moisturizers such as glycerin, cocoa butter, lanolin, cold cream and vitamins to the soap.

The mildness of soap bars toward the skin can also be enhanced by the process of *superfatting*. In superfatting, excess fatty acid is added to the soap during processing. This water-insoluble material functions as an emollient, significantly improving the mildness and the lathering of the bar.

Manufacture of Soap

Ingredients. The primary materials used in the manufacture of bar soaps are natural fats and oils. The performance and physical properties of soap bars can be varied by altering the blend of fats and oils used to make the neat soap. The most common materials used are top-quality animal tallows and coconut oil with blends ranging from 50% to 85% tallow. Generally it is found that bars containing higher proportions of coconut soap are physically harder, more brittle, lather more, and are more expensive to produce due to the higher cost of coconut oil. It is therefore common practice to vary the blend of tallows and coconut oil to meet the desired properties and price of each product.

These basic materials eventually are converted to their neutral salts by use of some alkaline material, such as sodium hydroxide. Additional, minor ingredients are added, e.g. sodium silicate or magnesium sulfate, to control alkalinity, odor, and aging stability.

The basic process is that of reacting fat stocks with alkali to form soap (direct saponification) and glycerin, followed by washing to remove the glycerin. Two methods of direct saponification are in common use (*kettle method* and *continuous saponification*). An alternative method is splitting fat stocks with water (hydrolysis) to form fatty acids and glycerine, followed by neutralization of the fatty acids with alkali.

Kettle Method. The pioneers used a simplified kettle process when they boiled animal fat and wood ashes (for alkalinity) for several hours in a large pot. The modern soap kettle has a capacity of 60,000–300,000 pounds (27,216–136,080 kg) and is equipped for heating, settling, and blending the fats, alkali, salt, and water.

The kettle first is charged with fat and a sodium hydroxide solution. Then follows a sequence of heating, separating, and washing to convert the raw materials to *finished base soap* and to separate the impurities and byproducts. The process normally takes several days for any single kettle. Although there have been improvements in handling and purification such as continuous centrifugation, the basic kettle process of saponifying fats directly with caustic remains unchanged.

Continuous Saponification. Fat stocks, plus caustic and salt solutions, are fed continuously into an autoclave operating under pressure at typically about 250°F (120°C). A recycle stream provides sufficient soap concentration to solubilize the fat stream for good contacting with the caustic. The soap-lye-glycerin mix moves to a mixer/cooler to complete saponification. The cooler temperature reduces the solubility of soap in the lye and aids separation. See also **Saponification**.

Glycerin and excess caustic are removed by several stages of countercurrent washing with fresh washing solution. The washing and separation stages usually take the form of a series of mixers and centrifugal separators or a continuous countercurrent contactor, such as a rotating disk contractor (RDC) in a vertical column. The mix from the saponifier is fed near the bottom of the RDC and washing solution near the top. The lower-density soap rises through the falling wash solution. Washed soap exits at the top while spent lye (glycerin plus lye solution) exits out the bottom of the RDC column. Spent lye is processed to recover the glycerin.

The washed soap is converted to finished base soap (neat soap) by a final composition adjustment called *fitting*. Fitting is accomplished by adding water (plus salt as needed), which causes a phase separation. Depending on the salt concentration the separated phase is either a lye or niger phase. A centrifuge or kettles can be used to separate the two phases.

Hydrolyzer Process. The development of continuous hydrolysis provides basic improvements in the processing of fats into soap. There are several advantages over the kettle process: (1) better quality soaps can be made from darker fats; (2) glycerin recovery is simplified, because no salt is needed and the resulting finished glycerin is of higher quality; (3) a single hydrolyzer unit produces about the same quantity of soap as 10 kettles, thus effecting savings in manufacturing space and a reduction of in-process inventory; and (4) greater flexibility is possible in controlling the chemical and physical properties of the finished soap. The hydrolyzing process consists essentially of (1) hydrolysis, (2) fatty acid distillation, (3) post-hardening (optional), (4) neutralization, and (5) glycerin recovery. The basic hydrolyzing process is shown in Fig. 1.

Hydrolysis. Development of continuous hydrolyzing was the key step toward this continuous soap making process. In this reaction, fat and water react to form fatty acid and glycerin:

$$(RCOO)_3C_3H_5O + H_2O \rightleftharpoons 3RCOOH + C_3H_5(OH)_3$$

where R is an alkyl of C_8 or larger. This equation represents the complete hydrolysis. Actually, the reaction takes place in a stepwise fashion, forming intermediate diglyceride and monoglyceride.

The reaction can be accomplished only through intimate contact between water and fat molecules. High temperature makes it possible to dissolve an appreciable quantity of water in the fat phase and to obtain this intimate contact. At room temperature, water and fat are essentially insoluble. At elevated temperature, the solubility of water increases to 12–25%, depending upon the type of fat. At the higher temperatures, high pressures also are necessary to keep the water from flashing into steam.

The reaction is reversible. In order to make it proceed to the right, the proportion of water to fat can be increased or the glycerin can be removed. Removal of glycerin is used as the reaction-forcing method. The required combination of high temperature, high pressure, and continuous glycerin removal is accomplished in a countercurrent hydrolyzer column. Fat stocks, blended in the proper formula, are mixed with dry zinc oxide catalyst. The mixture is maintained at about 212°F (100°) to ensure dryness and to keep the catalyst in solution. Hot water for the hydrolysis reactions is put under high pressure by piston-type feed pumps with adjustable drives so that the rates and proportions of fat to water can be accurately controlled. The fat and water are heated to the hydrolyzing temperature by direct steam injection or by heat exchangers. The fats are pumped into the column near the bottom, and the water enters near the top. Thus, a countercurrent flow of water downward through rising fatty material is obtained.

The hydrolysis occurs in a two-phase reaction system. The fats and fatty acids flow continuously with droplets of water falling through them. Glycerin from the hydrolysis is dissolved in the excess water falling through the column. The rate- limiting factor is the transfer of glycerin into the water droplets. Zinc oxide catalyzes the reaction of forming zinc soap, which increases the glycerin transfer across the oil-water interface. Fresh water entering the column at the top reduces the glycerin to the lowest possible point, while a glycerin-water seat maintained at the bottom of the column (where the glycerin content is highest) prevents fat from washing out.

The fatty material passes upward through the column with about 99% completeness in splitting. The fatty acids, saturated with water,

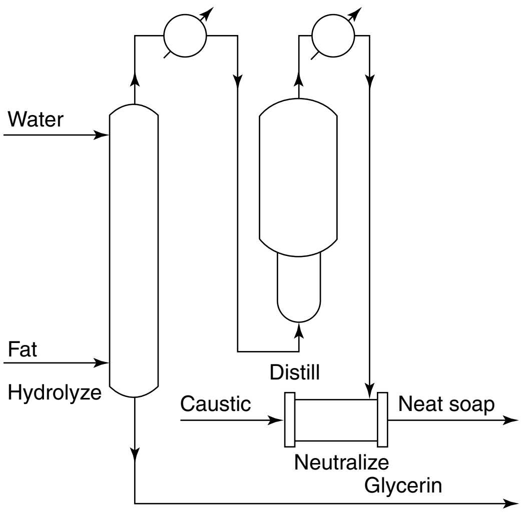

Fig. 1. Basic hydrolyzer process used in soap manufacture

are discharged through an orifice into a flash tank. The dissolved water vaporizes, cooling the fatty acids and blanketing them with steam. The fatty acid contains the zinc soap catalyst and the remaining unsplit fat.

The column, pumps, and piping in contact with the hot fatty acid are made from corrosion-resistant stainless steel. The column is a hollow vessel, containing no baffles, trays, or packing material of any kind. The quality of the hydrolyzing operation is determined by the degree of split obtained on the fat. The fatty acid stream contains very little free glycerin, if any.

Distillation. The second key step in continuous soapmaking is distillation. Originally, fatty acids made in hydrolyzers were acid washed to split out the zinc soap and then bleached to improve color, but continuous distillation of the hydrolyzer fatty acids results in lighter soap from darker stocks at lower cost.

The fatty acids from the hydrolyzer are collected in the still feed tank and vacuum-dried to reduce moisture to low levels. Then they are flash-distilled at an absolute pressure of 2–5 mm Hg. The still bottoms are recirculated through heat exchangers back to the still to carry the heat necessary for vaporizing the fatty acids. The still bottoms, which contain the zinc soap catalyst and unsplit fat, are removed from the system, acidulated to remove the zinc, and frequently used in animal feeds. The fatty acid vapors from the still pass to several water condensers in series. The condensed fatty acids drop to a surge tank for posthardening or directly for neutralization.

The two prime objectives of this process, maintenance of good odor and color in the distillate and proper bottoms yield, are achieved by effective control over vacuum, temperature, and distillation rate.

Posthardening. Not shown in the figure is an optional further treatment of the fatty acids known as *posthardening*. This operation involves hydrogenation of some of the unsaturated carbon-carbon bonds on the fatty acid molecules. Originally, the purpose of this step was to improve color and odor. As such, the hardening was intended only to eliminate polyunsaturates, leaving the majority of the monounsaturates unaffected. A greater amount of hardening can be performed, however, to tailor some of the physical properties of the finished bar characteristics. The fatty acids from distillation are heated and passed with a metered hydrogen supply through hardening tubes which contain a fixed bed of granular nickel catalyst where the hydrogenation takes place. The hardened fatty acids flow through a filter to remove traces of catalyst. The filtered stock drops to a flash tank, where excess hydrogen is removed. Hardening is controlled by temperature, pressure, hydrogen flow, residence time, and catalyst age. The fatty acids then are cooled for neutralization.

Neutralization. The saponification reaction between alkaline solutions and fatty acids is almost instantaneous:

$$\mathrm{RCOOH + NaOH \longrightarrow RCOONa + H_2O}$$

Each reactant is metered accurately into the neutralizer, where intimate mixing occurs and the reaction takes place. Soap from the neutralizer is discharged at about 200°F (93°C) to a blend tank equipped with agitation and recirculation to ensure uniform composition of the soap. This base soap (or *neat soap*) is stored until required for subsequent processing into finished bars.

The characteristics of the neat soap are controlled easily by accurately governing the composition of the alkaline solution used. Normal hydrolyzer neat soap contains about 69% actual soap, 30% water, and less than 1% NaCl, plus other stabilizers. Neat soap is a uniform, translucent, white, viscous fluid at 180–200°F (82–93°C).

Glycerin Recovery. The glycerin water stream from the hydrolyzer is concentrated by evaporation, purified, and subsequently sold or used in other processes.

Milled Bar Soap Manufacture. Milled soap is a high-grade soap in which critical crystal-phase changes have been brought about through the use of mixers, milling rolls, and plodders. The milled soap is made by drying a good grade of neat soap to about 15% moisture content, breaking up the crystalline structure that develops during drying and cooling, plasticizing and converting a sufficient portion of the soap to a desirable phase condition, de-aerating and compacting the resulting mass, and forming it into bars. Perfume, coloring matter, preservatives, and special additives are incorporated prior to the milling operation. A milled bar is particularly hard, dense, and smooth, and it lathers freely without forming excessive soft soap on the surface of the bar.

Drying. Liquid base soap is dried from a 30% water liquid form to a solid of about 15% water content. If desired, some minor ingredients may be blended into the soap stream prior to drying. Methods of drying used in common practice are (1) chip drying, (2) atmospheric flash drying, and (3) vacuum flash drying.

Chip Drying. Sometimes called *ribbon drying*, this process involves spreading a thin layer of hot base soap on a large chilled drum, which cools and firms up the soap. Drying is promoted primarily by the difference in water vapor pressure between the soap chips and the air surrounding them. No attempt is made to increase drying rate by heating the soap itself.

Atmospheric Flash Drying. A tower similar to a synthetic-granules spray-drying tower is used. The heat for drying, however, is put into the soap by heating it under high pressure before flashing it into the tower. During flashing, the pressure on the soap is abruptly relieved and soap moisture flashes to steam. Air to the tower is used for cooling. The soap temperature as it enters the flashing nozzles determines the final moisture of the dried soap.

An alternative method involves flashing the soap from the nozzle onto the surface of a chilled drum. The resultant solid soap is scraped off in flake form. This process called *chill flake drying*, is the method of choice for drying sticky soap/synthetic combination formulas.

Vacuum Flash Drying. In this most recent technique, drying takes place in a vacuum vessel similar to an atmospheric tower but smaller. The soap is similarly heated before flashing but under less pressure, so that boiling (actually drying of the soap) occurs in the heat exchangers. Since there is boiling in the heaters, the moisture of the dried soap depends primarily upon soap flow rate, soap pressure, and steam pressure to the heater and to a minor extent on the absolute pressure in the vacuum chamber. The final temperature of the soap depends entirely upon the absolute pressure in the vacuum chamber.

Mixing. After drying, the soap noodles or flakes are mixed with all additional ingredients required by the final product formula. Mixing is done in batch processes or continuously. These ingredients include dye, perfume, preservatives, deodorants, opacifier, and special purpose items. The type and proportion of these materials is largely what makes one brand of milled soap different from another.

In batch mixing, dried soap and additives are measured and dumped into a dry blender, where macro-mixing occurs. The batch process is cumbersome and slow, and it is difficult to maintain uniform quality. Continuous mixing operations for improving economy and efficiency of mixing include precision metering devices to measure the additives into the soap noodles as they are pulverized and conveyed through the mixer. Although these ingredients constitute but a small portion of the total product, their effect on the physical properties, e.g., softness, resistance to cracking, lathering, and resistance to dissolving, are considerable.

Milling. The three objectives of milling are: (1) thorough and intimate final mixing of the soap, perfume, and other ingredients without overheating; (2) crushing lumps of overdried soap and pulverizing them into pieces too small to appear as lumps or hard specks in the finished bar; and (3) conversion of a sufficient portion of the soap into the waxy, plastic phase of cold working. Soap is milled by forcing it through a series of rolls, thus subjecting it to a strong shearing action. This cold working at the proper moisture content changes the crystalline structure or phase of the soap. Temperature control during milling is important. If the temperature is too low, the wrong crystal structure will be formed, resulting in soft soap or a hard, brittle structure prone to cracking. If the temperature is too high, the soap will become sticky and difficult to process further.

Another method for complete mixing and working uses multiple plodding and screening, in which the soap and additives are pushed together through finer and finer mesh screens.

Plodding. After milling, it is necessary to form the soap into a shape for making the final bar. This usually is accomplished with a plodder, which essentially is a large-size meat grinder with a barrel that terminates in a cone. The plodder functions to compact the pellets or flakes of soap into a solid mass, squeeze out any pockets of entrapped air, and extrude it as a firm, uniform, and continuous strip.

Operations that follow include cutting, stamping, wrapping, and packing.

Transparent Bar Manufacture. Most milled bars are opaque and contain a whitening agent (titanium dioxide) to create a uniform appearance. By eliminating this whitener and carefully controlling processing conditions, a bar that is transparent can be produced. This

transparency results when the soap crystals are reduced to microscopic size which then allows light to pass through the structure. It is also important to achieve the correct soap phase. The control of soap phase is a function of the ratio of tallow to coconut soaps, the milling temperature, and soap moisture which must be maintained within very rigid limits.

Floating-Bar Manufacture. Base soap made from the desired blends of fat and oil first is flash-dried to a moisture content of about 22%. It then enters a mechanical mixer called a *crutcher*, where it is thoroughly mixed with perfume, preservatives, and air. The amount of air controls the density of the final product, giving the bar a density of less than one and making it floatable.

From the crutcher, the mix goes to a freezer to reduce the temperature of the soap to the point where it will hold its shape when extruded. In the earlier steps, the soap mix is in liquid form. Rapid chilling is required to put it into a solid state. The machine is similar to a commercial ice-cream freezer, consisting of a horizontal cylinder surrounded by a jacket and housing a rotating shaft (mutator) on which scraping blades are mounted. The liquid soap mix from the crutcher is pumped into one end of the cylinder. A refrigerated brine solution is circulated through the jacket to chill the soap. The scraping blades on the mutator remove the chilled soap from the cylinder walls and maintain uniformity of the mix. The nose of the freezer is equipped with an oblong orifice through which the soap is extruded, after chilling, in the form of a continuous ribbon, which has the same cross section as the final bar. There follows a series of cooling, storing, stamping, and packaging operations.

SODALITE. An isometric mineral, a sodium aluminum silicate containing sodium chloride, with the chemical composition $Na_4Al_3\ (SiO_4)_3Cl$, potassium sometimes replacing a small amount of sodium. It is commonly found as dodecahedrons or simply massive. When observed sodalite has a dodecahedral cleavage; conchoidal to uneven fracture; brittle; hardness, 5.5–6; specific gravity, 2.14–2.30; luster, vitreous to greasy; color grayish to greenish or yellowish, may be white. It is often a beautiful blue and may sometimes be red. It is transparent to translucent; streak, white. Sodalite is found in igneous rocks of nephelite-syenite type which have been produced from soda rich magmas. Sodalite also has been found in the lavas of Vesuvius. Common minerals associated with it are nephelite and cancrinite. It occurs in the Ilmen Mountains of the former U.S.S.R.; at Vesuvius and Monte Somma, Italy; in Norway and Greenland. In Canada, in British Columbia and in Ontario, beautiful blue sodalite is found; and in the United States similar material comes from Kennebec County, Maine. The mineral derives its name from the fact of its soda content.

SODA NITRE. The mineral soda nitre or Chile saltpeter is naturally occurring sodium nitrate, $NaNO_3$. Its hexagonal crystals are rare, this mineral usually being found in crystalline aggregates, crusts or masses. It is soft; hardness, 1.5–2; specific gravity, 2.266; vitreous luster; colorless or white to yellow or gray; transparent to opaque. Soda nitre is a most important mineral commercially, being used in the manufacture of nitric acid, other nitrates and fertilizers. The chief soda nitre deposits of the world are those found in the Atacama and Tarapaca deserts of northern Chile, although others exist in the Argentine and Bolivia. Some small deposits have been found in California, New Mexico and Nevada. The origin of these nitrate deposits is far from being well understood. They have been regarded as nitrates formed originally by oxidation of organic matter and subsequently leached out. Guano, the excrement of birds, might be the original source of the nitrates. Ground water and ancient marine deposits have been suggested as well as the possibility of derivation from nitric acid produced in the atmosphere during electrical storms. Some investigators consider that the nitrates may have come from volcanic sources.

SODA PULP PROCESS. See **Pulp (Wood) Production and Processing**.

SODDY, FREDERICK (1877–1965). A British physicist who won the Nobel prize in chemistry in 1921. His work was concerned with radioactive elements and atomic energy. His concept of isotopes and the displacement law of radioactive change is basic to nuclear physics. His education was at Oxford and Glasgow. He later worked in Canada and Australia.

SODIUM. [CAS: 7440-23-5]. Chemical element, symbol Na, at. no. 11, at. wt. 22.9898, periodic table group 1 (alkali metals), mp 97.82°C, bp 882.9°C, density 0.971 g/cm^3 (solid at 0°C), 0.9268 g/cm^3 (liquid at mp). Elemental sodium has a face-centered cubic crystal structure.

Sodium is a silvery-white metal. It can be readily molded and cut by knife. It oxidizes instantly on exposure to air, and reacts with water violently, yielding sodium hydroxide and hydrogen gas, consequently is preserved under kerosene, and burns in air at a red heat with yellow flame. Discovered by Davy in 1807.

There is only one naturally occurring isotope, ^{23}Na. There are five known radioactive isotopes, ^{20}Na through ^{22}Na, and ^{25}Na, all with short half-lives except ^{22}Na with a half-life of 2.6 years. See also **Radioactivity**. In terms of abundance, sodium ranks sixth among the elements occurring in the earth's crust, with an average of 2.9% sodium in igneous rocks. In terms of content in seawater, the element ranks fourth (due mainly to excellent solubility of its compounds), with an estimated 50,000,000 tons of sodium per cubic mile of seawater. First ionization potential 5.138 eV. Oxidation potential $Na \rightarrow Na^+ + e^-$, 2.712 V.

Other important physical properties of sodium are given under **Chemical Elements**.

Sodium does not occur in nature in the free state because of its great chemical reactivity. Sodium occurs as sodium chloride in the ocean (1.14% Na); in salt deposits (salt, halite, NaCl), e.g., in Michigan, New York, Louisiana, in Great Britain, and in Germany; in salt lakes, e.g., the Dead Sea (3% Na), Great Salt Lake; in common rocks (average of the solid shell of the earth 2.75% Na) as sodium nitrate (Chile saltpeter, $NaNO_3$) in Chile; as sodium borate (rasorite, kernite, $Na_2B_3O_7 \cdot 4H_2O$, in California; tinkal, $Na_2B_4O_7 \cdot 10H_2O$, in Tibet); and as sodium carbonate Na_2CO_2 and sulfate Na_2SO_4 in certain salt lake areas. See also **Sodium Chloride**.

Although sodium metal was isolated in 1807, it remained a laboratory curiosity until Oersted discovered in 1824 that sodium metal will reduce aluminum chloride to produce pure aluminum metal. This discovery led to the development of a commercial process for the manufacture of sodium. The first cell was designed by Castner in 1886 and a plant was built in Niagara Falls, N.Y., because of availability of low-cost electric power, for the electrolysis of fused NaOH. This process was made obsolete in 1921 by introduction of the Downs process in which a mixture of fused sodium chloride and calcium chloride is electrolyzed to produce metallic sodium. The modern cells have four anodes (graphite) surrounded by a steel cathode. Wire mesh diaphragms extend down into the electrolysis zone to prevent recombination of product sodium and chlorine. The use of calcium chloride in the cell significantly lowers the melting point of the mix. Sodium chloride has a mp 800°C, calcium chloride, mp 772°C, the two-salt eutectic, mp 505°C. Calcium has limited solubility in sodium. The excess calcium reacts with the sodium chloride present, $Ca + 2NaCl \rightarrow 2Na + CaCl_2$, and thus does not contaminate the sodium metal to a large degree. The sodium, which is saturated with calcium, is cooled in a riser pipe. This reduces the solubility of Ca in Na, precipitating Ca, which falls back into the cell, where it reacts to form more Na. The Na that overflows at the top of the riser pipe contains 1% or less of Ca. The Na is further purified by filtration at a temperature near its melting point, reducing the Ca content to about 0.05%. The cells operate at about 8 V, with groups of 25 to 40 cells connected in series.

Uses

Like so many of the chemical elements, the compounds of sodium are far more important than elemental sodium—by several orders of magnitude.

Among the attractions of molten sodium metal as a heat-transfer medium are: (1) low density compared with other metals and combinations of

salts, contributing to low cost per unit volume and thus relative ease of pumping, sodium being about one-half that of the more commonly applied nitrate-nitrite heat-transfer salts; (2) relatively low vapor pressure even at temperatures as high as 550°C; (3) greater heat capacity than most common metals in liquid form, the thermal conductivity being 5 to 10× greater than the conductivities of lead or mercury and 50× higher than for most organic heat-transfer media; and (4) the viscosity of molten sodium is quite low. Despite these fine qualifications, however, the use of sodium as a heat-transfer medium has enjoyed a mixed reception over the years, partially attributable to a lack of marketing thrust in its behalf. Sodium is fifth among the metals in terms of electrical conductivity—hence bus bars are constructed from steel pipe filled with sodium. The characteristic yellow sodium light, created by the passage of an electric current through sodium vapor, is used for commercial and industrial lighting. Sodium is used to modify aluminum-silicon alloys. Normally coarse and brittle, such alloys can be transformed into fine-grained alloys with good casting properties through the addition of a fraction of 1% of sodium. Sodium also has been used as a hardening agent in bearing metals. When added with an alkaline-earth metal, such as calcium, sodium increases the hardness of lead. The German alloy "Bahnmetal" is an alloy of this type.

Generally, plain carbon steel containers are sufficient for handling metallic sodium at temperatures not in excess of the metal's boiling point. All-welded pipeline construction and bellows-sealed packless valves are usually used. Because of the metal's violent reactivity with H_2O, conventional fire extinguishers, including CO_2 and chlorinated hydrocarbons, should not be used. The preferred fire-retarding agents are salt, graphite, and soda ash, but they must be dry. Sand usually is not recommended because it is difficult to obtain perfectly dry sand in an emergency. In manufacturing operations involving sodium, particularly at reasonably high temperatures, an apron, leggings, and a complete face covering should be used. At normal temperatures, or where only small quantities of the metal are required, as may be the case in a research laboratory, conventional protective gear and goggles and gloves usually suffice.

Chemistry and Compounds

Sodium metal is obtained by electrolysis of fused sodium chloride or hydroxide out of contact with air. Its uses are limited in extent, but important in particular cases, as in the liberation of a metal from its chloride by reaction of sodium to form sodium chloride, and in certain reactions of organic chemistry.

The ionization potential of sodium (5.138 eV) is second to that of lithium and higher than those of the other alkali metals. However, the measured value of its oxidation potential against a normal aqueous solution of its ion is 2.712 V, the lowest of the group. Potassium is more electropositive in many of its reactions, even with water; though both react vigorously to produce the hydroxide and hydrogen, the reaction of potassium is more vigorous. With bromine, sodium reacts only slowly without heating and with iodine scarcely at all even on heating; potassium reacts violently with bromine, and with iodine on heating.

Because of the ease of removal of its single $3s$ electron (5.138 eV) and the great difficulty of removing a second electron (47.29 eV), sodium is exclusively monovalent in its compounds, which are electrovalent. Some experimental work indicates that the sodium alkyls may be covalent, but even they form conducting solutions in other metal alkyls.

Sodium Atoms Confined. In an interesting experiment conducted at the National Bureau of Standards in 1985, Migdall and colleagues trapped slow-moving neutral Na atoms in a magnetic field that created an energy well for the atoms. Robinson (1985) reported that approximately 10^5 sodium atoms in a trap volume of 20 cubic centimeters were stopped for a brief instant of time. For many years, spectroscopists have visualized the ideal sample where a collection of atoms or molecules would reside motionless in space for a period of time. Because of this experiment, researchers are closer to this goal. In the experiment, it was found that the particles gradually leak out, with time constants ranging from 0.1 to 1 second. Similar experiments have been conducted at AT&T Bell Laboratories (Holmdel, New Jersey). The theoretical trapping time in a perfect vacuum has been estimated as greater than 1000 seconds. The importance of these experiments is explored in considerable detail by Robinson in the reference listed.

Like lithium, sodium and its compounds have been studied extensively in solution in liquid NH_3. Sodium metal in such solutions slowly or with catalysis forms the amide, $NaNH_2$. The solution of the metal is a powerful reducing agent, reacting with metallic salts to free the metal, with which it may form an intermetallic compound

$$Na + AgCl \longrightarrow NaCl + Ag$$

$$9Na + 4Zn(CN)_2 \longrightarrow 8NaCN + NaZn_4$$

Sodium chloride also forms the amide, or at low temperatures the pentammoniate, $NaCl \cdot 5NH_3$.

Like the other alkali metals, sodium forms compounds with virtually all the anions, organic as well as inorganic. These compounds are remarkable for their great variety and for the fact that the reactivity of sodium bicarbonate with many metallic oxides permits preparation of many compounds that are unstable in aqueous solution. While other alkali bicarbonates react similarly, the general discussion of these compounds, and of the inorganic alkali salts generally, is appropriately given in this book under this entry for sodium, from which such a great number of inorganic (as well as organic) salts has been prepared.

Thus, normal (ortho) sodium arsenates $Na_3AsO_4 \cdot xH_2O$ and acid arsenates exist both in solution and in the solid state, whereas the meta- and pyroarsenates exist only as solids, but are readily prepared by heating arsenic pentoxide, As_2O_5, and sodium bicarbonate in correct proportions to produce the primary and secondary sodium arsenates, whence the meta- and pyroarsenates are obtained by heating

$$NaH_2AsO_4 \longrightarrow \text{Heat } NaAsO_3 + H_2O$$

$$2Na_2HAsO_4 \longrightarrow \text{Heat } Na_4AsO_2O_7 + H_2O$$

Similarly, the boron salts include metaborates, $NaBO_2 \cdot xH_2O$, tetraborates, $Na_2B_4O_7 \cdot xH_2O$, other polyborates, $Na_2B_{10}O_{16} \cdot xH_2O$, at least one orthoborate, Na_3BO_3, and peroxyborates, such as $NaBO_3 \cdot H_2O$. See also **Boron**. Other important sodium salts include the carbonates, cyanides, cyanates, hexacyanoferrates, $Na_4Fe(CN)_4$ and $Na_3Fe(CN)_6$, halides, polyhalides, hypohalites, halites, halates, perhalates, permanganates, ortho-, pyro-, meta-, fluoro-, and peroxyphosphates, hyposulfites, sulfites, sulfates, thiosulfates, peroxysulfates, polythionates, tungstates, vanadates, uranates, etc.

In addition to the simple compounds, sodium forms double salts of various types, although because of the relatively small size of the Na^+ ion, the number of sodium alums (see also **Alum**) is relatively small.

In addition to the inorganic salts, sodium forms such binary compounds as a phosphide, Na_3P, by direct union with phosphorus, a nitride, Na_3N, by direct union with nitrogen when activated electrically (which decomposes partly to give sodium amide, NaN_3, also obtained by heating sodium nitrate with sodium amide) and the oxides. Sodium monoxide, Na_2O, is obtained by heating the nitrite with the metal, displacing the nitrogen. Sodium peroxide, Na_2O_2, is the most stable oxide, obtained by reaction of the elements. Sodium superoxide is known, NaO_2, and one other oxide, Na_2O_3, has been reported. Sodium hydroxide, NaOH, is very soluble in H_2O and soluble in alcohol. It is almost completely ionized in water at ordinary concentrations, although its basic character is less than those of the higher elements in the group ($pK_B = -0.70$).

The detailed chemistry and applications of some of the more important compounds, other than those already discussed, follow.

Aluminate: Sodium aluminate, [CAS: 11138-49-1], $NaAlO_2$, white solid, (1) by reaction of aluminum hydroxide and NaOH solution, (2) by fusion of aluminum oxide and sodium carbonate, the solution reacts with CO_2 to form aluminum hydroxide. Used as a mordant, and in water purification. See also **Aluminum**.

Aluminosilicate: Sodium aluminosilicate is used as a water softener for the removal of dissolved calcium compounds.

Amide: Sodamide, sodamine, $NaNH_2$, white solid, formed by reaction of sodium metal and dry NH_3 gas at 350°C, or by solution of the metal in liquid ammonia. Reacts with carbon upon heating, to form sodium cyanide, and with nitrous oxide to form sodium azide, NaN_3.

Bromide: Sodium bromide, [CAS: 7647-15-6], NaBr, white solid, soluble, mp 755°C. Used in photography and in medicine. See also **Bromine**.

Carbonates: Sodium carbonate (anhydrous), soda ash, [CAS: 497-19-8], Na_2CO_3, sodium carbonate decahydrate, washing soda, sal soda, $Na_2CO_3 \cdot 10H_2O$, white solid, soluble, mp 851°C, formed by heating sodium hydrogen carbonate, either dry or in solution. Commonly bought and sold in quantity on the basis of oxide Na_2O determined by analysis (58.5% Na_2O equivalent to 100.0% Na_2CO_3).

Soda ash is a very-high-tonnage chemical raw material and approaches a production rate of 10 million tons/year in the United States. About 40% of soda ash is used in glassmaking; approximately 35% goes into the production of sodium chemicals, such as sodium chromates, phosphates, and silicates; nearly 10% is used by the pulp and paper industry; the remainder going into the production of soaps and detergents and in nonferrous metals refining. The first process for preparing soda ash was developed by Leblanc during the first French Revolution. In the Leblanc process, sodium chloride first is converted to sodium sulfate and subsequently the sulfate is heated with limestone and coke: (1) $Na_2SO_4 + 2C \rightarrow Na_2S + 2CO_2$; (2) $Na_2S + CaCO_3 \rightarrow Na_2CO_3 + CaS$. During the mid-1800s, the Solvay process was introduced. In this process, CO_2 is passed through an NH_3-saturated sodium chloride solution to form sodium bicarbonate, then followed by calcination of the bicarbonate: (1) $NH_3 + CO_2 + NaCl + H_2O \rightarrow HNaCO_3 + NH_4Cl$; (2) $2HNaCO_3 + heat + Na_2CO_3 + CO_2 + H_2O$. A large proportion of soda ash now is derived from the natural mineral trona, which occurs in great abundance near Green River, Wyoming. Chemically trona is sodium sesquicarbonate, $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$. After crushing, the natural ore is dissolved in agitated tanks to form a concentrated solution. Most of the impurities (boron oxides, calcium carbonate silica, sodium silicate, and shale rock) are insoluble in hot H_2O and separate out upon settling. Upon cooling, the filtered sesquicarbonate solution forms fine needle-like crystals in a vacuum crystallizer. After centrifuging, the sesquicarbonate crystals are heated to about 240°C in rotary calciners whereupon CO_2 and bound H_2O are released to form natural soda ash. The crystals have a purity of 99.88% or more and handle easily without abrading or forming dust and thus assisting glassmakers and other users in obtaining uniform and homogeneous mixes.

Chlorate. Sodium chlorate, chlorate of soda, [CAS: 7775-09-9], $NaClO_3$, white solid, soluble, mp 260°C, powerful oxidizing agent and consequently a fire hazard with dry organic materials, such as clothes, and with sulfur; upon heating oxygen is liberated and the residue is sodium chloride; formed by electrolysis of sodium chloride solution under proper conditions. Used (1) as a weedkiller (above hazard), (2) in matches, and explosives, (3) in the textile and leather industries.

Chloride. Sodium chloride, common salt, rock salt, halite, NaCl, white solid, soluble, mp 804°C. See also **Sodium Chloride**.

Chromate. Sodium chromate [CAS: 7775-11-3]. $Na_2CrO_4 \cdot 10H_2O$, yellow solid, soluble, formed by reaction of sodium carbonate and chromite at high temperatures in a current of air, and then extracting with water and evaporating the solution. Used (1) as a source of chromate, (2) in leather tanning, (3) in textile dyeing, (4) in inks.

Citrate. Sodium citrate, $Na_3C6H_5O_7 \cdot 5\frac{1}{2}H_2O$ white solid, soluble, formed (1) by reaction of sodium carbonate or hydroxide and citric acid, (2) by reaction of calcium citrate and sodium sulfate or carbonate solution, and then filtering and evaporating the filtrate. Used in soft drinks and in medicine.

Cyanide. Sodium cyanide, [CAS: 143-33-9], NaCN, white solid, soluble, very poisonous, formed (1) by reaction of sodamide and carbon at high temperature, (2) by reaction of calcium cyanamide and sodium chloride at high temperature, reacts in dilute solution in air with gold or silver to form soluble sodium gold or silver cyanide, and used for this purpose in the cyanide process for recovery of gold. The percentage of available cyanide is greater than in potassium cyanide previously used. Used as a source of cyanide, and for hydrocyanic acid.

Dichromate. Sodium dichromate, [CAS: 10588-01-9], $Na_2Cr_2O_7 \cdot 2H_2O$, red solid, soluble, powerful oxidizing agent, and consequently a fire hazard with dry carbonaceous materials. Formed by acidifying sodium chromate solution, and then evaporating. Used (1) in matches and pyrotechnics, (2) in leather tanning and in the textile industry, (3) as a source of chromate, cheaper than potassium dichromate.

Dithionate. Sodium dithionate, "sodium hyposulfate," [CAS: 7775-14-6], $Na_2S_2O_6 \cdot 2H_2O$, white solid, soluble, formed from manganese dithionate solution and sodium carbonate solution, and then filtering and evaporating the filtrate.

Fluorides. Sodium fluoride [CAS: 7681-49-4], NaF, white solid, soluble, formed by reaction of sodium carbonate and hydrofluoric acid, and then evaporating. Used (1) as an antiseptic and antifermentative in alcohol distilleries, (2) as a food preservative, (3) as a poison for rats and roaches, (4) as a constituent of ceramic enamels and fluxes; sodium hydrogen fluoride, sodium difluoride, sodium acid fluoride, $NaHF_2$, white solid, soluble, formed by reaction of sodium carbonate and excess hydrofluoric acid, and then evaporating. Used (1) as an antiseptic, (2) for etching glass, (3) as a food preservative, (4) for preserving zoological specimens.

Fluosilicate. Sodium fluosilicate, Na_2SiF_6, white solid, very slightly soluble in cold H_2O, formed by reaction of sodium carbonate and hydrofluosilicic acid. Used (1) in ceramic glazes and opal glass, (2) in laundering, (3) as an antiseptic.

Formate. Sodium formate, [CAS: 141-53-7], $NaCHO_2$, white solid, soluble, formed by reaction of NaOH and carbon monoxide under pressure at about 200°C. Used (1) as a source of formate and formic acid, (2) as a reducing agent in organic chemistry, (3) as a mordant in dyeing, (4) in medicine.

Hydride. Sodium hydride, [CAS: 7646-69-7], NaH, white solid, reactive with water yielding hydrogen gas and NaOH solution, formed by reaction of sodium and hydrogen at about 360°C. Used as a powerful reducing agent.

Hydroxide. Sodium hydroxide, caustic soda, sodium hydrate, "lye," [CAS: 1310-73-2], NaOH, white solid, soluble, mp 318°C, an important strong alkali, not as cheap as calcium oxide (a strong alkali) nor sodium carbonate (a mild alkali), but of wide use. Formed (1) by reaction of sodium carbonate and calcium hydroxide in H_2O, and then separation of the solution and evaporation, (2) by electrolysis of sodium chloride solution under the proper conditions, and evaporation. Commonly bought and sold in quantity on the basis of oxide Na_2O determined by analysis (77.5% Na_2O equivalent to 100.0% NaOH). Used (1) in the manufacture of soap, rayon, paper ("soda process"), (2) in petroleum and vegetable oil refining, (3) in the rubber industry, in the textile and tanning industries, (4) in the preparation of sodium salts, (a) in solution, (b) upon fusion. See Fig. 1.

Hypochlorite. Sodium hypochlorite, [CAS: 7681-52-9], NaOCl, commonly in solution by (1) electrolysis of sodium chloride solution under proper conditions, (2) reaction of calcium hypochlorite suspension in water and sodium carbonate solution, and then filtering. Used (1) as a bleaching agent for textiles and paper pulp, (2) as a disinfectant, especially for water, (3) as an oxidizing reagent.

Hypophosphite. Sodium hypophosphite, [CAS: 7681-53-0], $NaH_2PO_2 \cdot H_2O$, white solid, soluble, formed (1) by reaction of hypophosphorous acid and sodium carbonate solution, and then evaporating, (2) by reaction of NaOH solution and phosphorous on heating (poisonous phosphine gas evolved).

Hyposulfite. Sodium hyposulfite, sodium hydrosulfite (not sodium thio sulfate), $Na_2S_2O_4$, white solid, soluble, formed by reaction of sodium hydrogen sulfite and zinc metal powder, and then precipitating sodium hyposulfite by sodium chloride in concentrated solution. Used as an important reducing agent in the textile industry, e.g., bleaching, color discharge.

Iodide. Sodium iodide, [CAS: 7681-82-5], NaI, white solid, soluble, mp 651°C, formed by reaction of sodium carbonate or hydroxide and hydriodic

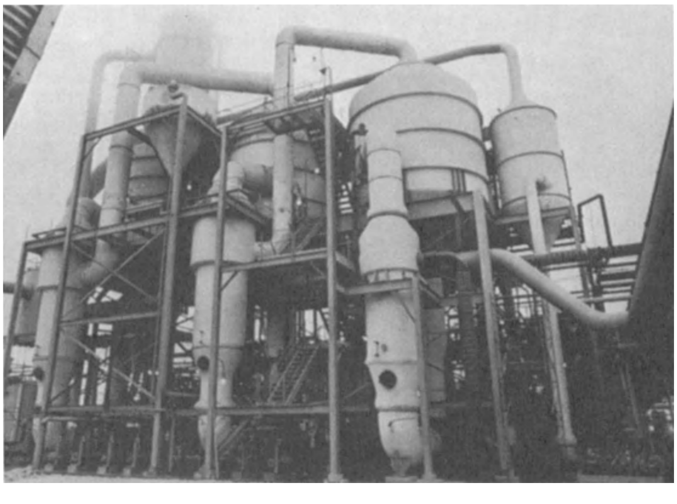

Fig. 1. Triple-effect evaporator used in concentrating soda solutions and preparation of solid sodium hydroxide

acid, and then evaporating. Used in photography, in medicine and as a source of iodide.

Manganate. Sodium manganate, Na_2MnO_4, green solid, soluble, permanent in alkali, formed by heating to high temperature manganese dioxide and sodium carbonate, and then extracting with water and evaporating the solution. The first step in the preparation of sodium permanganate from pyrolusite.

Nitrate. Sodium nitrate, nitrate of soda, Chile saltpeter, "caliche," [CAS: 7631-99-4], NaNO3, white solid, soluble, mp 308°C, source in nature is Chile, in the fixation of atmospheric nitrogen HNO_3 is frequently transformed by sodium carbonate into sodium nitrate, and the solution evaporated. Used (1) as an important nitrogenous fertilizer, (2) as a source of nitrate and HNO_3, (3) in pyrotechnics, (4) in fluxes.

Nitrite. Sodium nitrite, [CAS: 7632-00-0], $NaNO_2$, yellowish-white solid, soluble, formed (1) by reaction of nitric oxide plus nitrogen dioxide and sodium carbonate or hydroxide, and then evaporating, (2) by heating sodium nitrate and lead to a high temperature, and then extracting the soluble portion (lead monoxide insoluble) with H_2O and evaporating. Used as an important reagent (diazotizing) in organic chemistry.

Oleate. Sodium oleate, [CAS: 143-19-1], $NaC_{18}H_{33}O_2$, white solid, soluble, froth or foam upon shaking the H_2O solution (soap), formed by reaction of NaOH and oleic acid (in alcoholic solution) and evaporating. Used as a source of oleate.

Oxalates. Sodium oxalate, [CAS: 62-76-0], $Na_2C_2O_4$, white solid, moderately soluble, formed (1) by reaction of sodium carbonate or hydroxide and oxalic acid, and then evaporating, (2) by heating sodium formate rapidly, with loss of hydrogen. Used as a source of oxalate; sodium hydrogen oxalate, sodium binoxalate, sodium acid oxalate, $NaHC_2O_4 \cdot H_2O$, white solid, moderately soluble.

Palmitate. Sodium palmitate, $NaC_{16}H_{31}O_2$, white solid, soluble, froth or foam upon shaking the H_2O solution (soap), formed by reaction of NaOH and palmitic acid (in alcoholic solution) and evaporating. Used as a source of palmitate.

Permanganate. Sodium permanganate, permanganate of soda, [CAS: 10101-50-5], $NaMnO_4 \bullet 3H_2O$, purple solid, soluble, formed by oxidation of acidified sodium manganate solution with chlorine, and then evaporating. Used (1) as disinfectant and bactericide, (2) in medicine.

Phenate. Sodium phenate, sodium phenoxide, sodium phenolate, [CAS: 139-02-6], $NaOC_6H_5$, white solid, soluble, formed by reaction of sodium hydroxide (not carbonate) solution and phenol, and then evaporating. Used in the preparation of sodium salicylate.

Phosphates. Trisodium phosphate, tribasic sodium phosphate, [CAS: 7601-54-9], $Na_3PO_4 \bullet 12H_2O$, white solid, soluble, formed (1) by reaction of sodium hydroxide and the requisite amount of phosphoric acid, and then evaporating, (2) by reaction of disodium hydrogen phosphate plus sodium hydroxide, and then evaporating. Used (1) as a cleansing and laundering agent, (2) as a water softener, (3) in photography, (4) in tanning, (5) in the purification of sugar solutions; disodium hydrogen phosphate, dibasic sodium phosphate, $Na_2HPO_4 \cdot 12H_2O$, white solid, soluble, formed (1) by reaction of dicalcium hydrogen phosphate and sodium carbonate solution, and then evaporating the solution, (2) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating. Used (1) in weighting silk, (2) in dyeing and printing textiles, (3) in fireproofing wood, paper, fabrics, (4) in ceramic glazes, (5) in baking powders, (6) to prepare sodium pyrophosphate; sodium dihydrogen phosphate, monobasic sodium phosphate, $NaH_2PO_4 \cdot H_2O$, white solid, soluble, formed (1) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating, (2) by reaction of calcium monohydrogen phosphate and sodium carbonate solution, and then evaporating the solution. Used (1) in baking powders, (2) in medicine, (3) to prepare sodium metaphosphate; sodium pyrophosphate, $Na_4P_2O_7 \cdot 10H_2O$, white solid, soluble, mp about 900°C, formed by heating disodium hydrogen phosphate to complete loss of water, followed by crystallization from water solution. Used in electroanalysis; sodium metaphosphate, $NaPO_3$, white solid, soluble, mp 617°C, formed by heating sodium dihydrogen phosphate or sodium ammonium phosphate to complete loss of water, is an easily fusible phosphate forming colored phosphates with many metallic oxides, e.g., cobalt oxide. The hexametaphosphate, $(NaPO_3)_6$, is an important water-conditioning agent forming soluble complex compounds with many cations, e.g., Ca^{2+}, Mg^{2+}. Many polyphosphate compounds are known; their various uses include water softening and ion exchange. They are widely formulated in detergents, as are several of the simpler phosphates.

Phosphites. Disodium hydrogen phosphite, $Na_2HPO_3 \cdot 5H_2O$, white solid, soluble, formed by reaction of phosphorous acid and sodium carbonate, and then evaporating at a low temperature, mp of anhydrous salt is 53°C, at higher temperatures yields sodium phosphate and phosphine gas; sodium dihydrogen phosphite, $NaH_2PO_3 \cdot 2\frac{1}{2}H_2O$, white solid, soluble, formed by reaction of phosphorous acid and NaOH cooled to −23°C when the crystalline salt separates.

Salicylate. Sodium salicylate, [CAS: 54-21-7], $NaC_7H_5O_3$, white solid, soluble, formed by reaction of sodium phenate and CO_2 under pressure. Used as a source of salicylate and for salicylic acid.

Silicate. Sodium silicate, sodium metasilicate, "water glass," [CAS: 6834-92-0], Na_2SiO_3, colorless (when pure) glass, soluble, mp 1,088°C, formed by reaction of silicon oxide and sodium carbonate at high temperature; solution reacts with CO_2 of the air, or with sodium carbonate solution or ammonium chloride solution, yielding silicic acid, gelatinous precipitate. Sodium silicate solution is used (1) in soaps, (2) for preserving eggs, (3) for treating wood against decay, (4) for rendering cloth, paper, wood noninflammable, (5) in dyeing and printing textiles, (6) as an adhesive (e.g., for paper boxes) and cement. Sold as granular, crystals, or 40° Baumé solution.

Silicoaluminate. (See aluminosilicate, above.)

Silicofluoride. (See fluosilicate, above.)

Stearate. Sodium stearate, [CAS: 822-16-2], $NaC_{18}H_{35}O_2$, white solid, soluble, froth or foam upon shaking the water solution (soap), formed by reaction of NaOH and stearic acid (in alcoholic solution) and evaporating. Used as a source of stearate.

Sulfates. Sodium sulfate (anhydrous), "salt cake," [CAS: 7757-82-6], Na_2SO_4, sodium sulfate, decahydrate, "Glauber's salt," $Na_2SO_4 \cdot 10H_2O$, white solid, soluble, formed by reaction of sodium chloride and H_2SO_4 upon heating with evolution of hydrogen chloride gas. Used (1) in dyeing, (2) along with carbon in the manufacture of glass, (3) as a source of sulfate, (4) to prepare sodium sulfide; sodium hydrogen sulfate, sodium bisulfate, sodium acid sulfate, "nitre cake," $NaHSO_4$, white solid, soluble, formed by reaction of sodium nitrate and H_2SO_4, upon heating, with evolution of HNO_3. Used (1) as a cheap substitute for H_2SO_4. (2) in dyeing, (3) as a flux in metallurgy; sodium pyrosulfate, $Na_2S_2O_7$, white solid, soluble, formed by heating sodium hydrogen sulfate to complete loss of H_2O.

Sulfides. Sodium sulfide, [CAS: 1313-82-2], Na_2S, yellowish to reddish solid, soluble, formed (1) by heating sodium sulfate and carbon to a high temperature. Used (1) as the cooking liquor reagent (along with sodium hydroxide) in the "sulfate" or "kraft" process of converting wood into paper pulp, (2) as a depilatory, (3) in sheep dips, (4) in photography, engraving and lithography, (5) in organic reactions, (6) as a source of sulfide, (7) as a reducing agent; sodium hydrogen sulfide, sodium bisfulfide, sodium acid sulfide, NaHS, formed in solution by reaction of NaOH or carbonate solution and excess H_2S.

Sulfites. Sodium sulfite, [CAS: 7757-83-7], Na_2SO_3, white solid, soluble, dilute solution readily oxidized in air, but retarded by mannitol (carbohydrates), formed by reaction of sodium carbonate or hydroxide solution and the requisite amount of SO_2, at high temperature yields sodium sulfate and sodium sulfide. Used (1) as a source of sulfite, (2) as a reducing agent, (3) to prepare sodium thiosulfate, (4) as a food preservative, (5) as a photographic developer, (6) as a bleaching agent and antichlor in the textile industry; sodium hydrogen sulfite, sodium bisulfite, sodium acid sulfite, $NaHSO_3$, white solid, soluble, formed by reaction of sodium carbonate solution and excess sulfurous acid. Uses similar to those of sodium sulfite.

Tartrate. Sodium tartrate, [CAS: 868-18-8], $Na_2C_4H_4O_6 \cdot 2H_2O$, white solid, soluble, formed by reaction of sodium carbonate solution and tartaric acid. Used in medicine; sodium potassium tartrate, Rochelle salt, $NaKC_4H_4O_6 \cdot 4H_2O$, white solid, soluble. Used (1) in medicine, (2) as a source of tartrate.

Thiosulfate. Sodium thiosulfate, "Hypo" [CAS: 7772-98-7], $Na_2S_2O_3 \cdot 5H_2O$, white solid, soluble, formed by reaction of sodium sulfite and sulfur upon boiling, and then evaporating. Used (1) in photography as fixing agent to dissolve unchanged silver salt, (2) as a reducing agent and antichlor. See also **Sodium Thiosulfate**.

Tungstate. Sodium tungstate, (sodium wolframate), [CAS: 13472-45-2], $Na_2WO_4 \cdot 2H_2O$, white solid, soluble, by reaction of NaOH solution

and tungsten trioxide upon boiling, and then evaporating. Used (1) in fireproofing fabrics, (2) as a source of tungsten for chemical reactions.

Uranate. Sodium uranate, uranium yellow, Na_2UO_4, yellow solid, insoluble, formed by reaction of soluble uranyl salt solution and excess sodium carbonate solution. Used (1) in the manufacture of yellowish-green fluorescent glass, (2) in ceramic enamels, (3) as a source of uranium for chemical reactions.

Vanadate. Sodium vanadate, sodium orthovanadate, Na_3VO_4, white solid, soluble, formed by fusion of vanadium pentoxide and sodium carbonate. Used (1) in inks, (2) in photography, (3) in dyeing of furs, (4) in inoculation of plant life.

The larger number of organic compounds of sodium are for great part derivatives of oxygen-containing compounds such as salts of organic acids (several of which are discussed above), alcoholic and phenolic compounds (carboxylates, alkoxides, phenoxides, etc.). However, in some cases, sodium derivatives of nitrogen-containing compounds, as sodium benzamide, $C_6H_5C(O)NHNa$, and sodium anilide, C_6H_5NHNa, contain sodium-nitrogen bonds, while even sodium-boron bonds exist in certain boron-containing compounds, as sodium triphenylborene, $NaB(C_6H_5)_3$, and others; and in a number of compounds sodium is carbon-connected, as in methylsodium, CH_3Na, ethylsodium, C_2H_5Na, cyclopentadienylsodium, C_5H_5Na, and sodium triphenylmethane, $NaC(C_6H_5)_3$.

The organometallic compounds of sodium may be divided into two groups, differing in properties. One group, e.g., ethylsodium, consists of compounds that are colorless, insoluble in organic solvents, and that electrolyze readily in diethylzinc solution. Another group, e.g., benzylsodium, $C_6H_5CH_2Na$, are colored, and soluble in organic solvents. Like all the alkali metals, sodium coordinates with salicylaldehyde. Its tetracovalent compounds, with those of potassium, are the more stable of the group, for the following reasons: (1) Increasing ionic size carries with it increasing electropositiveness and ease of ionization, which diminishes the tendency to coordinate. (2) The increasing distance of the nucleus from the coordinating electrons with increasing atomic volume makes it less likely that additional electrons will be held with ease. (3) On the other hand, there is an increase in the maximum coordination number with the elements of higher atomic number. These factors are in keeping with a maximum stability for the tetracovalent compounds occurring with sodium.

Sodium in Biological Systems. Sodium is essential to higher animals which regulate the composition of their body fluids and to some marine organisms. The several important roles played by the sodium cation in biological systems, frequently in concert with the potassium cation are described in the entry on **Potassium and Sodium (In Biological Systems)**.

SODIUM CARBONATE. See **Leavening Agents**.

SODIUM CHLORIDE. NaCl, formula weight 58.44, white solid, cubic crystal structure, mp 800.6°C, bp 1,413°C, sp gr 2.165. Commonly called "salt," the mineral name for rock salt is *halite*. See also **Halite (Rock Salt)**. The compound is soluble in H_2O (35.7 g/100 g H_2O at 0°C; 39.8 g/100 g H_2O at 100°C), only slightly soluble in alcohol, and insoluble in HCl. Sodium chloride is produced in nearly all nations of the world, but some only have a sufficient supply for local needs. The leading salt-producing nations include the United States, China, the former U.S.S.R., West Germany, France, the United Kingdom, India, Italy, Canada, and Mexico. In 28 states of the United States and in several provinces of Canada, salt occurs as bedded or domed deposits. Most of the rock salt produced in the United States comes from Michigan, New York, Texas, Ohio, Louisiana, and Kansas. Purity ranges from 97% NaCl for Kansas salt to 99% purity and higher for Louisiana salt. The main impurities are calcium sulfate (0.5–2%), dolomite, quartz, calcite, and traces of iron oxides. Natural rock salt is mined much as coal and usually marketed without purification, after crushing and screening. For most industrial and consumer requirements, the impurities are harmless. There is no evidence that bacteria exist in rock salt. Additionally, there is some solar salt production in the Great Salt Lake area of Utah and on the west coast. Salt deposits date back to past geologic ages and are believed to be the results of evaporated impounded sea water.

Purified salt for table and industrial processing requirements of a special nature is made by dissolving raw sodium chloride in H_2O and then evaporating the H_2O to form a final product. There are several types of evaporated salt, including *granulated salt* in which each crystal is a tiny cube, and *grainer* or *flake salt*, made up of irregularly shaped crystals, often thin and flaky and unusually soft. A process for producing evaporated salt is shown in Fig. 1. Holes are drilled into the salt deposits, after which H_2O is pumped into the beds to create a brine which then is brought to the surface for refining. In this method, all insolubles are left in the bed. After some pretreatment to remove hardness and dissolved gases, the semipure brine is evaporated in multiple-effect vacuum pans. The salt crystallizes as perfect cubes of NaCl. In the system shown, each vacuum pan performs not only as an evaporator, but also as a boiler. The vapors from a preceding pan are used to heat the contents of the following pan. This system of heat economizing is possible because each succeeding pan in the series is under less pressure—hence the contents boil at a lower temperature. See Fig. 2. The lower pressure in succeeding pans results from condensation of the vapors as well as assistance from vacuum pumps. Crystal size is controlled by evaporation rate, the latter depending on the degree of vacuum, temperature, and agitation maintained. When grown to proper size, the crystals drop to the bottom of the pans and fall into the salt legs, from which they are drawn continuously in the form of a slurry. After washing, filtering, cooling, and screening, they are packaged. See also **Evaporation**.

Grainer salt is made by surface evaporation of brine in flat pans open to the atmosphere. Heat usually is furnished by steam pipes located a few inches below the tank bottom. Crystals form at the surface of the brine and are held there temporarily by surface tension. Thus, they grow laterally for awhile and form thin flakes. But, as they grow, they tend to sink and this process imparts a peculiar, hollow pyramid-like structure to them. Such crystals are called *hopper crystals*. Ultimately, the crystals sink to the bottom where they are scraped to one end of the pan. The crystals are fragile and during handling they break up, finally assuming a flake-like shape. Thus, the term *flake salt*.

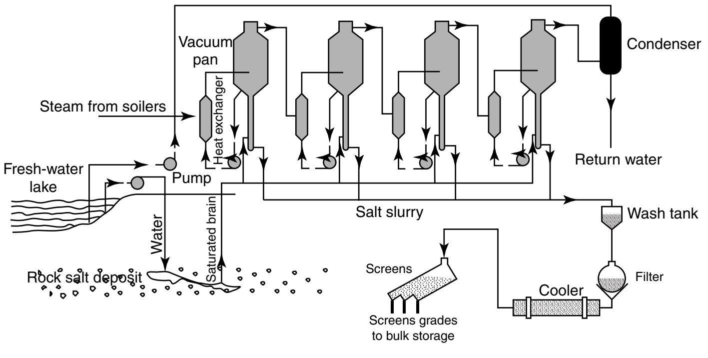

Fig. 1. Multiple-effect vacuum pans used in production of sodium chloride from brine. The saturated brine is formed by pumping fresh water directly into the rock salt deposit, leaving insoluble materials in the deposit

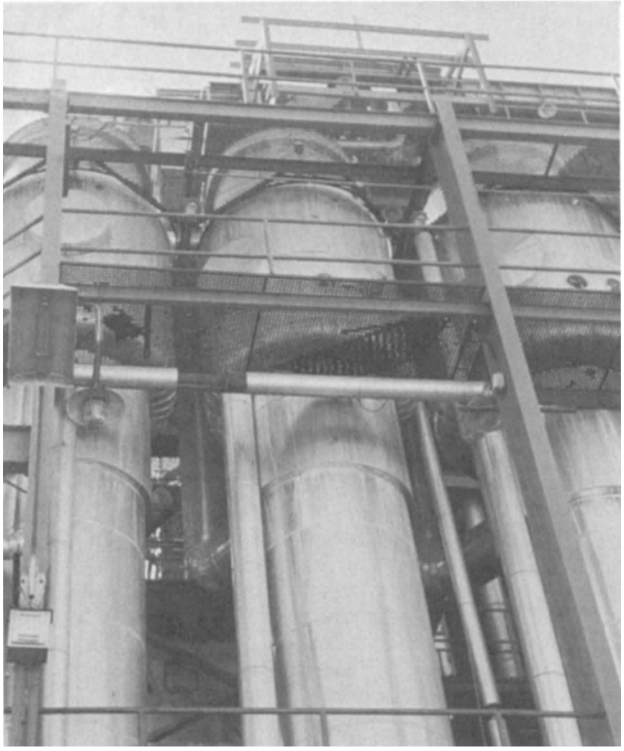

Fig. 2. Portion of train of evaporator bodies in a multiple-effect vacuum evaporation system used in production of sodium chloride

In the *recrystallizer process* for making salt, advantage is taken of the fact that the solubility of NaCl increases with temperature whereas the solubility of the principal impurity, $CaSO_4$, decreases with temperature. In *solar* facilities, the raw brine is pumped into concentrating ponds where most of the H_2O is evaporated. Some of the impurities are precipitated out in this stage, after which the saturated brine is transferred to crystallization ponds where the salt crystallizes out at a high degree of purity. Since evaporation occurs at the surface of the ponds, hopper crystals are formed as in the grainer process, with flake salt being the final product.

Uses. Sodium chloride is a very high-tonnage material. In addition to its familiar use in the diets of man and animals, representing a small part of total production, large quantities are used by highway departments to control icy road conditions, in agriculture, and as a basic chemical raw material. The chemical industry consumes about two-thirds of the salt produced, the majority of it going to electrolytic plants. Some of the basic inorganic chemicals that require salt as a starting material include soda ash, calcium chloride, caustic soda, sodium sulfate, sodium bisulfate, HCl, sodium cyanide, sodium hypochlorite, and chlorine. See also **Chlorine**; and **Sodium**.

Salt and the Diet

In food processing, the preservative and organoleptic qualities of salt are well established and it is fully appreciated why use of salt even to excess is attractive to food processors. Excessive usage is also habitual among people who "salt first and taste later." Reports show over 1 million tons (900,000 metric tons) of salt are used in foods and in connection with eating in the United States in a given year. Nearly an additional 2 million tons (1.8 million metric tons) are used in the agricultural field, much of which is consumed by livestock. The total daily intake of the North American consumer as of 1980 is estimated to be in the range of 10–12 grams of salt, which reduces to a range of 3900–4700 milligrams of sodium. Highly salted snack foods, the consumption of which has increased markedly in many parts of the world during recent years, accounts for a significant consumption of salt. In addition, certain other food ingredients, such as monosodium glutamate and soy sauce, sometimes used in excess, also contribute to the average intake of sodium.

Sodium and chloride are not normally retained in the body even when there is a high intake. See also **Chloride (Biological Aspects)**. Amounts consumed in excess of need are excreted, so that the level in the body is maintained within very narrow limits, as is also the chloride, regardless of intake. The primary route of excretion is via the urine, with substantial amounts also lost in sweat and feces. About 50% of the sodium in the human body is located in the extracellular body fluids; 10% inside the cells; and 40% in the bones. Chloride is found mainly in the gastric juice and other body fluids.

Essential though sodium is to the normal functioning of the human body, there has been considerable concern over the last few years, about the amount of salt in the diet. This concern centers mainly on possible relationship between salt and hypertension (high blood pressure).

Hypertension afflicts more than 20% of the world population, with an estimated 24 million cases in the United States as of 1980. In 1976, Marx reported that, in about 90% of these cases, the actual causes of hypertension cannot be pinpointed.—This was in face of the fact that research on the possible role of sodium in essential hypertension had been underway for 60 years or longer. Tests of unmedicated persons with essential hypertension have been found to indicate a lowering of blood pressure when sodium intake is restricted below one gram per day—and that the blood pressure rises again if additional sodium is taken. However, in other studies, some persons have retained a normal blood pressure level even when fed substantially increased amounts of salt (or other sodium-ion-furnishing substances). In 1976, Freis reported positive correlations between estimated average salt consumption of various ethnic populations and their incidence of hypertension. But such studies are complicated by many factors, including the inability to control or eliminate other possible causes of hypertension, such as obesity, genetic predisposition, general nutritional status, and potassium intake. It also has been generally proved extremely difficult to determine differences between individuals within these cultures.

Nevertheless, the concern remains on the part of a large number of professional people who feel that someday a definitive correlation will be made. And, with considerable awareness of the lay public in this regard, very definite pressures are being exerted on food processors to reduce salt usage and to more accurately label their merchandise in this regard.

The physiology of the sodium-potassium relationship is explained in some detail in the entry on **Potassium and Sodium (In Biological Systems)**.

Concerning the sodium content (much of which is derived from salt), the following composition data may be of interest. The figures in parentheses are milligrams of sodium per 100 grams of food.

Meats: Canadian bacon (2555), bacon (1077), cured ham (860), beef liver (136), pork chops (60), ground beef (48).

Cheeses: Parmesan (1848), process (1421), blue (1396), brick (557), cream cheese (294).

Other dairy products: Ice cream (83), whole milk (50), sherbet (45).

Miscellaneous foods: Pretzels (7800), soy sauce (regular) (6082), dill pickles (4000–5000), soy sauce (mild) (3569), green olives (2400), soda crackers (1100), salted peanuts (groundnuts) (418), eggs (122).

Vegetables: Beet greens (130), celery (126), dandelion greens (76), kale (75), spinach (60), beets (60), watercress (52), turnips (49), carrots (47), artichokes (43), collards (43), mustard greens (32), Chinese cabbage (20). Other common vegetables range between (10) and (18).

Sodium Chloride and Energy

As pointed out by Wick (*Oceanus*, **22**, 4, 28, 1980), most of the energy in the oceans is bound in thermal and chemical forms. Although thermal energy is presently commanding the most attention, within the past few years another, rather unusual, form has received notice. Where rivers flow into the oceans a completely untapped source of energy exists—represented by a large osmotic pressure difference between fresh and salt water. If economical ways to tap these salinity gradients could be developed, large quantities of energy would be available. See also **Solar Energy**.

SODIUM HYPOCHLORITE. See **Bleaching Agents**.

SODIUM THIOSULFATE. [CAS: 7772-98-7], $Na_2S_2O_3 \cdot 5H_2O$, formula weight 248.19, white crystalline solid, decomposes above 48°C, sp gr 1.685. Also known as "hypo" and sometimes misnamed "hyposulfite," sodium thiosulfate is very soluble in H_2O (301.8 parts in 100 parts H_2O at 60°C), soluble in ammonia solutions, and very slightly soluble in alcohol. When sodium thiosulfate is added to an acid, thiosulfuric acid $H_2S_2O_3$ may

be formed, but only for an instant, immediately decomposing into sulfur and SO_2.

Sodium thiosulfate is used: (1) to dissolve silver chloride, bromide, iodide in the photographic "fixing" bath, soluble sodium silver thiosulfate being formed plus sodium chloride, bromide, iodide; (2) in reaction with iodine in solution, sodium tetrathionate and sodium iodide being simultaneously formed, or with ferric salt solution, sodium tetrathionate and ferrous being simultaneously formed; and, (3) in reaction with chlorine as an "antichlor" forming sulfate and chloride. Sodium thiosulfate reacts with silver nitrate solutions yielding silver sulfide, brown precipitate, and with permanganate yielding manganous. Sodium amalgam changes sodium thiosulfate to sodium sulfide plus sodium sulfite.

Sodium thiosulfate is formed: (1) by reaction of sodium sulfite solution and sulfur upon warming; (2) by reaction of sodium sulfite solid and sulfur upon heating; and, (3) by complex reaction of sulfur and sodium hydroxide solution upon warming. Sulfur yields sodium sulfide plus sodium sulfite, and the latter reacts with excess sulfur, forming sodium thiosulfate. The sodium sulfide present may be converted into sodium thiosulfate by passing in SO_2 until the solution changes from yellow to colorless.

There are numerous other thiosulfates, including potassium, magnesium, calcium, barium, mercury, lead, and silver. All are soluble in H_2O except Ba, Pb, and Ag thiosulfates.

Thiosulfates are commonly identified as follows:

1. Dilute acids precipitate sulfur from thiosulfates (difference from sulfides and sulfites).
2. Zinc sulfate and sodium hexacyanoferrate(II) give no color (difference from sulfites).

SOFT. A nontechnical word used by chemists in several senses, it describes the following: (1) an acid having little or no positive charge and whose valence electrons are easily excited; (2) water that is relatively free from calcium compounds. See also **Water (Hard)**; (3) wood from coniferous trees.

SOFTENER. 1. A substance used when dry powders are added to a polymeric material (e.g., rubber or plastic) to reduce the friction of mechanical mixing and to facilitate subsequent processing. It exerts both lubricating and dispersing action, often by means of emulsification. Examples are vegetable oils, asphaltic materials, and stearic acid, the latter being especially effective with carbon black. It is difficult to distinguish precisely between softeners and plasticizers; in general, softeners do not enter into chemical combination with the polymer, and their softening effect tends to be temporary.

2. A fatliquoring agent used to soften leather.

3. A sulfonate oil, fatty alcohol, or quanternary ammonium compound used in textile finishing to impart superior "hand" to the fabric and facilitate mechanical processing.

4. A substance that reduces the hardness of water by removing or sequestering calcium and magnesium ions; among those used are various sodium phosphates and zeolites.

SOFTENING (Water). See Water Conditioning; **Water Treatment (Boiler)**.

SOIL. All consolidated earth material over bedrock. Soil is approximately equivalent to regolith.[1] Agriculturally, soil is any one of many varied natural media that support or can support land plant growth outdoors; or, when in containers, indoors. The lower limit of *topsoil* is normally the lower limit of biologic activity, which usually coincides with the common rooting of native perennial land plants. The word *soil* is derived from the Latin *solum* for "ground."

The upper part of the regolith is divided into topsoil and subsoil. The topsoil is usually a relatively thin layer or zone of the more highly decomposed mineral constituents of the regolith and contains a varying proportion of organic material called *humus*. This soil zone is the habitat of the shallow-rooted plants, such as most grasses. The topsoil usually passes gradationally into the subsoil, which supplies some of the moisture and food for the deeply rooted plants and trees. The subsoil may or may not pass gradationally into the underlying bedrock. Topsoil is easily destroyed by erosion when not protected by a mantle of vegetation.

Soil serves: (1) As a foundation for holding plants in place, whether tiny grasses or huge trees; (2) as a protective covering for the root structures of plants; (3) as a source and/or medium of exchange for supplying plants with nutrients; (4) and as a reservoir for moisture upon which growing plants can draw. Soil also must be capable of allowing excessive moisture to pass through its pores and drain to a lower level so that the soil will not remain excessively wet. Properties such as permeability and strength are not only of importance to the agriculturist, but to civil engineers and construction people who excavate, drill through, and handle soil in connection with buildings, roads, tunnels, etc.

Soil is a subsystem that interacts as part of a four-element system: (1) The *climatic or environmental subsystem* prevails immediately above the ground level and thus is the microclimate for a particular location. The principal variables of this subsystem are temperature, humidity, precipitation, and solar radiation—all of which interact constantly with soil. (2) The characteristics and patterns of the *hydrologic subsystem* determine essentially how water reaches the soil, both from above and below, and how water is carried away or drained from the soil. (3) The *plant subsystem* reduces the nutrient and moisture content of the soil, depending upon the particular uptake characteristics of a given plant. The plant subsystem also contributes in a major way to hold the soil in place and to protect it from disintegration and destruction by water and wind erosion. The plant subsystem also distributes moisture over the top of the soil so that all porous paths of the soil can be used to transport water rather than overloading and hence enlarging only some of the pores. The plant subsystem also protects the top of the soil against drying into a hard crust during periods of drought. Once disturbed, the characteristics of soil are difficult to replicate—a problem that arises when large projects, such as strip-mining, remove vast amounts of soil. (4) The *soil subsystem*, the properties of which are described briefly in this entry.

Lack of sufficient attention to the long-term protection of soil has caused innumerable problems and losses over the years. Although warnings of gross problems arising from soil destruction and land mismanagement were given in North America as early as the latter part of the 1600s, it required the rudest of awakenings to precipitate national interest and action in soil conservation. This came in the early 1930s in the form of the Great Dust Bowl, a national disaster that affected some 96 million acres (38.4 million hectares) of farmland in the southern part of the Great Plains region, involving parts of Kansas, Oklahoma, Texas, New Mexico, and Colorado. During just a few years of severe droughts, accompanied by frequent high winds, literally billions of tons of soil were lost. Organic matter, clay, and silt were lifted and carried for great distances. There were times when the heavily laden skies as far east as the Atlantic coast were darkened. Sand and silt dunes from 4 to 10 feet (1.2 to 3 meters) in height were formed in many locations. In some parts of the Dust Bowl, as much as 80% of the land suffered from wind erosion. Parallel situations have occurred in several other areas of the world.

The Soil Conservation Service of the U.S. Department of Agriculture was established in 1935. Concentrated and participative programs with land users in the Great Plains region from the mid-1950s to the present time have provided impressive improvements: (1) 2.4 million acres (1 million hectares) of permanent vegetative cover have been established; (2) 1.0 million acres (0.4 million hectares) of field and wind stripcropping have been introduced; (3) 169 thousand (68 thousand hectares) of grasslands have been reestablished; (4) 41 thousand acres (16.8 thousand hectares) of trees or shrubs have been placed as windbreaks; (5) 81 thousand miles (150 thousand kilometers) of terraces have been constructed; (6) 5.4 million acres (2.2 million hectares) of brush control have been provided; and (7) 9 thousand miles (16.7 thousand kilometers) of pipelines to provide water for livestock grazing lands have been installed.

Soil Characteristics and Classification

A soil is a naturally occurring three-dimensional body with morphology and properties resulting from effects of climate, flora and fauna, parent rock materials, topography, and time. A soil occupies a portion of the land surface, is mappable and is composed of horizons that parallel the land surface. A vertical section downward through all the horizons of the soil is called a *soil profile*. See Fig. 1.

[1] A general term for the entire layer or mantle of fragmental and loose, incoherent, or unconsolidated rock material, of whatever origin (residual or transported) and of a much varied character, that nearly everywhere forms the surface of the land and overlies or covers the more coherent bedrock. It includes rock debris (weathered in place) of all kinds, volcanic ash, glacial drift, alluvium, loess and aeolian deposits, vegetal accumulations, and soils.

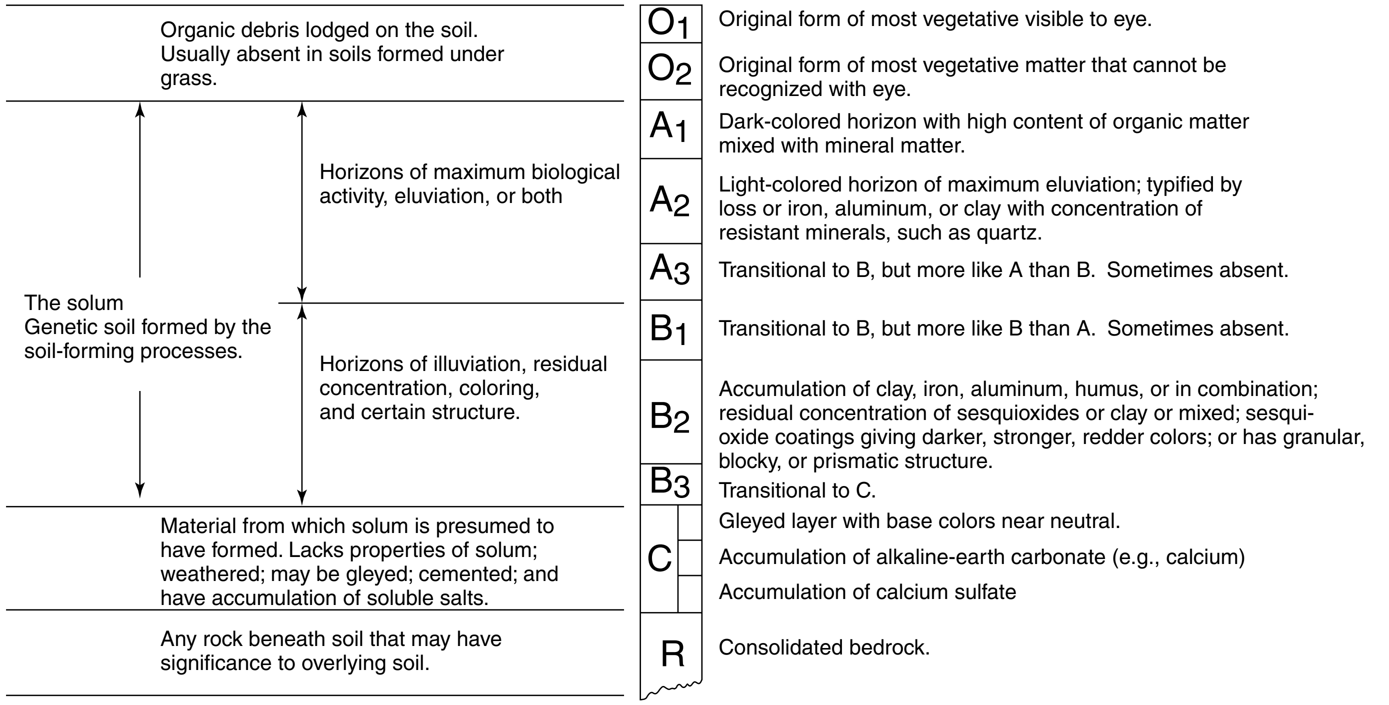

Fig. 1. Hypothetical soil profile that has all principal horizons. Not all horizons shown are present in any given profile, but every profile has some of them. Terms used in diagram: *Eluviation* is the downward movement of soluble or suspended material in a soil from the A horizon to the B horizon by groundwater percolation. The term refers especially, but not exclusively, to the movement of colloids, whereas the term *leaching* refers to the complete removal of soluble materials. *Illuviation* is the accumulation of soluble or suspended material in a lower soil horizon that was transported from an upper horizon by the process of eluviation. *Gleying* is soil mottling, caused by partial oxidation and reduction of its constituent ferric iron compounds, due to conditions of intermittent water saturation. Process is also called *gleization*. (*Adapted from USDA diagram*)

Characterization of a soil requires selection of a representative profile that is described as quantitatively as possible, utilizing comparative charts for color, structure, and other properties, and accurately measuring soil horizons. Soils are collected from horizons and analyzed for particle-size distribution, pH, organic carbon, nitrogen, free iron oxide, calcium carbonate equivalent, moisture tension, cation-exchange capacity, extractable cations (calcium, magnesium, hydrogen, sodium, potassium), base saturation, and bulk density, among other factors.

Soil classification has been oriented to soil properties in recent years, but still is tempered with concepts of soil genesis, with external associations, and with the use of the soil. The first systematic classification was by Dokuchaiev in Russia in 1882. Based upon field and laboratory characteristics, soils were grouped into three categories—*normal soils* of the dry-land vegetative zones and moors, *transitional soils* of washed or dry land sediments; and *abnormal soils*. The system involved properties of the soil with external associations of climate and vegetation. Later, an associate (Sibirtsev) renamed the highest classes *zonal, intrazonal*, and *azonal*.

A traditional classification of soils includes three categories: (1) *Young soils*. These usually show their relationship to the parent material and are typical flood plain and hilly land deposits, when the soil surfaces are constantly being replenished or disturbed. (2) *Mature Soils*. These usually cover relatively flat lands where there are good drainage conditions but relatively little erosion. The development of these soils has gone so far in some cases, particularly in semi-arid regions, that little relation is shown to the parent material and their nature has therefore been principally determined by climatic and organic factors. (3) *Old Soils*. These usually cover old flat surfaces that have not been disturbed by erosion or sedimentation for a long time. Such soils, due to the dominance of climatic factors in their formation, have lost many of their original characteristics and have, therefore, developed abnormal features. When soils are intensively cultivated their mineral and organic constituents are rapidly depleted and must be replenished by rotation of crops and the application of natural fertilizers. The method of allowing the land to remain fallow is now known to be inefficient. The complete removal of vegetable cover, such as may result from overgrazing, deforestation, or dry farming, exposes the soil to rapid erosion and destruction.

A more scientific classification of soils, adapted by the U.S. Department of Agriculture, is given in Table 1. Systematic classification of soils in the United States began with the work of Coffey in 1912 and resulted in the first comprehensive system by Marbut in 1936. Considering the size of the earth and the large number of soils represented, the detailed cataloging of soils for any country is a tremendous task. To simplify the task to some extent and to make findings more meaningful from a practical viewpoint, the European Commission on Agriculture (Working Party on Soil Classification and Survey) in 1966 correlated types of soils (soil units) with several regions designated by geography, geology, and climatology, and, to some extent, by the traditional use of the soils. Mixed criteria enter into soil classification schemes simply because the various physical or chemical characteristics, considered separately or together, do not fully identify a soil. The principal categories adopted by the European Commission include: Lowlands, Mountainous Areas and Highlands, Volcanic Areas, Zones of the Tundras and Fields, Zones of the Boreal Forests of Conifers and Birch, Zones of Mixed Forests of Conifers and Broadleaved Trees, Zones of the Central European Beech Forests and Oak Forests, Zones of the Oak Forests and of the Atlantic Heaths, Zones of the Continental Oak Forest, Zones of the European Grassland, Zones of the Mediterranean Sclerophyll Forests, Zones of the Juniper Forests and the Mediterranean Steppes, Zones of the Montane Mediterranean Forests, Zones of the Subalpine Mediterranean Forests, and Zones of the Arabo-Caspian Steppes.

Soil Genesis. The origin and processes of soil formation usually are inferred, by relating measured morphological, physical, and chemical properties of a part to other parts of a given soil. And, during the last several decades, laboratory experimentation has revealed a better understanding of many of these processes. A factor to be stressed is that, in general, these processes occur over very long periods of time and frequently under multivariate conditions—conditions that are extremely difficult to duplicate and speed up in the laboratory. In the late 1950s, an interesting group of experiments revealed information concerning the formation of something similar to podzolic soil. Organic and distilled water leachates from tree leaves were passed through columns of different soil materials. Bleached surface layers and subjacent layers of stronger color formed in the columns. Effluent solutions from the base of the columns contained detectable amounts of calcium, magnesium, iron, manganese, phosphorus,

TABLE 1. SOIL CLASSIFICATION SYSTEM (U.S.D.A)

Order and suborders	Definitions and properties
Entisols	Weakly developed soils on freshly exposed rock or recent alluvium without genetic horizons. While alluvium may be rich in plant nutrients, entisols often are too shallow, too wet, or too dry for agricultural purposes.
E1	*Aquents*. Seasonally or perennially wet.
E2	*Orthents*. Loam or clay texture, often shallow to bedrock.
E3	*Psamments*. Sand or loamy sand texture.
Vertisols	Clay soils that have deep wide cracks during periods of moisture deficiency. During rainfall, vertisols swell, slide and produce warping.
V1	*Uderts*. Usually moist, with cracks open less than 90 days/year.
V2	*Usterts*. Dry and cracked more than 90 days/year.
Inceptisols	Soils that are beginning to show development of genetic horizons. Inceptisols lack evidence of weathering and usually are found in humid climates where leaching is active.
I1	*Andepts*. Soils containing amorphous or allophanic clay, often associated with volcanic ash and/or pumice.
I2	*Aquepts*. Seasonally or perennially wet.
I3	*Ochrepts*. Soil with thin, light colored surface horizons.
14	*Tropepts*. Continuously warm or hot.
15	*Umbrepts*. Dark surface horizons; medium to low base supply.
Aridisols	Soils which contain little organic matter or nitrogen. They are usually dry for more than 6 months/year. In numerous areas, salts accumulate on or near the soil surface. Since the nutrient content, except nitrogen, of aridisols is often high, these soils can be productive with irrigation and nitrogen application. Salt accumulation can be a problem with some crops.
D1	*Undifferentiated aridisols*.
D2	*Argids*. Soils with horizons of clay accumulation.
Mollisols	Soils with dark, thick, organic-rich surface horizon, high base supply. Mollisols are highly fertile and can support a variety of crops.
M1	*Albolls*. Soils with seasonally high water tables.
M2	*Borolls*. Cool or cold soils.
M3	*Rendolls*. Soils with subsurface accumulations of calcium carbonate, but no clay.
M4	*Udolls*. Temperate or warm, usually moist.
M5	*Ustolls*. Temperate or hot. Dry more than 90 days/year.
M6	*Xerolls*. Cool to warm. Moist in winter and continuously dry more than 60 days/year.
Spodosols	Soils found primarily in cool and humid forested regions. Spodosols have subsurface accumulations of amorphous materials, mainly iron and aluminum oxides. These soils are usually strongly leached, but can be used for crop support with addition of lime and fertilizer.
S1	*Undifferentiated spodosols*.
S2	*Aquods*. Seasonally wet.
S3	*Humods*. Soils with subsurface accumulations of organic matter.
S4	*Orthods*. Soils with subsurface accumulations of organic matter, iron, and aluminum.
Alfisols	Soils of middle latitudes and degraded grasslands soils. Alfisols are strongly weathered, with gray to brown surface horizons, a subsurface clay accumulation, and a medium-to-high base supply. With adequate lime and fertilizer, the alfisols will continue to produce a variety of crops.
A1	*Boralfs*. Cool soils.
A2	*Udalfs*. Temperate to hot. Usually moist.
A3	*Ustalfs*. Temperate to hot. Dry more than 90 days/year.
A4	*Xeralfs*. Temperate to warm. Moist in winter and continuously dry more than 60 days in summer.
Ultisols	Strongly weathered soils of the middle and low latitudes. Ultisols are usually moist and low in organic matter. These soils have experienced a high degree of mineral alteration and extensive leaching. With fertilizer additions and good management, ultisols can support crops.
U1	*Aqults*. Seasonally wet.
U2	*Humults*. Temperate or warm. Moist all year. High content of organic matter.
U3	*Udults*. Temperate to hot. Usually moist.
U4	*Ustults*. Warm or hot. Dry more than 90 days/year.
Oxisols	The predominant soils of the Tropics. Oxisols have experienced the greatest degree of mineral alteration and horizon development of any soil. The humus breakdown is rapid and the soils are usually deep and porous. Oxisols require fertilization to support continued crop production.
O1	*Orthox*. Hot and nearly always moist.
O2	*Ustox*. Warm or hot. Dry for long periods, but moist for at least 90 days/year.
Histosols	Bog or peat soils composed primarily of vegetative debris in various stages of decomposition.
Mountain	Soils with various temperature and moisture parameters. Altitude, aspect, steepness of slope, and relief cause these soils to vary greatly within short distances. In many places, soil will be entirely absent.
Soil-absent	Rugged mountains and icefields.

Note: Further details can be obtained from "Soil Classification, A Comprehensive System, 7th Approximation," Soil Conservation Service, U.S. Department of Agriculture, Washington, DC. (Published periodically).

potassium, and sodium. Very fine silicate clays, e.g., illite, montomorillonite, vermiculite, and chlorite, also were suspended in the effluent. Removal, transfer, and transformation were demonstrable experimentally. Examination of the columns showed that clay was partially removed from the bleached layers and was deposited in voids in the lower layers. The experiments showed removal (*eluviation*) and addition (*illuviation*) actually occurring and at a much accelerated pace.

Organic matter probably best illustrates additions to a soil and is formed in the biological decomposition of plant and animal residues by soil microorganisms. Plants supply most of the organic matter as a dry material added to the soil surface and as roots in the subsurface. It has been estimated that short grass prairie in semiarid regions may annually add 0.7 ton/acre (1.6 metric tons/hectare) of dry matter; tall grass prairie in subhumid regions, 0.8 to 1.7 tons/acre (1.8 to 3.8 tons/hectare); pine forest in more humid areas, 2.1 tons/acre (4.7 metric tons/hectare); and tropical rain forest, from 45 to 90 tons/acre (101 to 202 metric tons/hectare). Under bluegrass roots, additions may amount to 2.4 tons/acre (5.4 metric tons/hectare) in the top 4 inches (10 centimeters) of soil.

During decomposition, plant materials are converted to carbon dioxide, water, mineral elements, and other chemically altered substances. Less-resistant materials are consumed first by soil microbes—so that more resistant plant materials remain with the new organic compounds that are synthesized by the organisms. At any time, the organic matter at a place in the soil reflects an equilibrium state of the addition of new material to the system, removal of more readily decomposable materials, and transformation to other forms by microorganisms and other agents. Organic matter also may be transferred within the soil by physical and physicochemical processes. Burrowing animals, worms, and insects turn over the soil and physically mix adjacent portions. Freezing and thawing and wetting and drying also assist in the process. Colloidal organic matter may be flushed downward or laterally and coagulate as coatings on structural aggregates in the soil.

The more unstable organic compounds are rapidly oxidized to carbon dioxide and water by various biochemical processes, while the more stable fractions accumulate. Conjugated ring compounds containing carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur and other elements in small quantities accumulate in relatively stable organic and organomineral colloidal complexes. Lignin-like, phytin-like, and nucleo-protein-like compounds are included. Sorption of the organic matter on mineral colloid surfaces, particularly layer silicates, such as montmorillonite, helps to stabilize the organic matter against biochemical oxidation. In tropical soils, high stability of soil organic matter is imparted by coatings of aluminum hydroxide and red ferric oxide. Organic and iron oxide colloids, when fairly abundant, stabilize the soil into porous aggregates through which ample air and water can circulate.

Localized spots of decomposing organic matter are important in reducing small but important quantities of iron to ferrous form and manganese to divalent form so that they become available to plants. Moderately to highly alkaline soils sometimes have inadequate activity of the reduced forms of iron and manganese, particularly in the absence of sufficient organic matter.

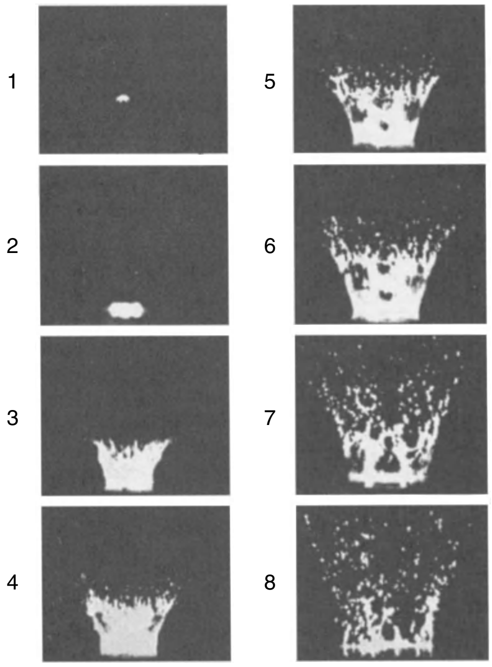

Fig. 2. Interaction of raindrops with the soil surface is an important component of the erosion process. Frames shown here were made by a 16-millimeter movie camera capable of speeds from 150 to 8000 frames per second. In the experiment, water drops are released from a tower 40 feet (12 meters) high and strike a plate glass target table. Drops from 5 to 6 millimeters in diameter are produced. Target plate is covered with water approximately 0.5 millimeter deep. (*North Central Soil Conservation Research Center, U.S. Department of Agriculture, Morris, Minnesota*)

Radiocarbon dates of organic matter from the surface horizons of soils not only reflect the equilibrium status, but point out the turnover of the system. One example of research, for example, has shown that in the Edina soil in southern Iowa, organic matter is 410 ± 110 years old in the 6-inch (15-centimeter) top layer. In the next subjacent layer, the age is 840 ± 220 years. At depths of 23 to 25 inches (58.4 to 63.5 centimeters), the organic carbon is 1545 ± 110 years old. The entire soil has been estimated as 14,000 years old.

The four kinds of changes that develop soil horizons are dependent upon many basic processes, such as hydration, oxidation, reduction, solution, precipitation, freezing, thawing, wetting, drying, among others. These processes, in turn, are dependent upon the four fundamental factors of soil formation: (1) nature of the parent material; (2) topography; (3) climate; and (4) biological activity that occurs in the upper strata of the soil. To

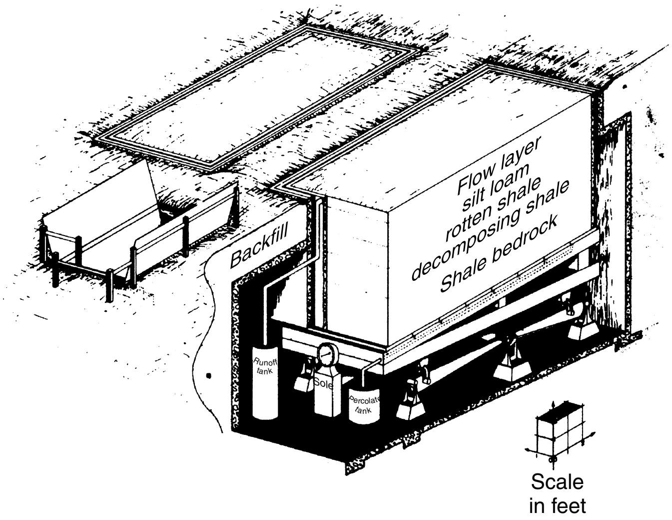

Fig. 3. A lysimeter, which provides a means for isolating soil masses and recording weight changes and water percolation. Such instruments provide accurate assessments of moisture behavior in soil. The lysimeter shown here represents $\frac{1}{500}$ acre (0.0008 hectare) and is 8 feet (2.4 meters) deep. The soil weighs 65 tons (58.5 metric tons), yet can be weighed to a precision of 5 pounds (2.3 kilograms). Soil scientists use lysimeters to study evapotranspiration, moisture consumption by crops, precipitation, water movement, and pollution. (*USDA diagram*)

these factors must be added time and imposed manual and mechanical manipulation (as by tilling, planting, etc.) and chemical manipulation (as by fertilizing and use of various control chemicals that seep into the soil).

Soil is destroyed by two principal processes—*water erosion* and *wind erosion*. The word *erosion* is the physical removal of all or part of established soil by washing or blowing away. Erosion, in some instances, also brings soil to convenient locations, but usually in so doing, unless carried out over long periods as in the development of bottomlands and deltas where crops can be grown, the new muddy, fine, highly unconsolidated and disintegrated soil causes more problems than immediate benefits. The bringing in or transfer of soil by water is commonly referred to as *sedimentation*. Much research has been carried out in connection with water and wind erosion. Typical of fundamental research is the study of splash patterns as shown in Fig. 2. The lysimeter, as shown in Fig. 3, also has been effectively used. The effects of wind erosion have been extensively studied, as exemplified by Figs. 4 and 5.

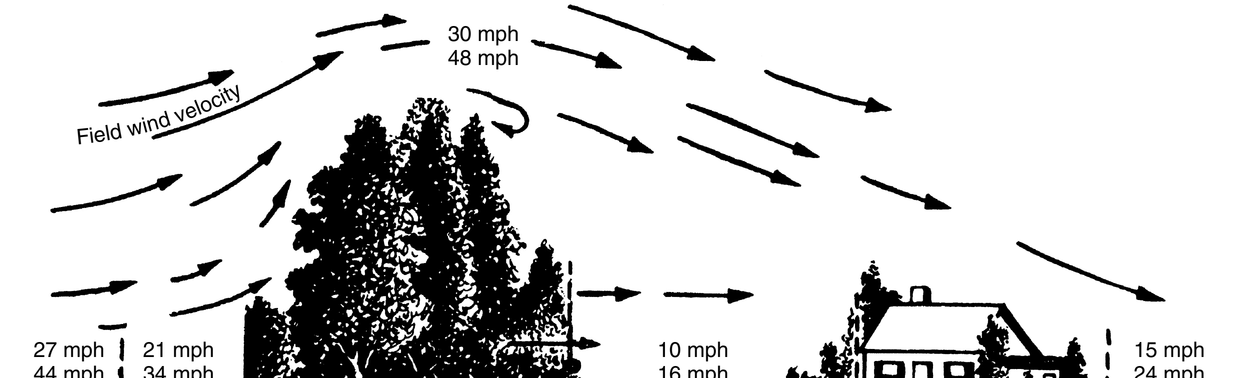

Fig. 4. Windbreaks reduce wind currents. Part of the air current is diverted over the top of the trees and part of it filters through the trees. Breaks like this reduce wind erosion of soil. Farmstead, livestock, and wildlife windbreaks should be relatively dense and wide to permit maximum protection close to the trees. Field, orchard, and garden-type windbreaks need not be so wide and dense. (*USDA diagram*)

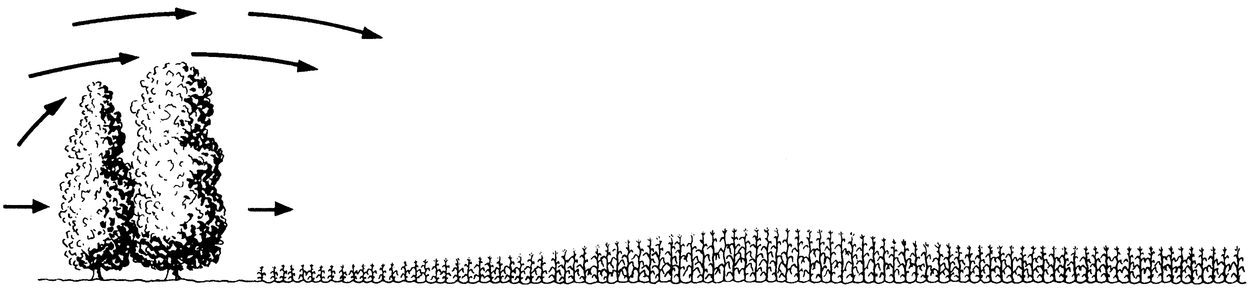

Fig. 5. Sometimes crop yields are lowest next to a tree windbreak. A common error made by some growers is to observe only the immediately adjacent area. The greatest gains are from a distance of 30 to 45 feet (9 to 13.5 meters) from the windbreak. (*USDA diagram*)

SOIL CHEMISTRY. This field includes all aspects of the study of soil as a chemical system. The eight chemical elements in soils which generally surpass 1% by weight are oxygen, silicon, aluminum, iron, calcium, magnesium, potassium, and sodium; the eleven elements making up 0.2 to 1% include titanium, hydrogen, phosphorus, manganese, fluorine, sulfur, strontium, barium, carbon, chlorine, and chromium. The most abundant minerals present in less-weathered soils are quartz, feldspars, micas and colloidal layer silicates including vermiculite, chlorite, and montmorillonite. Calcareous soils contain calcite and dolomite. More-weathered soils contain larger amounts of more resistant minerals such as kaolinite, halloysite allophane, hematite, goethite, gibbsite, anatase, pyrolusite, tourmaline, and zircon. The organic matter, or humus, content of soils varies from less than 1% to over 80%. Generally, upland soils range from 1 to 8% organic matter, while less well-drained soils are frequently higher.

Soils developed under coniferous forests often accumulate acid organic matter at the surface; the resulting leaching through the soil of chelating organic acids bleaches (*podzolizes*) the mineral soil beneath. These soils are gray when plowed. Organic matter from hardwood trees and grasses which are high in bases, particularly calcium, accumulates in the soil and causes a dark color in the surface horizon. Poor drainage leads to the development of light-colored gray horizon within the soil column (*profile*), owing in part to the reduction of iron oxides to ferrous form. A bluish color is sometimes present, particularly when vivianite, $(Fe)_3(PO_4)_2 \cdot 8H_2O$, forms. Soluble soil salts, mainly chlorides and sulfates of sodium, calcium, and magnesium, when present in quantities over 0.1 to 0.7% cause a condition known as salinity or soil alkali. If much Na_2CO_3 is present, some organic matter is mobilized and together with FeS, colors the soil black, giving rise to the name black alkali.

The most reactive portion of the soil resides in colloidal organic matter, layer silicates, and hydrous oxides of iron, aluminum, and occasionally manganese and titanium. The colloids of soil have a negative electrostatic charge arising through carboxyls of organic compounds and through excess negative charge of oxygen in the silicate structure. The negative charge is neutralized by exchangeable cations, giving systems known as colloidal electrolytes. When these exchangeable ions, i.e., counterions, are hydrogen or aluminum, the colloids act as a moderately strong acid. Different colloids range in the strength of acidity as evidenced by the shapes of the titration curves, which are analogous to the shapes of those of weak and strong soluble acids. The colloids are hydrophilic and subject to flocculation in the presence of dilute salt solutions, owing to repression of the charge developed by dissociated cations. The flocculation is reversible.

Important chemical characteristics of the soil include the total exchange capacity for cations, expressed as total meq of cations per 100 gm of soil, and the base status, which is the percentage saturation of the negative charge with cations such as calcium, magnesium and sodium. The more productive soils are about 80% saturated with calcium and magnesium. Excessive hydrogen and aluminum saturation (much over 15%) is termed soil acidity. Excess sodium saturation (12% or more) leads to dispersiveness of the soil and poor productivity.

There are also positive charges associated with aluminum and iron colloids of soils. These charges give rise to phenomenon known as anion exchange capacity, which is mainly concerned with phosphorus chemistry; the usual soluble anions such as nitrate, chloride, and sulfate are little held. Synthetic organic soil conditioners are long-chain organic molecules with carboxyl charges along the chain which react with the positive charges of the soil particles. These colloidal molecules can bind the soil particles into aggregates. Natural humus of soil acts in a similar way until oxidized by soil organisms.

Analytical methods employed in soil chemistry include the standard quantitative methods for the analysis of gases, solutions, and solids, including colorimetric, titrimetric, gravimetric, and instrumental methods. The flame emission spectrophotometric method is widely employed for potassium, sodium, calcium, and magnesium; barium, copper and other elements are determined in cation exchange studies. Occasionally arc and spark spectrographic methods are employed.

The most commonly made chemical determination is that of soil pH measurement, as an indicator of soil acidity. The glass electrode has proved the most satisfactory method for soil pH measurement because the moistened soil rapidly equilibrates in contact with the glass surface, no reagents are added to the soil, and the soil CO_2 tension is not disturbed by bubbling through of gases. Colorimetric indicators are also employed. Soils of pH 4.3 to 5 are highly acid, of pH of 5 to 6 are moderately acid, of pH 6.3 to 6.6 are very slightly acid, of pH 6.7 to 7.3 are considered neutral; soils of pH 8 to 9 are moderately alkaline, and of pH 9 to 11 are very alkaline. For acid soils, pH measurement serves as a guide to agricultural liming practices. For many crops, such as alfalfa, the soil is adjusted to pH 6.5 to 7 by the addition of ground limestone, the active ingredients of which are $CaCO_3$ in calcic limestone and $CaCO_3$ $MgCO_3$ in dolomitic limestone. A soil colloidal acid may be represented as HX. Then the liming reaction, by which the exchangeable calcium is increased, is

$$CaCO_3 + 2HX \longrightarrow CaX_2 + CO_2 + H_2O$$

The proton donor, X, represents a variety of organic and inorganic donors, including the reaction $Al(OH_2)_6 \longrightarrow Al(OH)(OH_2)_5 + H^+$. The reaction is hastened by fine grinding of the limestone, and liming materials are graded on the basis of fineness and $CaCO_3$ equivalence. Burned lime (CaO), marl ($CaCO_3$), and sugar refinery wastes [$Ca(OH)_2$] are also used in liming. For some crops, owing to disease susceptibility and preferences, soils are kept more acid, as low as pH 5.3. Calcium and magnesium, necessary to plant growth, are furnished to plants from exchangeable form.

Fine grains (finer than 20 μ in diameter) of mica [$KAlSi_3Al_2O_{10}(OH)_2$], and potassium feldspar ($KAlSi_3O_8$) slowly undergo chemical weathering in soils with the release of potassium into exchangeable form. Other ions such as calcium, sodium, and iron are also released by mineral weathering. In subhumid and arid regions the release of potassium is fast enough for crop production but must be supplemented by the addition of potash fertilizer salts in more leached soils of humid regions.

Soil chemists have rapid chemical tests for measurement of the amounts of plant-available K, P, and N, as well as other elements in soils which are essential to plants. When the quantity of an element is too low for efficient crop production, it is added as fertilizer, such as KCl, $Ca(H_2PO_4)_2$, or ammonium or nitrate salts. Large chemical fertilizer industries are required for mining, refining, and preparation of chemical salts for soil application as fertilizers.

Extraction of soils for analysis of the readily available nutrients include replacement of exchangeable cations by salt solutions, dilute acids, and dilute alkalies such as $NaHCO_3$. Fluoride solutions are employed to repress iron, aluminum, and calcium activity during the extraction of phosphorus. Extraction of the soil solution is effected by displacement in a soil column, often through the application of pressure across a pressure membrane. The soil solution is analyzed by conductance and elemental analysis methods. Also, the total elemental analysis of soils is made by Na_2CO_3 fusion of the soil followed by classical geochemical analysis methods.

Organic compounds of great variety have accumulated in soils as residues from plant and animal life of the soil. The more unstable compounds of these residues are rapidly oxidized to CO_2 and H_2O by biochemical processes, while the more stable fractions accumulate. Conjugated ring compounds containing the elements C, H, O, N, P, S, and several other elements in small quantities accumulate in relatively stable organic and organomineral colloidal complexes. Lignin-like, phytin-like, and nucleoprotein-like compounds are included. Sorption of the organic matter on mineral colloid surfaces, particularly on layer silicates, such as montmorillonite, helps to stabilize the organic matter against biochemical oxidation. In tropical soils, high stability of soil organic matter is imparted by coatings of aluminum hydroxide and red ferric oxide. Organic and iron oxide colloids, when fairly abundant, stabilize the soil into porous aggregates through which ample air and water can circulate. Decomposition of soil organic matter, especially when hastened by tillage, gradually releases HNO_3, H_2SO_4, and H_3PO_4 in amounts which are highly significant in nutrition of crops. Much of the nitrogen, sulfur, and phosphorus required by crops is furnished in this way.

The oxidation potential of well-aerated soils is low (−0.5 V) and of reduced soils is high (+0.30 V). These relationships are sometimes expressed by soil scientists as reduction potentials or redox potentials, in which case the algebraic signs are the opposite. The oxidation potential is advantageously measured with a platinum-blackened electrode in the soil in place in the field. Moderately good aeration is a requirment of a productive soil. The oxidation status may also be tested in the field by rapid spot tests for ferric and ferrous iron in soils. Most of the dilute acid-soluble iron is in ferric form in well drained soils. Localized spots of decomposing organic matter are important in reducing small but important quantities of iron to ferrous form and manganese to divalent form so as to be available to plants. Moderately to highly alkaline soils sometimes have inadequate activity of the reduced forms of iron and manganese, particularly in the absence of sufficient organic matter. Small quantities of Cu, Zn, B, and Mo must be present in productive soils in forms which have enough activity to be available to growing plants.

SOL AND SOLATION. See **Colloid Systems**.

SOLAR ENERGY. The vast quantity of energy received by Earth from the sun and the potential for converting that energy into more useful forms for society has intrigued scientists, engineers, and social planners for decades. This interest was sharpened by the oil embargo of the 1970s and, for about a decade after that, tremendous interest was displayed, by the scientific and lay community alike, in alternative energy sources, including a turn to solar energy. Energy from the sun was considered by many people as a relatively low-cost and essentially pollution-free source, particularly in contrast with polluting, nonrenewable, so-called fossil fuels and with nuclear fuels, which many people consider in a negative light. During the 1970s, but tapering off in the 1980s, many, many millions of dollars were invested by governments worldwide and by private institutions, architectural and solar equipment firms, and energy supply firms toward the development of practical, economically competitive solar energy systems.

As a result of that activity, progress in designing passive solar energy systems into office and factory buildings has been impressive, but not nearly so extensive as once estimated. Active solar energy systems, in which solar radiation is converted into another energy form (usually electrical) has also progressed, but the number of outstandingly successful installations is relatively limited, and essentially these are presently regarded as still in an experimental phase. In contrast, considerable research continues to be directed toward solar cells (solid-state devices that convert solar radiation into electric power), but it should be immediately stressed that solar cells for communication and other satellites and space vehicles are vitally needed, because they provide an energy source difficult to obtain in other ways. Cost, in this instance, is not supercritical, but one finds that solar cells for building, etc. heating and power still are essentially noncompetitive. Some relatively low-cost, small solar-powered devices designed mainly for public consumption have appeared in recent years.

To put solar energy into perspective, one should review other energy resources as well. Fortunately, throughout this encyclopedia, such energy information is available. See list of articles at end of this description and also consult alphabetical index.

Availability of Solar Energy

Not to be confused with insulation, the word *insolation* (acronym for "incoming solar radiation") defines the rate at which direct solar radiation is incident upon a unit horizontal surface at any point on or above the surface of the earth. The unit of insolation is the Langley, named after Samuel Pierpoint Langley (1834–1906), an American astronomer, physicist and pioneer in the utilization of solar energy:

$$\begin{aligned} 1\ \text{langley} &= 1\ \text{gram calorie per square centimeter} \\ &= 3.687\ \text{Btu per square foot} \end{aligned}$$

Fundamental to the practical application of real-time solar energy systems is the amount of energy received from the sun at any given location at any particular time. The energy received varies with the geometry of the sun-earth system—and thus varies with latitude, season of the year, time of day, as well as with local weather conditions. On a typical day in June, anywhere from 500 to 700 langleys of solar energy can be expected in most parts of the United States, whereas in December, with shorter days and more inclement weather, only from 100 to 300 langleys can be expected. In June, for example, both Saskatoon, Canada and Tampa, Florida receive about 600 langleys of solar energy daily, but in December, the amount of such energy received in Saskatoon drops to 75 langleys per day (only 12% of the June value at that location), whereas, in Tampa, more than 50% of the June amount is received in December. In terms of equipment costs, this translates into needing four times the solar-energy collector surface in Saskatoon as that required in Tampa in order to supply the same amount of power year-round. Maps of the type shown in Fig. 1 can be helpful in this regard.

The solar constant (intensity of solar radiation outside the Earth's atmosphere at the mean distance between the earth and the sun) has been determined by measurements from satellites and high-altitude aircraft and is 1.353 kilowatts per square meter. This extraterrestrial radiation,

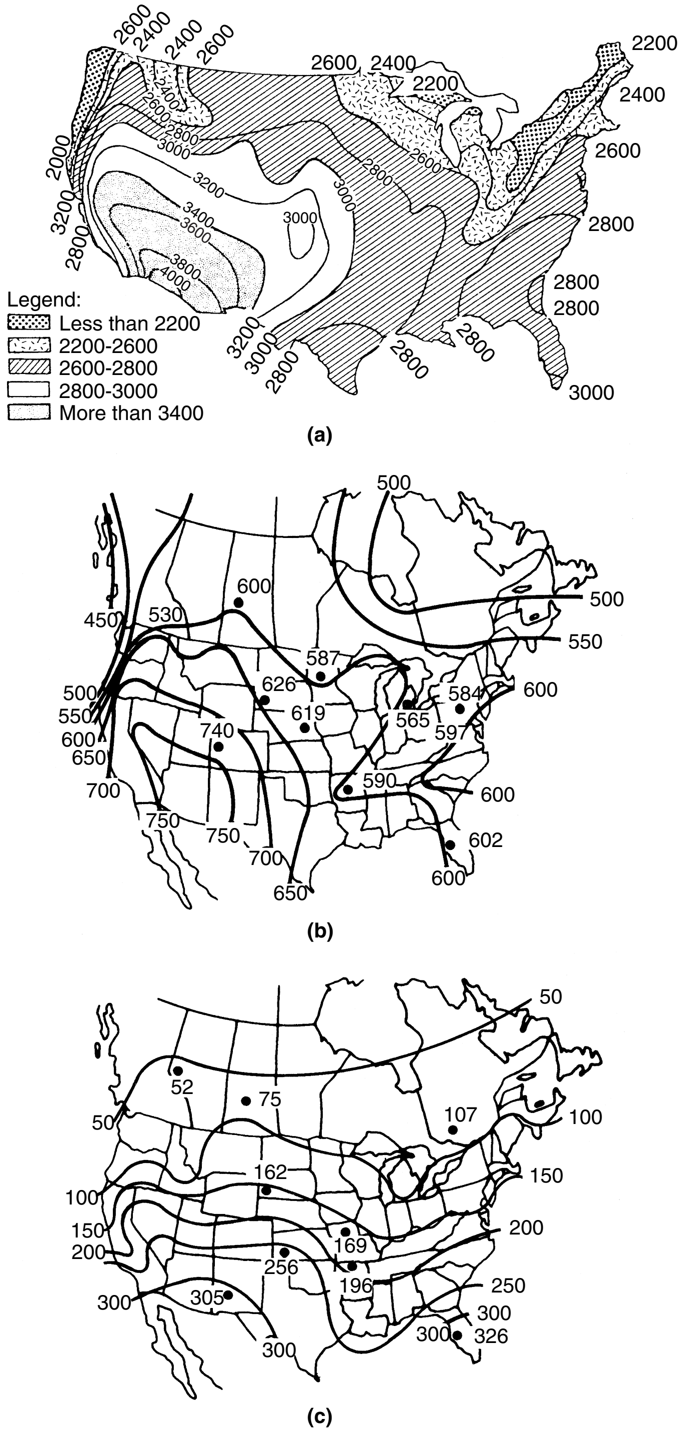

Fig. 1. Availability of solar energy (insolation): (**a**) Average number of hours of sunshine per year (United States); (**b**) median daily insolation in langleys (North America in June); (**c**) in December. (*National Oceanic and Atmospheric Administration*)

which corresponds closely to that of a blackbody at 5762°K, is 7% in the ultraviolet range (wavelength less than 0.39 micrometer) and 47% in the visible range (wavelengths from 0.38 to 0.78 micrometer), with the balance in the near-infrared (largely with wavelengths of less than 3 micrometers). Radiation is depleted as it passes through the atmosphere by a combination of scattering and absorption; the radiation that reaches the ground—the raw material of this energy source—can vary from almost none, under heavy cloud cover, to 85–90% of the solar constant under *very clear* skies.

SOLAR ENERGY FOR BUILDING AND RESIDENCE COMFORT

The application of solar energy for residences and commercial and public buildings tends to fall into three categories of increasing complexity: (1) heating only; (2) cooling only; and (3) combined heating and cooling.

Simple Heating System with Hot Storage. As shown in Fig. 2, the basic elements of this system, exclusive of pumps, valves, and controls, are: (a) a solar collector; (b) an auxiliary heating device; (c) hot storage system; and (d) heater element fan and air duct system. The solar collector absorbs heat energy from the sun and transfers it to a heat-transfer fluid, which conveys the heat to a hot storage system. From the hot storage, heat is withdrawn from storage through a heater coil, where an air-circulating fan carries heat from the coils into an air duct system. When the solar collector cannot provide an adequate amount of heat to maintain the hot storage at a minimum temperature, the auxiliary heating device, such as a fuel burner, electric resistance heating, or an electric driven heat pump, comes on. This auxiliary heat could be added to hot storage as shown in Fig. 2, or used to directly heat the room air. For the case of electric heating, heat addition to storage will provide the opportunity to limit auxiliary heat addition to nonpeak hours.

Solar Cooling System. As shown in Fig. 3, the basic elements of this system are: (a) a solar collector; (b) an auxiliary heating device; (c) a cold storage system; and (d) a heat-actuated refrigeration loop (absorption cycle). The solar collector absorbs heat energy and transfers it to a heat-transfer fluid, which in turn conveys the solar heat to the generator or boiler of the heat-actuated refrigeration loop. This loop can also be driven by auxiliary heating when the solar heat input is not adequate. If the heat-actuated refrigeration loop were of the Rankine-cycle type, rather than an absorption cycle, it might also be possible to drive the refrigeration loop with auxiliary power rather than auxiliary heating—a more favorable situation if the auxiliary is electric rather than fuel. The refrigeration loop cools the cold storage reservoir from which home cooling is supplied upon demand.

Combined Solar Heating and Cooling System. A system of this type is shown in Fig. 4. This is only one of a variety of possible systems. The major elements of this system are: (a) a solar collector; (b) an auxiliary furnace with heating coils; (c) a storage system (hot in winter; cold in summer); (d) absorption refrigeration cycle; and (e) necessary valving and controls. The system is designed to provide both heating and cooling upon demand. The heat energy generated by the solar collector is directed to either the hot storage tank or the refrigeration cycle generator, according to the seasonal mode of operation. When solar energy (either direct or stored) cannot supply the required heating or cooling load, auxiliary heating or cooling can be used.

In the winter mode of operation, solar energy is gathered at the collector and is pumped directly to the storage system. From the storage system, heat is extracted according to household needs through the heating/cooling coil in the main air duct. This coil is controlled by 3-way valves which are open to heating and shut to cooling. Heat is then extracted from the coil by air fans and carried into the house. At certain times, the solar collector and storage system will not be able to provide enough heat to maintain the heat needs of the household. In these cases, the auxiliary furnace will assume the heating load until the solar system is able to provide heating.

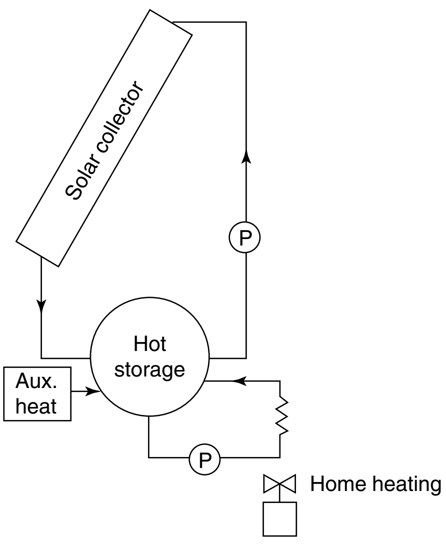

Fig. 2. Basic elements of solar heating system

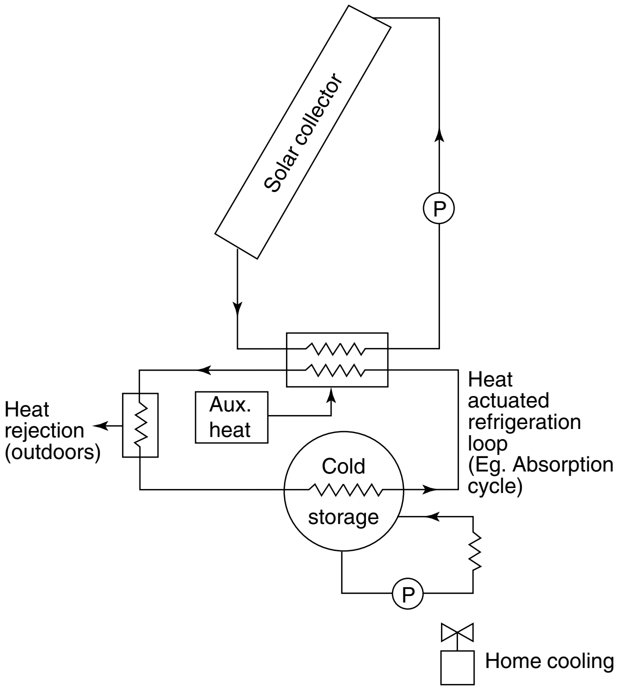

Fig. 3. Basic elements of solar cooling system. Cold storage only

This furnace will also provide auxiliary heat for domestic hot water when solar energy cannot provide this function. At times, while on winter mode operation, there will be days when cooling may be required. When this condition exists, the auxiliary furnace will drive the absorption cycle. The two 3-way valves on the heating/cooling coil will be actuated to permit chilled water from the absorption machine to circulate through this coil.

In the summer mode of operation, solar energy is gathered at the collector and pumped in the form of heat directly to the absorption refrigeration machine and to the domestic hot water heater. The collected energy serves as the main driving force for the cooling system. When the collector is unable to provide the necessary energy for the cooling system, the auxiliary furnace is activated to supplement the energy load. Once the cooling cycle is activated, the cooling produced is directed to the same storage system used for storing heat in the winter. Cooling is extracted per household needs from the storage system through the heating/cooling coil. In this mode, the 3-way valves of the coil are open to storage system and shut to direct cooling from the cooling cycle. Should the storage system not be able to provide the cooling, these valves would be closed to the storage system and open to direct cooling. While on the summer mode, the auxiliary furnace can be used to heat the house on occasional cold nights.

The foregoing systems are representative of general concepts and not necessarily of final designs or optimum arrangements. The final detail system design will, in particular, be dependent upon whether fuel or electricity is used for auxiliary heating. For the near term, natural gas or fuel oil may be preferable to electric heating. However, in the longer term, as developments in solar collection and heat storage reduce the amount of auxiliary heat required, and as heat pump technology is improved, electricity may become more attractive.

Architectural and Building Factors. Solar climate control systems will have to be integrated with different building designs. New buildings can be designed to fit the requirement of a solar climate control system while applications to existing buildings will have to be determined individually. Collectors can be installed on flat roofs of buildings, or designed to fit the sloping roofs of a wide variety of buildings. Collectors could serve a single building or a cluster of buildings. As previously pointed out,

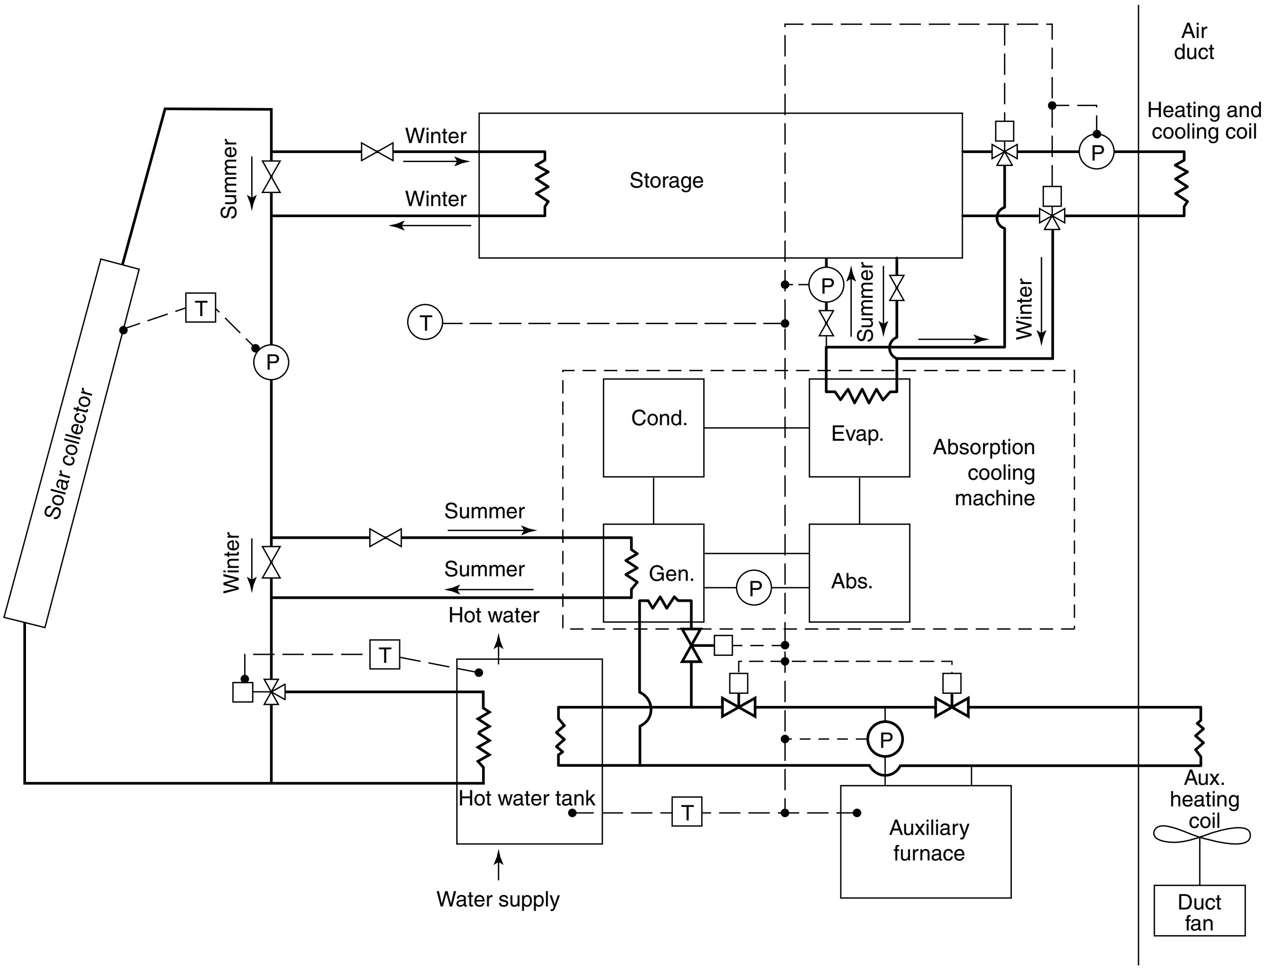

Fig. 4. Combined solar climate heating and cooling system

the geometry of the collector installation varies with location latitude. Economics to a large degree will be determined by availability of reasonably sustained sunshine.

Flat-Plate Collectors. Essentially since the outset of solar energy technology for environmental heating and cooling of living and working enclosures, the flat-plate collector has dominated the field. Within recent years, however, some of the initial needs for collectors of this nature have been obviated by more attention being given to the design of passive solar collectors, described a bit later. Also, for very large commercial installations, there has been a trend toward the use of nonfocusing or trough or line-focusing concentrators, also described later.

The essential features of a flat-plate solar collector are shown in Fig. 5. A blackened receiver surface covered by one or more special glass plates is used. Since the glass is transparent to the incident solar radiation, but opaque to the reradiated energy, the solar collector, like a greenhouse, serves to trap solar energy. The working fluid used to remove the heat from the collector can be either air flowing between the blackened surface and the glass plate or water (or some other liquid) flowing in tubes attached to the blackened plate. Solar collection efficiency is defined as the ratio of usable energy collected per unit time to the incident solar flux. Efficiency, η, may be calculated as:

$$\eta = \alpha\tau - \frac{q_L}{q_{in}}$$

where: α is the absorptivity for sunlight; τ is the transmittance of the glass plate; q_L is the heat loss from the collector; and q_{in} is the incident solar flux. The heat loss q_L is, in turn, dependent upon the emissivity, $\in$, for low-temperature radiation. Typical performance characteristics for a solar energy collector are shown in Fig. 6, which is a plot of collector efficiency versus temperature of the absorber plate for an incident radiation of 300 Btu/(hour) (square feet); 814 kcal/(hour) (square meter). Note that the efficiency falls off as absorber temperature rises. Efficiency, of course, also drops off rapidly as the incident radiation is reduced, since the heat loss term is a function of absorber temperature only.

A problem that must be faced by architects and engineers is the need to integrate collectors into building and residence design in a way to maximize thermal performance and, at the same time, provide an esthetically satisfactory structure. A major variable, depending upon energy requirements and the average solar insolation over a year, is the amount of collector area needed. Obviously, the larger the energy requirements and the less favorable the insolation, the greater the problem. Because collectors

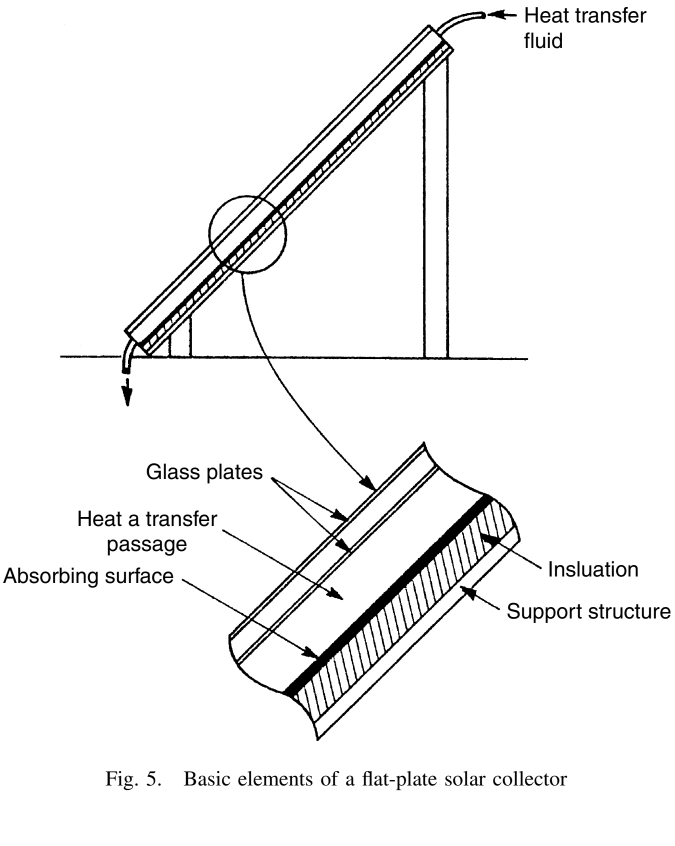

Fig. 5. Basic elements of a flat-plate solar collector

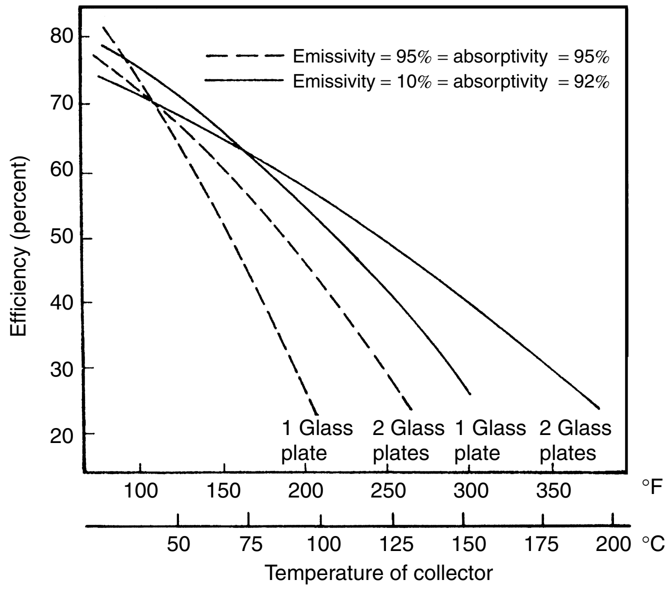

Fig. 6. Relative solar collection efficiency of plate-type solar collectors with different emissivities

must be oriented within rather narrow limits if they are to maximize their capture of solar radiation, the problem of retrofitting many existing structures sometimes renders a project impractical. Thus, the general pattern has been one of concentrating on new construction, particularly for low-rise, flat-roofed buildings, such as schools and shopping centers, where cooling may be more important than heating. Where surrounding area is available, as, for example, an adjacent parking area or facility, the collectors can be installed apart from the structure to be heated and/or cooled. Also, by turning to advanced collector designs, which provide greater efficiency, even at greater initial cost, architects and builders can better cope with the problem of collector area required. Passive heating of buildings is also a possibility in many cases.

Evacuated-Tube Collectors. In this type of collector, an inner glass cylinder, blackened to absorb solar radiation, is enclosed within an outer protective cylinder. The space between the two cylinders is evacuated. The inner cylinder is usually coated with material that reduces energy loss through reradiation. Transfer of heat is accomplished by a fluid (air or liquid) that flows through the inner cylinder. These collectors are similar to flat-plate collectors in that they can use both direct and diffuse light. However, the evacuated-tube collectors operate better during the early and late parts of the day. The vacuum provides such excellent insulation that they are less affected by high winds and cold weather than the flat-plate collectors. The output of the evacuated-tube collectors is essentially independent of ambient temperature and their efficiency is generally 40–50%. Ordinarily these collectors operate at about 180°F (82°C) for space-heating applications and certain process heating uses. Equipped with reflectors, they can operate up to 240°F (116°C), which is sufficient to drive absorption air conditioners. Cylindrical evacuated tube collectors can absorb radiation coming from any direction (360° aperture). Usually, they are mounted in arrays with a spacing of about one cylinder diameter between tubes and with a reflective material behind them.

Large-scale collectors, with or without focusing (radiation concentrators) are described a bit later.

Heat Storage. A comparison of heat-storage capacity on a volumetric basis between various storage media shows that water can store 62.5 Btu per cubic foot per degree Fahrenheit (311.5 kcal per cubic meter per degree Celsius. Rocks, bricks and gravel can store about 36 Btu/cu. ft/degree F (179.4 kcal/cu. meter/degree C). In addition to fluid media and solid media, advantage can be taken of the latent heat of a phase transition. Some salts, which melt in the desired temperature range, can store about 60 Btu/cu. ft/degree F (299 kcal/cu. meter/degree C) as sensible heat, and 9500 Btu/cu. ft./degree F (47,348 kcal/cu. meter/degree C) at the melting point as heat of fusion. However, these salts tend to undercool rather than crystallize during the cooling cycle. While undercooling can be prevented by use of nucleating agents, the fixed rate of crystal growth is very slow in

most salt hydrates. Heat cannot be withdrawn more rapidly than it can be supplied by the growth of crystals. This is a serious problem, which can only be partially overcome by the design of the storage container to provide a large heat-transfer area. Based upon these alternatives, an insulated tank of water to store heat is one of the most efficient solutions. Early work concentrated on $Na_2SO_4 \cdot 10H_2O$ which undergoes a phase transition when heated at 32°C (89.6°F). Because phase separation of this hydrate occurs on cycling, other chemical systems are being sought which can undergo thousands of cycles without loss of storage capacity.

Typically optimum storage capacity varies from 1 to 3 typical winter days' solar energy supply, depending upon the site, and for a medium-size residence or small commercial building would be in the range of 1000–2000 gallons (38–76 hectoliters). A section of a comparatively small solar-heated building is shown in Fig. 7.

Collectors also can be used as energy dissipaters by designing them to lose heat by convection and radiation to the clear night sky. The role of the collector is thus fully reversed for the cooling cycle. This requires a system for moving insulation, unless design compromises in collector design are made for both the heating and cooling cycles.

Solar collectors also can be combined with heat pumps. The latter can serve as an independent (auxiliary) source of heating energy, or the collector-storage system can serve as the energy source for the evaporator of the heat pump. The latter system has apparent advantages of lowering mean collector temperature and raising the mean evaporator temperature of the heat pump, thus improving the performance of each. See Fig. 8.

In addition to close cycle absorption cooling, open cycles are of potential interest. Desiccants can be used to absorb water vapor from room air, which then can be evaporatively cooled. The desiccant is regenerated and recycled. Löf has suggested the use of triethylene glycol as a desiccant, with solar-heated air for regeneration. Lithium chloride also has been proposed as a desiccant.

Heat-Actuated Refrigeration. A variety of heat-actuated refrigeration cycles has been proposed for solar air conditioning. These can be divided into heat engine types, such as the Rankine and Stirling cycles, and the absorption machines. Most successful to date have been the lithium bromide-water and the ammonia-water absorption cycles. Regardless of type, operating temperature is a tradeoff when coupling a solar collector to a heat-actuated refrigeration machine. The efficiency of solar collectors decreases with temperature. On the other hand, the coefficient of heat-actuated refrigerators increases with generator temperature. Figure 9 shows Carnot coefficient of performance as a function of generator temperature for an evaporator temperature of 45°F (7°C) and for heat rejection temperatures of 120°F (49°C) (typical of air cooling) and 100°F (38°C) (warm water cooling, such as might be achieved with well water). For the case of absorption machines, it is assumed that absorber and condenser operate at a common heat-rejection temperature. Using these plots, the collection efficiency–Carnot coefficiency of performance product for the simple single-pane black collector reaches a maximum rate at about 175°F (80°C) and falls off rapidly at higher temperatures. For a more refined collector, such as a single pane with selective surface collector, the efficiency coefficient of performance-product is maximum and nearly constant in the range of 200 to 300°F (93 to 149°C).

To achieve temperatures above the boiling point of water, concentrators are required as well as collectors. One of the largest high-temperature solar energy systems for building heating and cooling commenced operation in late 1978, at an eight-story office building (Minneapolis), which houses about 500 employees, and has over 100,000 square feet (929 square meters) of working space. During an average year, the system was designed to generate about 50% of heating needs, 80% of cooling energy needs, and 100% of heat for hot water needs. On the roof of a parking ramp adjacent to the building, 252 trough-like collectors track the sun to focus its rays on liquid-filled pipes. The liquid, which may reach 177°C (350°F), is pumped to an isolation heat exchanger that allows different fluids, pressures, and

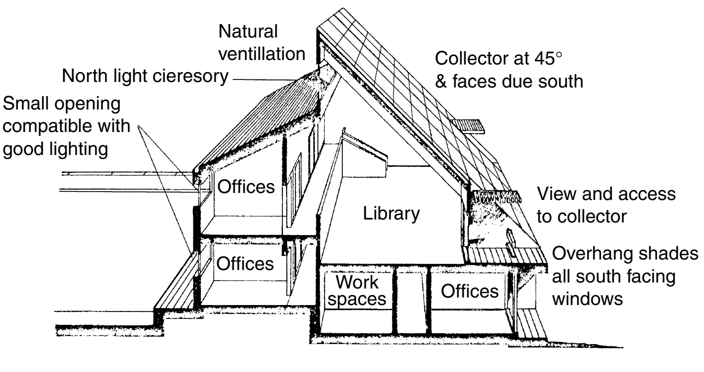

Fig. 7. Section of solar-heated building. Solar collector has an area of 3500 square feet (325 square meters) facing south at an angle of 45 degrees. There are about 8000 square feet (743 square meters) of working space. Estimates of heat loss indicate heat demand is in range of 40,000–70,000 Btu (10,080–17,640 kcal) per day. Located in the northeastern United States, the building was designed to furnish between 65 and 75% of total seasonal heating load

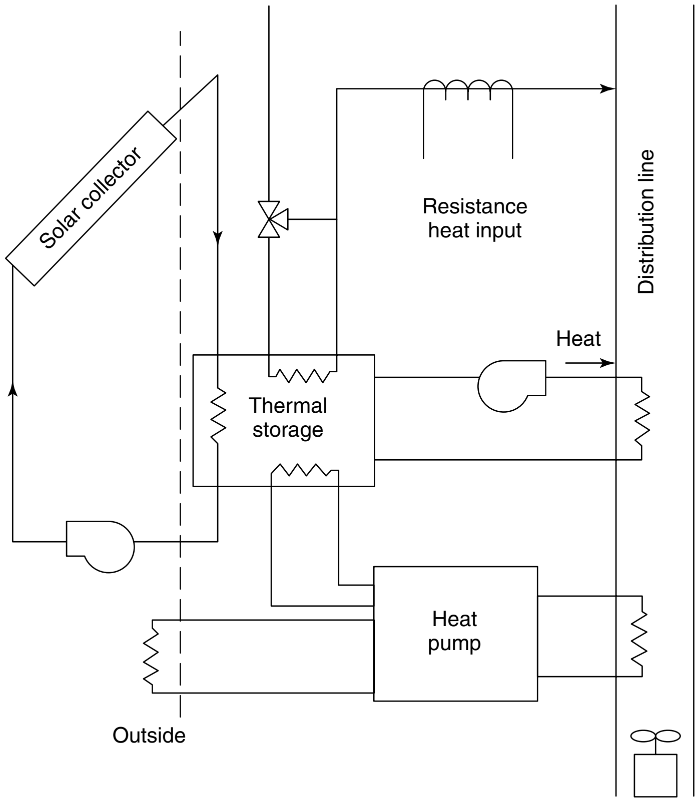

Fig. 8. Solar heating system with heat pump auxiliary

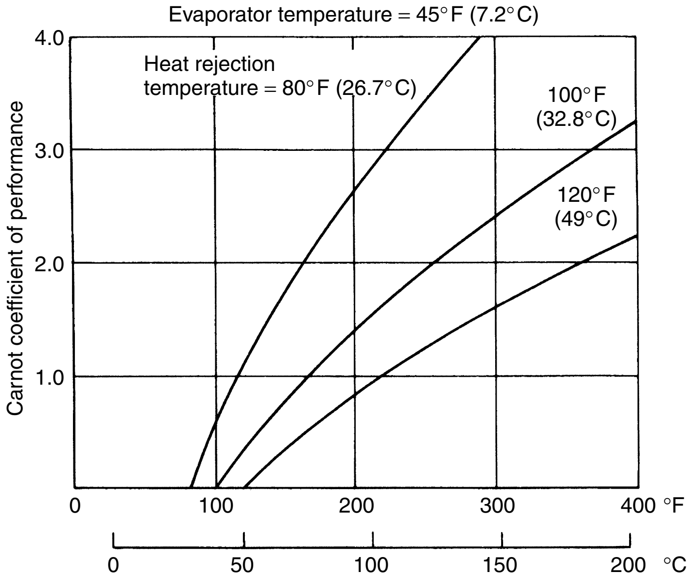

Fig. 9. Carnot coefficient of performance of heat-actuated refrigerators

flow rates to be used in the two-loop system, dictated because of the cold winter temperatures. Excess heat is stored underground in two 18,000-gallon (681 hectoliters) tanks until required. Each row of solar collectors is under the control of a local system that uses a photosensitive sun tracker and bidirectional electric drive A.C. motor. Wind, solar isolation and other safety control circuits are continuously monitored to protect the collector field from damage by weather excesses.

Passive Solar Heating and Cooling. Although not always the practical solution, one of the most sensible approaches to the utilization of solar energy does not require pumps, fans, etc., but utilizes the building or residence structure per se as the solar radiation absorber (or insulator). An example of the modern approach to passive approaches is, ironically, incorporated in Montezuma's Castle, built around 700 A.D. by the cliffdwelling Indians of Arizona. The basic philosophy is to design the structure to capture and retain heat during winter and to remain cool during summer. For example, the windows that face north are made small or largely eliminated. These windows do not contribute much to heat collection during summer or winter and thus, if small, diminish heat leakage in either direction during all seasons. South-facing windows are made large because they are required as radiation collectors during winter. However, they are protected during the summer season by an overhanging roof. These features alone, of course, are common-sense ideas that have been used by some designers for many years. Passive systems also take advantage of heavy masonry walls (or other sources of thermal mass) which can absorb solar radiation during the day and reradiate some of it at night. Such an arrangement could be called a "concrete collector." The designer can improve the effectiveness of extensive south-facing windows by constructing an interior masonry wall adjacent to the windows (lighting becomes a problem for special design). In an experimental building (Wallasey School, Liverpool, England), the south wall of the two-story concrete structure is made up essentially of double-glass windows with a heat-storage (or insulating) wall. The only supplementary heat required is derived from body heat of the students and heat radiated by electric lights. A structure of this type, of course, is subject to wider interior temperature variations than those to which much of society has become accustomed. Temperature swings can be reduced by partially decoupling thermal storage from the living and working space. In this concept, solar radiation entering the south-facing windows is absorbed by a masonry wall (sometimes called a Trombe wall) or by a water wall in which water-filled drums are placed. This wall insulates the building from high temperatures during daytime and transmits stored energy to the structure for warming during nighttime. There is an office building and warehouse in northern New Mexico which incorporates a water wall passive system and which provides 95% of the energy required for heating.

Some designers use a "roof pond," in which plastic bags filled with liquid are exposed to the sun during the day. They are covered with an insulating panel at night so that they can radiate stored heat downward to the structure. The cycle can be reversed to provide cooling during summer.

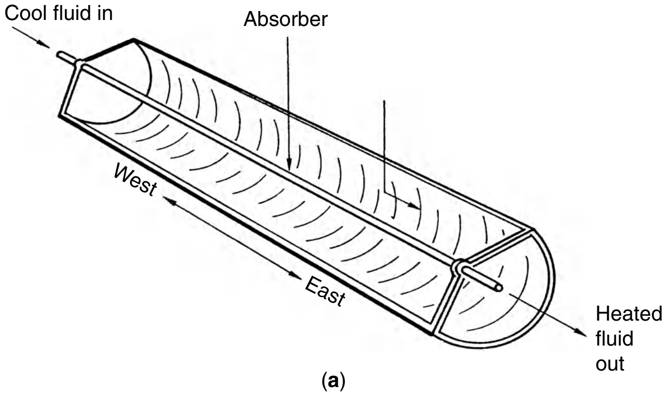
Investigations indicate that the optimum thickness for concrete thermal storage walls is about 30–40 centimeters (1–1.3 feet). Innovations in passive systems are appearing at a rapid rate. Some of these include movable insulation for shielding glass areas at night, and more compact thermal storage systems, such as ceiling tiles which have been developed by the Massachusetts Institute of Technology. These tiles contain a material that undergoes a phase change at 75°F (24°C), storing heat as the material melts and later releasing the heat to the room as the material solidifies. It is expected that, as passive systems improve, there will be a considerable impact on the traditional flat-plate collector.

Large-Scale, High-Temperature Solar Energy Systems

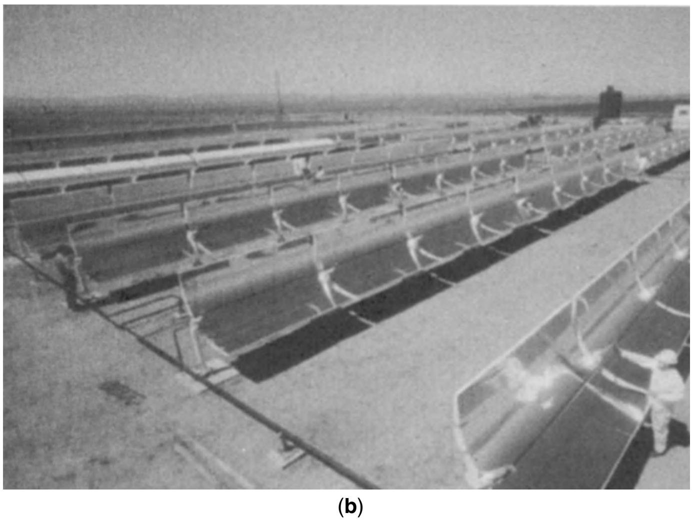
Systems in this category require concentration of solar radiation prior to its collection and utilization. Concentrators fall into three categories:

(1) *Nonfocusing concentrators* have the advantage that they do not have to continuously track the sun and thus do not require optical precision. Also, they can utilize both diffuse and direct radiation and thus are partially operable on cloudy days. They do not, however, operate as efficiently as focusing types, particularly during the early and late periods of the day. A simply designed nonfocusing concentrator essentially will consist of a stationary mirror or reflector located next to a flat-plate collector. In another approach, placing reflectors behind evacuated-tube collectors also accomplishes a modest degree of concentration. An advanced nonfocusing concentrator, known as the *compound parabolic concentrator* (CPC) was developed by the Argonne National Laboratory as the result of experience gained from designing light-concentrating devices for use in high-energy physics experiments. The device incorporates a parabolic surface designed to provide the maximum amount of radiation to an absorber for a given concentration ratio. In one configuration, the radiation is concentrated 1.8 times and, when operated in conjunction with a stationary collector, will reach temperatures as high as 250°F (121°C). Units with even higher concentration ratios (3× up to 6×) have been developed for use with evacuated-tube collectors and can achieve temperatures between 300 and 450°F (150 and 232°C). At a concentration ratio of 6, it is necessary to reorient the collector once each month. Currently, manufacturing costs are relatively high, but the CPC holds promise for a number of future applications.

(2) *Trough or line-focusing concentrators* track the sun by focusing in one direction only. Concentrations in this category of device range from 10× to 100× and they are capable of achieving temperatures between 200 and 600°F (93 and 316°C). On average, these devices deliver a minimum of 50% of the solar energy available to the heat-transfer medium in the absorber. In one configuration, mirrors form a parabolic trough that focuses radiation onto a linear absorber. Usually the mirrors are constructed of polished metal or coated plastic; the absorbers are blackened metallic pipe or evacuated-glass tubes. See Fig. 10. The entire assembly or array tracks the sun. Although normally considered in terms of relatively large thermal capacities, versions have been offered for residence and small building applications. Other, more sophisticated versions, operating at the high-temperature range, are used to drive Rankine-cycle heat engines for pumping irrigation water in a number of locations in the southwestern United States. Other installations include water heating for industrial processes. In another type of line-focusing concentrator, the optics are altered to utilize plastic Fresnel lenses for focusing the radiation onto the absorbers. Apparently a similar thermal result can be



(a)



(b)

Fig. 10. (**a**) One configuration of an optical-type concentrator with axial absorber; (**b**) parabolic troughs under test for various uses, including irrigation pumping for croplands

accomplished, as compared with the parabolic mirror approach, with a smaller optical surface.

(3) In another one-axis tracking concentrator, a fixed trough is made up of flat mirrors and tracking is accomplished by moving the absorber. Known as the *Russell collector*, this unit apparently can reach temperatures up to 900°F (482°C).

Two-axis focusing systems will be described a bit later.

High-Temperature Solar Energy

Prior to the serious consideration of high-temperature solar energy as a source of electric power, much was learned from the design of solar furnaces, the objective of which was the production of extremely high temperatures for materials testing, a very useful research function that continues. Much knowledge was and is continuing to be learned from the operation of solar furnaces—knowledge that is helpful in the design of solar power plants. It is fitting here, as a backdrop to describing the solar power tower concept, to present information on solar furnaces. Historically, solar furnaces have been selected for high-temperature research and development activities where a highly concentrated source of nonpolluting radiant energy is required. Generally such activities can be categorized as: (1) high-temperature chemistry involving the formation of very pure or otherwise unique materials; (2) high-temperature processing by which a material is fused, purified or otherwise improved; (3) high temperature property measurements involving the determination of the behavior of a material under conditions which require a noncontaminating environment; (4) determination of the thermal shock resistance or other behavior of materials in a high-temperature, high-heat flux radiant energy environment; and (5) study of high temperature solar-thermal conversion systems. Certain of these applications may be refined further by conducting the operation in an optically transparent vessel or one containing a transparent window such as fused quartz through which the radiant energy may pass and in which the composition and pressure of the atmosphere can be controlled.

A few examples of the types of high temperature studies which have been conducted in the previously described categories are: (1) gas phase reactions to form pyrolytic graphite; (2) production of very high purity fused aluminum oxide and fused silica, the production of stabilized zirconia and the purification of reactive metals in a controlled atmosphere; (3) determination of microwave transmission characteristics of dielectric materials at very high temperatures; (4) study of the thermal shock resistance of materials under high heat flux thermal radiation conditions simulating exposure to the thermal radiation pulse provided by a nuclear explosion; and (5) study of heat exchangers, such as boilers and superheaters for the production of steam for electric power generation.

Although the motivation for the design of such furnaces may be for high-temperature research, much can be learned from them that is applicable to the design of solar energy facilities for power generation. Up to the point of conversion, the problems are essentially parallel.

Solar Furnaces in France

In 1948, under the leadership of Professor F. Trombe, the Centre National de la Recherche Scientifique (CNRS) in Paris undertook the design, construction, and development of the world's first large solar furnace at Montlouis in the French Pyrenees mountains. This furnace was completed in 1952, and provided 50 kilowatts of thermal energy. The Montlouis solar furnace became the prototype design for other large high-temperature solar furnaces. Basically, this design utilized a single large heliostat (array of numerous flat mirror elements) which continuously tracked the sun to direct the sun's rays onto a concentrating reflector (parabolic or spherical) consisting of many smaller mirror elements each of which was contoured to concentrate the incident radiation at a common focal point. In the case of the Montlouis furnace, the heliostat was 43 feet (13.1 meters) wide and 34 feet (10.4 meters) tall and contained 540 flat mirrors each 50 × 50 centimeters. The concentrating reflector was made up of 3,500 mirrors 16 × 16 centimeters arranged in a parabolic configuration 36 feet (11 meters) wide and 30 feet (9.1 meters) high with a focal length of 6 meters. Each of the 3,500 flat mirror elements in the parabolic concentrator was mechanically contoured and aligned to focus the radiation received from the heliostat onto the focal point of the parabola.

The successful performance of Montlouis solar furnace led to the use of its design as the prototype for the next three large single heliostat-concentrator solar furnaces which were to be built during the next twenty years. All three of these furnaces were similar to the Montlouis furnace in size, operation and thermal power level and were constructed by: (1) U.S. Army Quartermaster Corps, Natick, Massachusetts; (2) Tohoku University, Sendai, Japan; and (3) the French Army's Laboratoire, Central de L'Armement, Odeillo, Font-Romeu, France. In 1973 the U.S. Army's solar furnace was moved to the Nuclear Weapon Effects Laboratory, White Sands Missile Range, New Mexico, where it became operational in 1974.

Although the Montlouis solar furnace played a major role in developing applications for high-temperature solar energy, and in providing design information for the three other large solar furnaces, its most valuable contribution to the field of high-temperature solar energy was the experience and background it provided the CNRS Solar Energy Laboratory. This led them to design and construct the CNRS 1,000-kilowatt solar furnace.

The CNRS 1,000 kilowatt solar furnace is located at Odeillo, Font-Romeu, altitude of 5,900 feet (1798 meters) about 25 miles (40 kilometers) east of Andorra and 5 miles (8 kilometers) west of Montlouis. At this location, the sun shines as many as 180 days a year and solar intensities as high as 1,000 watts per square meter are common. The solar furnace was completed on October 1, 1970, after more than 10 years of construction.

Figure 11 is a schematic of the CNRS 1,000-kilowatt solar furnace. This furnace utilizes 63 heliostats to direct the sun's rays onto the surface of the giant parabolic concentrator.

The 63 heliostats are each 7.5 meters wide by 6 meters high and contain 180 single flat mirror elements 50 × 50 centimeters. The total area of mirror surface in the 63 heliostats is 2,835 square meters or over one-half the playing area of a football field.

The heliostats are located directly north of the parabola and are arranged on eight terraces. Each terrace corresponds in elevation to one of the floors of the building supporting the concentrating parabola. A solar beam of constant energy is thus directed horizontally and southward from the heliostats to the mirrors that make up the concentrating parabola.

Each heliostat is designed to illuminate a specific area on the parabola and is equipped with a dual optical control system, which maintains the proper orientation for each heliostat by means of a dual hydraulic system. This dual system permits each heliostat to be operated in either a "search" or "track" mode. In both cases, the optical guidance system uses an optical tube, which contains four photodiodes that control the heliostat motion in east-west and up-down direction.

When operating in the "search" mode a short (10-centimeter) optical tube with a 40 degree acceptance angle is used to activate the "fast" hydraulic system, which operates in an on-off mode to quickly bring the heliostat to within the operating range of the "track" system. In the "track" mode a 100-centimeter optical tube is used to control a slower acting hydraulic system which operates in a proportional control mode. The size of the sun's image at the base of the 100-centimeter tube is $\frac{1}{2}$-inch (13 mm) in diameter and the accuracy of the control is one minute of arc.

The concentrating parabola has a focal length of 18 meters, is 40 meters high and 54 meters wide, and the focal axis is 13 meters above the first floor. The parabola consists of 9,500 initially flat glass mirrors that were mechanically curved and adjusted to provide a solar image of minimum diameter at the focal point. Almost two years were required to accomplish these two precise adjustments which were completed on 1

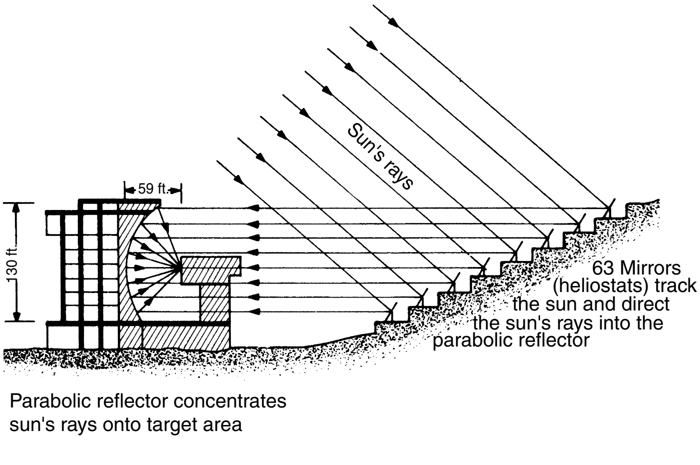


Fig. 11. Schematic representation of the 1000-kilowatt solar furnace at Odeillo, Font-Romeau, France. (*Centre National de la Recherche Scientifique*)

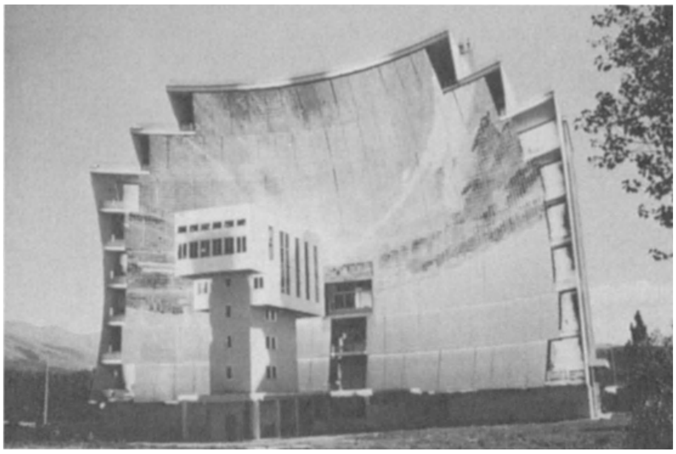

Fig. 12. Large parabolic reflector and focal building in foreground. Concentrated energy is directed at the solar furnace located within the focal building. Installation is at Odeillo, Font Romeu, France. (*Photo by Glenn D. Considine*)

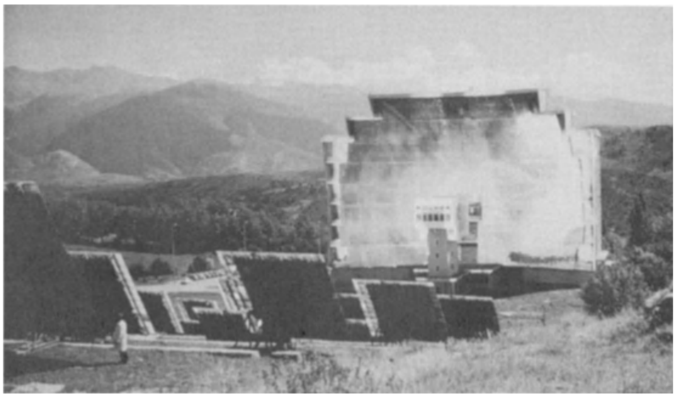

Fig. 13. Field of heliostat-controlled collector-reflector mirrors, which direct their energy to the parabolic reflector at the solar furnace installation at Odeillo, Font-Romeu, France. (*Photo by Glenn D. Considine*)

October 1970. Figure 12 shows the parabola and the focal building into which the concentrated solar energy is directed. See also Fig. 13.

The solar energy incident on an area of about 2,000 square meters is concentrated by the parabolic reflector onto an area of less than 0.3 square meters. Sixty percent of the total thermal energy (about 600 kilowatts) is concentrated in an area of less than 0.08 square meter at the center of the focal plane of the parabola.

The diameter of the image of the sun at the focal point is 17 centimeters and 27% of the thermal energy (about 270 kilowatts) is concentrated in this area. Heat flux data in watts per square centimeter in the focal area are presented graphically in Fig. 14. Curve 0 represents the heat flux at the focal plane. Curve d/2 shows the heat flux and temperature at a plane removed one-half the diameter of the solar image (8.5 centimeters) behind the focal plane. Curve d presents the same data on a vertical plane removed one diameter of the solar image (17 centimeters) behind the focal plane.

Solar Tower Energy Collector

Authorities have observed that solar energy can be usefully collected optically from one square mile (2.6 square kilometers) of surface area, or even larger, and concentrated onto a central receiver by an array of heliostats, i.e., independently steered mirrors. By judiciously spacing mirrors over 35% of the area, such a system in the desert southwest of the United States, for example, could collect 2800 megawatt-hours thermal per day in midwinter and almost twice that amount of energy in midsummer. In order that the reflected radiation from this field be efficiently intercepted, the central receiver would have to be several hundred meters high.

Unlike the Odeillo installation, previously described, where a field of heliostats finally focus their energy to a small aperture by way of a huge parabolic reflector, in the solar tower approach, the energy from each mirror is directed to a central receiving tower, located high above the field, as

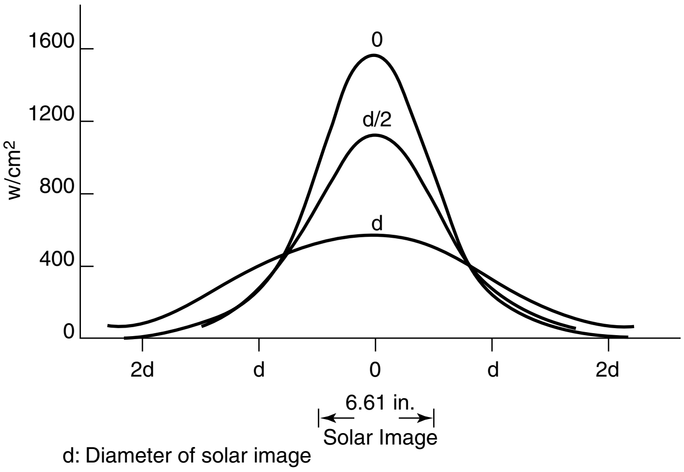

Fig. 14. Solar energy versus distance from focal point in Odeillo solar furnace. (*Georgia Institute of Technology*)

shown schematically in Fig. 15. Shown is a large array of heliostats by which essentially flat mirrors are automatically steered to reflect or redirect the incident solar radiation to a high tower. It is assumed that the terrain of the heliostat field is flat. However, a gentle slope southward would be advantageous. After reflection from the mirrors, the redirected solar energy can be absorbed and converted to heat by a black body receiver placed in the focal region. The heat can be transported down the supporting tower by way of liquid metal and/or steam lines and can be stored or used to operate a conventional turbine generating station. Alternate uses would be direct conversion to electricity by way of high-power-density solar cells placed in the focal region, or use of the heat to produce a fuel thermodynamically. Two-axis control can be obtained by either hydraulically or electrically operated servo-mechanisms that derive a signal from a simple position-sensing element.

It requires energy collected from an area like a square mile to be of interest to power utilities. Energy collection from hundreds of such installations would be required to make a significant impact on the energy supply. If one replaces the 300-meter tower with geometrically identical systems using 100-meter towers, it is found that 9 such towers would be required. Although the cost of nine smaller towers would compare with the cost of a single, large tower, additional costs and losses would be incurred in connecting heat-transfer lines to a central generator to handle 9 collectors. Also, heliostats smaller than about 20 square meters are not economical because the cost per heliostat of the support, actuator, and steering systems have a substantial fixed component.

The first choice of heat-transfer fluid would be steam because it would appear not to require any new technology. However, because the flux density that must be absorbed and transferred to the fluid can be appreciably higher than in conventional steam plants, efficient operation may require some new technology. Also, because of the large daily and seasonal heat flux variations, the design of the receiver is not trivial and may ultimately be best accomplished by utilization of liquid metal, such as sodium, for heat transfer from the receiver surface to a steam line. Liquid sodium technology has been developed for nuclear reactors and operating temperatures of 550 to 650°C appear reasonable. Sodium also presents a promising high-temperature thermal storage medium. In general, the

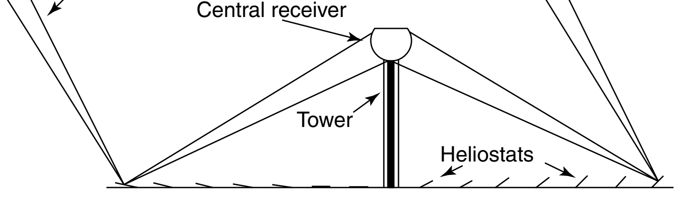

Fig. 15. Schematic diagram of solar tower energy concept

thermal cycling due to the intermittent nature of solar energy of this high-temperature system will have to be considered in any detailed design. The black body boiler surface should not deteriorate at high temperature in the presence of air. If deterioration is a problem and if convective losses are appreciable an inverted cavity design can be used in order to avoid the use of vacuum jacketing.

Solar energy may best be utilized at first by a steam generator operating in a solar-only mode with short-term storage of an hour or less to provide operational stability. Because utilities require very high reliability, little new plant capacity credit would be given such a plant because of possible cloudiness. New plant credit could be given if there were possibilities of using liquid fuels, such as liquid petroleum gas or oil for backup. This could be accomplished by adding a simple low-cost, but possibly inefficient burner to add heat. Although liquid fuels may be in short supply, they are easily stored and afford an ideal way of giving a solar plant high reliability as an intermediate plant. Depending on actual operating conditions, it may be that very little liquid fuel is burned. The comparison of such a hybrid plant should be made with a solar plant that has a gas turbine as a backup. An alternate approach might be to store solar energy as sensible heat, perhaps in underground cavities, or as latent heat.

Some authorities believe that close ties between solar power and conventional electric power plants—so-called solar thermal electric designs—represent an ideal approach to the large-scale use of solar energy. In this concept, instead of a solar-powered facility being linked to traditional power-generating facilities by way of the electric grid, a fossil fuel backup for a solar system would be located at the same site as the solar electric plant. Savings could be realized through the common usage of certain equipment items. In one design, the oil-fired backup would use the same turbine as a power tower system. Some designers have estimated that this additional capability would add only about 0.26% of the total cost of the solar electric facility.

There are other authorities who believe that adapting solar energy to electric utilities will limit the economic potential of solar energy. The basic problem, is that both technologies are very capital intensive and that the electric utility, because of the high fixed costs of generation, transmission, and distribution capacity, represents a poor backup for solar energy systems. On the other hand, the solar collection system, because it represents pure, high-cost capital and because of its outage problems, cannot be considered as a part-load source of auxiliary energy for the electric utility system.

Solar Energy Plant at Electric Utility Level

Construction commenced in 1975 on an experimental 10 MWe central receiver pilot plant in a combined effort by two electric utilities in the southwestern United States, Southern California Edison and the Los Angeles Department of Water & Power, who worked in cooperation with the U.S. Department of Energy and the California Energy Commission. The start of continuous electric power production commenced in August 1984 and the plant is now up to its design capacity of 10 MWe. The plant, known as *Solar One*, is located in Daggett, California just off Highway 40 and east of Barstow. A panoramic view of the facility, clearly showing nearly 2000 heliostat-controlled mirrors focusing their collected energy on a boiler atop a 300-foot (91-meter) tower, is given in Fig. 16.

Although large and very impressive, *Solar One* is regarded as an experimental pilot plant for proving and testing technological improvements that can be incorporated in future commercial-size plants. The Daggett plant is a scale model of a 100 MWe generating plant. On its own, *Solar One* is currently furnishing the electricity requirements for a community of about

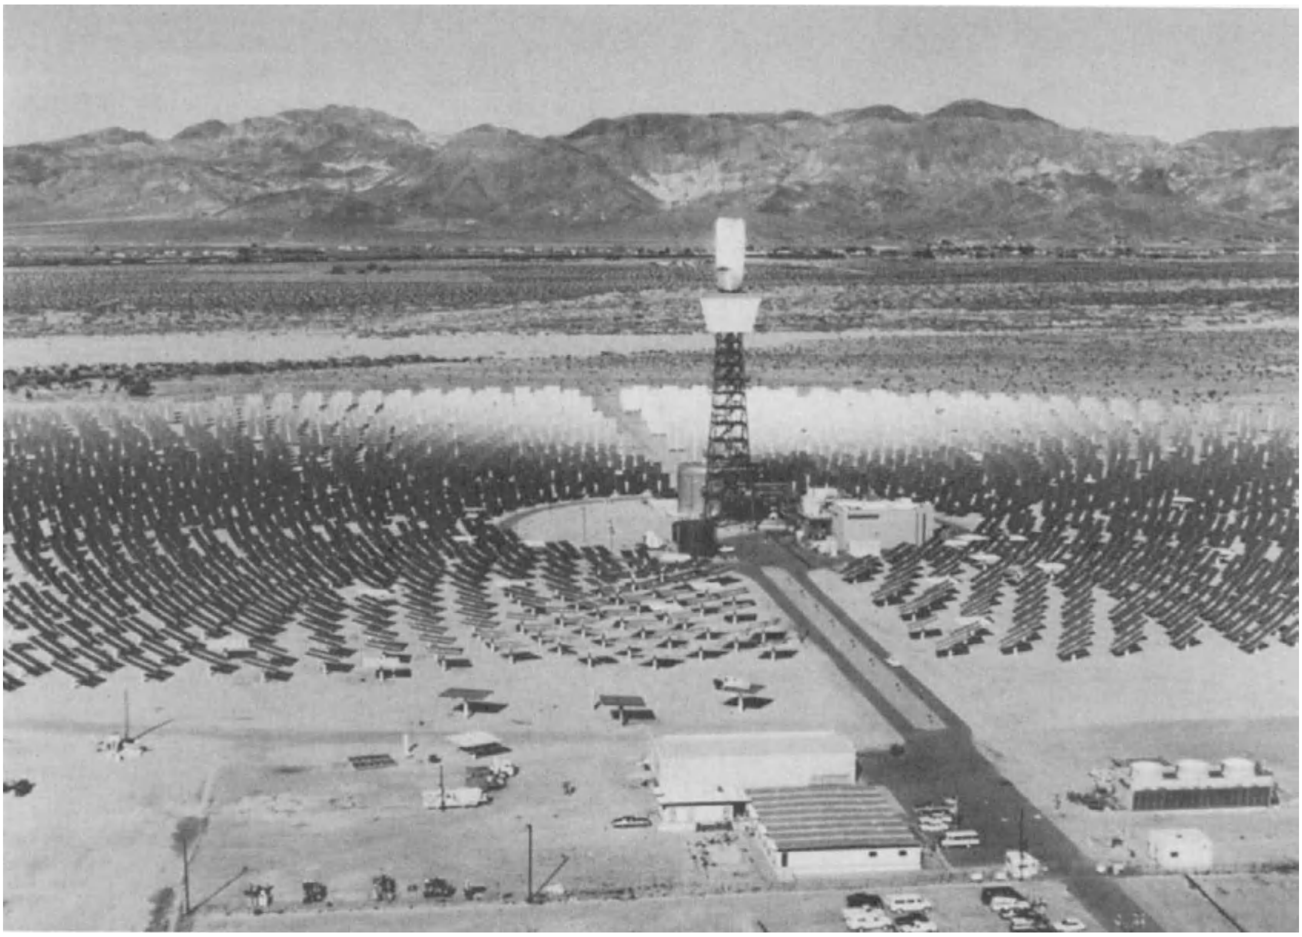

Fig. 16. Panoramic view of the world's largest solar thermal electric power plant, located on the Mojave Desert, near Daggett, California. The 10 megawatt (electric) facility commenced operation in 1982 and achieved design capacity in 1984. The collector tower (receiver upon which solar energy is reflected) is located atop a 300-foot (91-meter) tower. The north field of heliostats (mirrors kept in synchronism with the movement of the sun), 1240 in number, is shown in background; the south field (578 heliostats) is shown in foreground. Operating facilities, turbine generators, and storage tank are shown in circular middle section under the tower. The facility is operated by Southern California Edison and the Los Angeles Department of Water and Power, in conjunction with the U.S. Department of Energy and the California Energy Commission

6000 people. *Solar One* relies on a combination of both old and new solar technology. Certain features not found in typical commercial generating plants allow great flexibility in plant operation. Several different types of solar central receiver plants can be simulated within this one project.

The Basic Concept of Solar One. Computer-controlled mirrors (helio stats) totaling 1818 in number form a circular array around a central tower. Within the receiver, the solar energy is transformed into high-temperature thermal energy in a water-steam heat transport fluid. The thermal energy can be converted to electric power immediately or stored to extend plant operation. See Fig. 17. The collected solar energy is most efficiently put to work as receiver steam to power a turbine-generator (Path A). If the energy is to be stored, receiver steam follows path B and heats oil that is routed to and from the thermal storage tank. Energy is discharged from storage by using hot oil from the tank (path C) to generate steam, which is then sent to the turbine along path D.

The thermal storage system uses oil as both a thermal storage medium and a heat transport fluid. The maximum operating temperature of the storage system is 575°F (300°C). As a result, electricity is generated less efficiently than when 960°F (515°C) receiver-supplied steam is used directly in the turbine.

The operating temperature of the storage system simulates steam generation conditions in industrial plants and the chemical processing industry. Furthermore, because storage-supplied heat can supplement solar-supplied energy, *Solar One* can simulate a plant that uses both conventional fuels and solar energy.

Heliostats. The facility receives 3600 to 4000 hours of sunlight/year (9.8 to 10.9 hours/day). Construction of the 1818 heliostats for the pilot plant demonstrated that prototype designs can be successfully produced in volume quantities with conventional manufacturing techniques. Each heliostat has a reflective area of 430 square feet (39.3 square meters). The heliostat glass is specially formulated to contain a minimum amount of impurities. As a result, 91% of the incident sunlight can be reflected when the mirror surface is clean. A close-up of a set of mirrors (in a vertical position for demonstration purposes) is given in Fig. 18.

The vertical and horizontal movement of the heliostats is directed by a control system—a microprocessor in each heliostat, a controller to regulate groups of up to 32 heliostats, and a central computer. Over 97% of the heliostats are available more than 98% of the time. Operation of the heliostats has suggested areas for further research and development; for example, rain water may be sufficient to maintain the cleanliness of the mirrors, and mechanical rinsing may be required only in dry months.

The heliostats, as shown in Fig. 19, are distributed in a south field (578) and a north field (1240). The mirrors are slightly concave (approximately 1000 foot focal length with $\frac{1}{6}$-inch curvature in a 10-foot length). The total weight of a heliostat, as previously shown in Fig. 18, is 4312 pounds (1956 kg). The heliostats are normally stowed in a vertical position except when high wind conditions exist. During daylight hours, of course, the mirrors are rotated by a drive mechanism to follow the direct solar rays as closely as possible. It is interesting to note that the sun's position is calculated rather than sensed—so that even when clouds briefly cover the sun, maximum energy is reflected.

Receiver. On top of the steel tower rests the cylindrical receiver, a superheated steam boiler that is 14 meters (46 feet) tall and 7 meters (23 feet) in diameter. The receiver weighs almost 50 tons and is positioned over 20 stories above the ground. Feedwater is pumped to the bottom of the receiver, where it is vaporized to superheated steam in a single pass to the receiver's top. The steam is then piped to the turbine-generator at the foot of the tower. This steam can also provide heat to the thermal storage system.

Thermal Storage System. On a clear day, the receiver can generate sufficient steam to simultaneously operate the turbine and also deliver

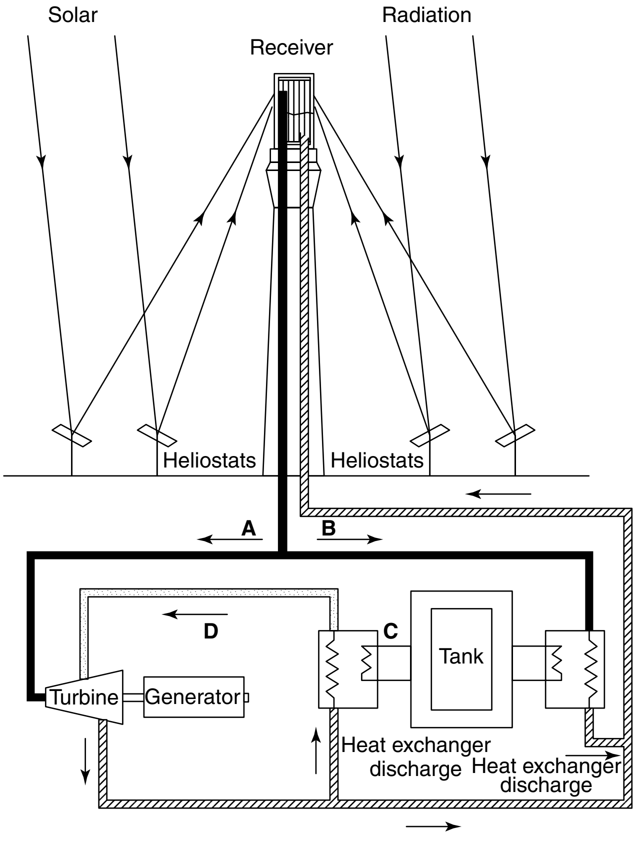

Fig. 17. General concept of *Solar One*. Within the receiver, the solar energy is transformed into high-temperature thermal energy in a water-steam heat transport fluid. The thermal energy can be converted to electric power immediately or stored to extend plant operation. The collected solar energy is most efficiently used as *receiver steam* to power a turbine-generator (Path A). If the energy is to be stored, receiver steam follows Path B and heats oil that is routed to and from the thermal storage tank (Path C) to generate steam, which is then sent to the turbine along Path D. The thermal storage system uses oil as both a thermal storage medium and as a heat-transport fluid

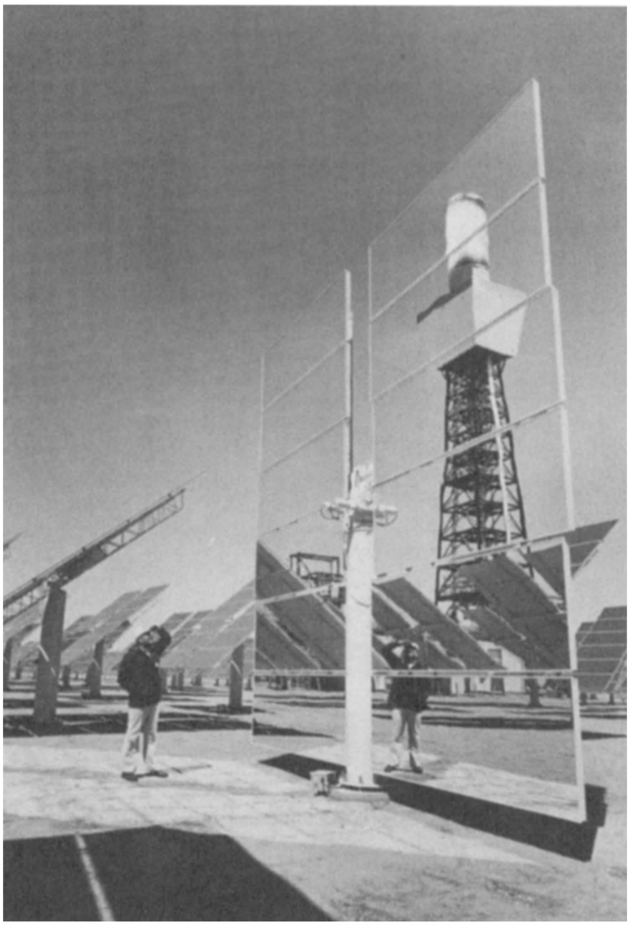

Fig. 18. Close-up of a heliostat rack assembly shown in vertical position for demonstration purposes. Note reflection of tower in mirrors. *Solar One* has a total of 1818 heliostats

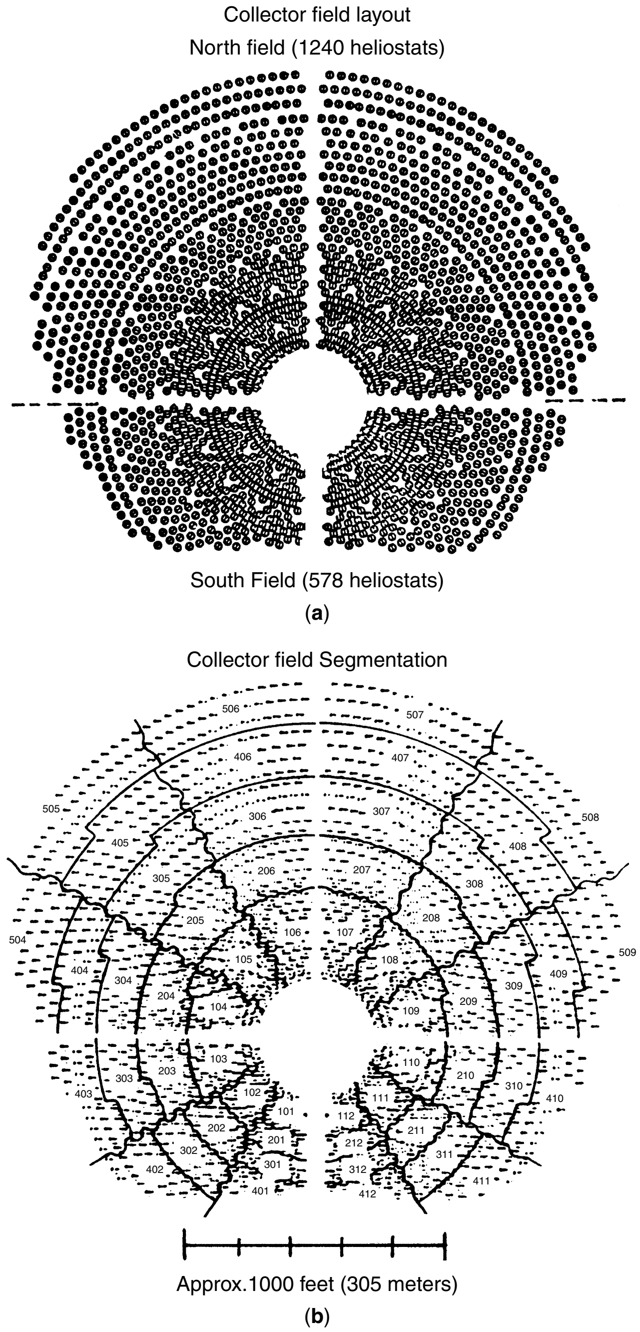

Fig. 19. (**a**) The heliostats are distributed in two fields—North and South; (**b**) for control purposes, the heliostats are segmented

heat to the storage system. The thermal storage can generate power in the evening or during periods of cloud cover. It also provides steam for start-up in the morning and for keeping selected portions of the plant warm when the plant is not operating. The steel-walled insulated storage tank has a capacity of 3.5 million liters and sits on lightweight insulating concrete. The tank is filled with sand, rocks, and a high-temperature thermal oil. Steam from the receiver is routed through heat exchangers to heat the thermal oil, which is then pumped into the tank to heat the rock and sand. This stored thermal energy can then be transferred to the turbine generator for electrical power production.

Power Generation Station. The turbine-generator is rated at 12.5 megawatts and is sized to handle the full plant system output plus all internal plantloads. The dual-admission turbine has a high-pressure steam inlet for steam produced by the receiver and a low-pressure inlet for steam produced from thermal storage. The rated turbine thermal-to-electric efficiency from receiver to steam is 35%. The efficiency is 25% from the lower quality thermal storage system.

Master Control System. In the morning the operator, through keyboard commands, positions the heliostats at standby operating points, begins water circulation in the receiver, and then issues a command to the system to start up the plant. At this point, a computer takes over and automatically directs heliostats to track the receiver. When receiver steam conditions are correct, steam is routed to the turbine. The operator then synchronizes the turbine to the electric grid, after which the minimal manual attention is needed. If conditions change, such as a cloud passing over, the control system automatically makes adjustments to keep the plant in the best operating state. If some abnormal event occurs, alarm messages tell the operator which parameters are out of normal operating range. The operator can, at any time, make changes in any plant operating condition. While the pilot plant control system was designed for controlling a water-steam central receiver solar plant, the basic functions and operating philosophy are readily adaptable to other power plants.

Performance. The requirement for production of 10 MWe was exceeded by a peak production of 12.1 MWe. Similarly, the required 7 MWe net generation from storage was exceeded by an output of 7.3 MWe. The plant also has successfully operated down to 0.5 MWe, which is considerably lower than the designed minimum operating production level of 2 MWe. The minimum sunlight threshold for operation was designed as 450 W per square meter, yet the plant has operated in direct solar radiation levels as low as 300 W per square meter. In an endurance test, the receiver and storage system kept the turbine continuously on-line for 33.6 hours and generated 127 MWe net.

Solar One was designed to have 95% of the heliostats available at any one time. Between April 1982 and April 1983, 98% of the heliostats were available for operation. This percentage later increased to 99%. The establishment of the sharp thermal gradient (thermocline) needed for the storage system has been verified. Gradients of 49°C/meter have been measured. Equally important is the very low rate of heat loss from the storage tank. The tank heat loss has been measured at 1.3% day.

Central Receiver Test Facility

The largest facility specifically designed for testing central receiver components and subsystems was built in Albuquerque, New Mexico in the late 1970s. At this facility, a 15-meter (49-foot) diameter concrete-and-steel receiver tower rises some 60 meters (197 feet) above the ground. Within the tower, three test bays at different levels are used for experiments. A huge elevator can transport equipment weighing as much as 100 tons to these test bays. There is a total of 222 heliostats; when all of them are focused on a receiver in one of the test bays, temperatures in excess of 2000°C (3632°F) can be generated. In practice, lower temperatures are used for receiver testing. The test facility has been used to try out innovative receivers that use gas, liquid sodium, or molten nitrate salts for thermal transport. In one system, molten salt has been used as the heat transport fluid and storage medium in an integrated central receiver system to produce an electrical power output of 750 kWe.

Solid-Particle Central Receiver. A new type of receiver has been under investigation. A novel concept for a central receiver uses sandsize refractory particles that free-fall in a cavity receiver. A conceptual design is shown in Fig. 20. Scientists observe that the advantages of a solid particle receiver over traditional fluid in-tube receivers are: (1) the particles can directly absorb solar radiation, and (2) the particles maintain their integrity at high temperatures. These advantages, coupled with the possibility that the particles can serve as the storage medium, could provide a cost-effective means of high-temperature solar energy utilization. High temperatures are attractive for fuels and chemical production, industrial process heat applications, or Brayton cycle electricity generation. The concept is in an early experimental stage.

Heat Engine Cycles for Solar Power

Heat engines for conversion of solar energy to electric power ideally should have the following attributes: (1) low cost per kilowatt output capacity; (2) long life and reliable operation with minimal maintenance; (3) safe and environmentally acceptable operation; (4) characteristics compatible with cycle top temperatures up to 1,000 K; and (5) efficiency approaching Carnot values.

Heat engines that are potential candidates for coupling a solar heat source include thermoelectric, thermionic, thermochemical, magnetohydrodynamic, Rankine, Brayton (simple or recuperated), and cascaded cycles.

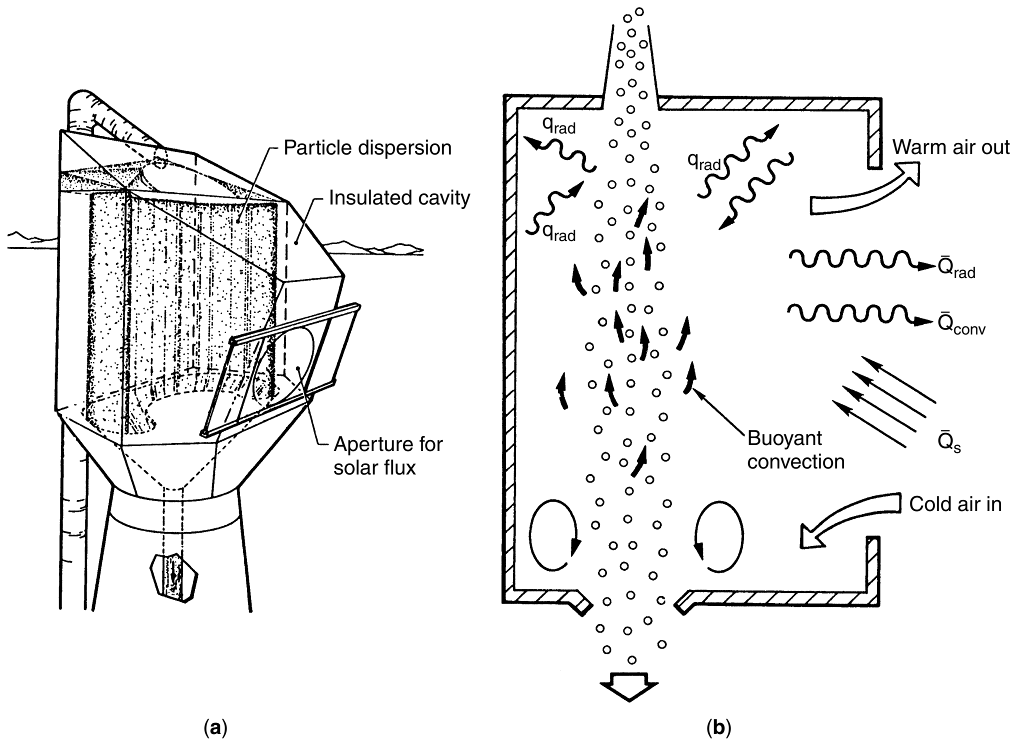

Fig. 20. Solid-particle central solar energy receiver: (**a**) conceptual design; (**b**) thermal phenomena in a solid particle receiver. (*Sandia National Laboratories*)

Rankine Cycle. The steam-Rankine cycle employing steam turbines has been the mainstay of utility thermal electric power generation for many years. The cycle, as developed over the years, is sophisticated and efficient. The equipment is dependable and readily available. A typical cycle (Fig. 21) uses superheat, reheat, and regeneration. Heat exchange between flue gas and inlet air adds several percentage points to boiler efficiency in fossil-fueled plants. Modern steam Rankine systems operate at a cycle top temperature of about 800 K with efficiencies of about 40%. All characteristics of this cycle are well suited to use in solar plants.

Brayton Cycle. In recent years, attention has been drawn to the Brayton cycle as a potential and practical alternative to the steam Rankine cycle for solar power and for high-temperature gas-cooled nuclear reactors. The Brayton cycle is most familiar in its open form as used in aircraft gas turbines. The open Brayton cycle cannot compete with steam-Rankine in efficiency. In a power-generation application, cycle efficiencies on the order of 20% would be expected. However, the Brayton cycle can achieve higher efficiency through recuperation, sometimes called regeneration. A representative cycle diagram is given in Fig. 22. The working fluid is an inert gas, typically helium. Inert gas mixtures, such as helium-xenon, have been studied and have potential advantages.

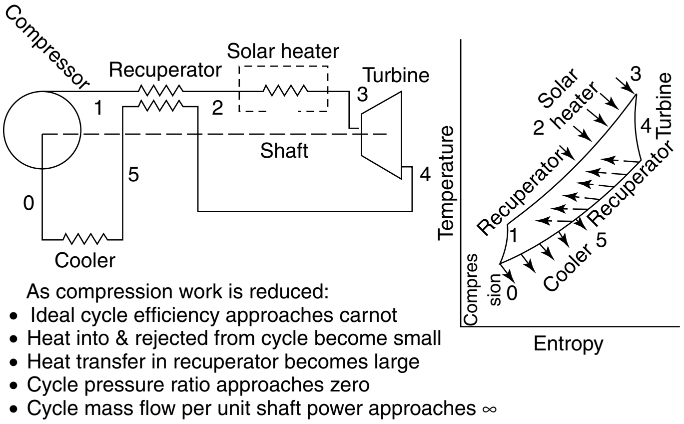

Fig. 22. Recuperated Brayton cycle diagram

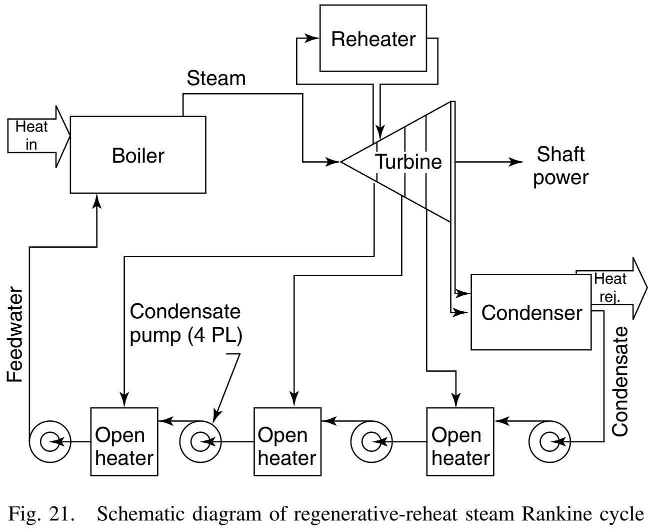

Fig. 21. Schematic diagram of regenerative-reheat steam Rankine cycle

The recuperated Brayton cycle approaches Carnot efficiency in the ideal limit. As compressor and turbine work are reduced, the average temperatures for heat addition and rejection approach the cycle limit temperature. The limit is reached as compressor and turbine work (and cycle pressure ratio) approach zero and fluid mass flow per unit power output approaches infinity. It can be expected from this that practical recuperated Brayton cycles would operate at relatively low pressure ratios, but be very sensitive to pressure drop. With the assumption of constant gas specific heat over the cycle temperature range, a good assumption for helium, the cycle efficiency of a recuperated Brayton cycle may be expressed:

$$\eta e = 1 - \left[\frac{\dfrac{r_{pc}\zeta - 1}{\eta_b} + \dfrac{\Delta T_r}{T_0}}{\dfrac{T_3}{T_0}\eta_T \left[1 - \left(\dfrac{G}{r_{pc}} \right)^{\zeta} \right] + \dfrac{\Delta T_r}{T_0}} \right]$$

where r_{pc} is compressor pressure ratio ($r > 1$)
η_b is compressor efficiency

ΔT_r is temperature difference across recuperator ($T_4 - T_2$ in Fig. 21)
T_0 is cycle lower limit temperature
T_3 is cycle top temperature
η_T is turbine efficiency
ζ is specific heat factor, $(\gamma - 1)/\gamma = 0.4$ for $\gamma = 1.67$ as for helium
G is the product of the four pressure drop factors,

$$\left(\frac{P_1}{P_2}\right)\left(\frac{P_2}{P_3}\right)\left(\frac{P_4}{P_5}\right)\left(\frac{P_5}{P_0}\right)$$

Solar Energy for Industrial/Metallurgical Processes

It is interesting to note that experiments on melting large masses of metals were conducted at the French Odeillo solar furnace as early as the mid-1970s. Since the mid-1980s, solar furnaces in other locations have researched what promises to be an important technology in the near future—namely, Solar Induced Surface Transformation of Materials (SISTM). In the past, numerous heat-treating methodologies have been practiced widely. Less traditional methods have been developed in recent years, including cladding/coating, self-propagating high-temperature synthesis, thin-film deposition, and ion-, laser-, and electron-beam processes.

Researchers have found that, for delivering large fluxes on target, the solar furnace is less capital intensive than competing methods that require an intermediate energy-conversion step. For example, a 1-square-meter (11 ft^2) solar dish can deliver about 1 kW of optical power to a target. To deliver the same amount of radiant energy, an arc lamp would have to be powered by the electrical output of an 11-square-meter (120 ft^2) dish, and a carbon dioxide laser would require the energy supplied by 26-square-meter (280 ft^2) disk.

The automotive industry, which turned to laser transformation hardening of engine and other drivetrain components, is now seriously investigating the "solar hardening" process.

Solar Furnaces No Longer Uncommon. The past decade has brought increased interest in using solar energy for industrial processes, not just to conserve energy or avoid the use of fossil fuels. Some of the important installations, as of the early 1990s, are listed in Table 1.

The time required to bring a part to treating temperature also is an important consideration. Solar furnaces have no competition on this point. See Table 2.

Chemicals Directly from Solar Energy. Whereas the early solar furnace located in Odeillo, France, was constructed for solar energy studies in general and later used for melting huge masses of metals and materials and the solar plant in the Mojave Desert in California is being used directly to generate electric power, scientists in the early 1990s were taking a somewhat different approach.

Researchers have recognized that the regions where ample sunshine is available for harvesting seldom coincide with the population and industrial centers of the world. Further, solar energy is of an intermittent nature because it depends upon clear skies with no cloud cover. I. Dostrovsky (Weizmann Institute of Science) observes that most of the limited amount of research on solar energy focuses on converting sunlight to electricity, mainly by photovoltaic and thermal methods, or, in the case of the Daggett, California, utility installation, to furnish heat to supply steam turbines.

TABLE 1. COMPARISON OF HIGH-FLUX SOLAR FACILITIES

Location	Total power Kw	Peak flux MW/m^2
Albuquerque, New Mexico		
Central receiver test facility	5000	2.4
Furnace	22	3.0
Atlanta, Georgia		
Furnace	1.3	9.5
Golden, Colorado	10.0	2.5
(measured using nonimaging secondary concentrator)		20.0
White Sands, New Mexico	30	3.6

An alternative approach is that of using solar energy to produce chemicals that can be stored and transported much as present fossil fuels. One installation along these lines is now undergoing demonstration operation in Saudi Arabia. This project, known as *HYSOLAR*, is a joint venture of Saudi Arabia and Germany. In essence, the facility consists of a plant that produces hydrogen. See also **Hydrogen (Fuel)**.

One process involves the high-temperature decomposition of sulfuric acid, using recoverable iodine as an intermediate reactant. In a first stage, sulfuric acid yields water and sulfur dioxide. In a second stage, the sulfur dioxide plus water and iodine yield hydrogen iodide and sulfuric acid. In the third stage, the hydrogen iodide yields hydrogen (the desired product) and recoverable iodine.

In an electrolytic process, hydrogen is produced by electrolyzing a mixture of sulfur dioxide and water to produce sulfuric acid and hydrogen. In still another electrolytic process, bromine, sulfur dioxide, and water react to form hydrogen bromide and sulfuric acid. By applying 0.62 V to the hydrogen bromide molecules, hydrogen is yielded and the original bromine is recovered.

This type of approach is somewhat reminiscent of the chemistry of coal gasification. More detail is given in the Dostrovsky reference listed.

Solar Energy for Detoxifying Hazardous Chemicals. The Solar Energy Research Institute, Golden, Colorado, has developed a system for detoxifying hazardous chemicals in polluted groundwater. In essence, a photocatalyst is added to the polluted water and then pumped through long, narrow glass tubes that are exposed to sunlight. High- energy photons activate the catalyst, which in turn breaks the pollutants down into nontoxic components. The tubes are mounted in reflecting glass troughs to improve the efficiency of the process. The system has proved particularly effective against trichloroethylene, once a common industrial cleaner. In this application, the polluted water is mixed with titanium dioxide catalyst. Hydroxyl radicals are created that break the offending solvent into water, carbon dioxide, and very dilute hydrochloric acid. The next step is that of determining how effective the process may be in removing other chlorinated hydrocarbons, as well as such substances as benzene, various pesticides, and textile dyes.

Photovoltaic Conversion (Solar Cells)

Photovoltaic devices made of selenium have been known since the 19th Century. Pioneering research in semiconductors, which led to the invention of the transistor in 1947, formed the basis of the modern theory of photovoltaic performance. From this research, the silicon solar cell was the first known photovoltaic device that could convert a sufficient amount of the sun's energy to power complex electronic circuits. The conventional silicon cell is a solid-state device in which a junction is formed between single crystals of silicon separately doped with impurity atoms in order to create *n* (negative) regions and *p* (positive) regions which respectively are receptors to electrons and to "holes" (absence of electrons). See also **Semiconductors**. The first solar cell to be demonstrated occurred at Bell Laboratories (now AT&T Bell Laboratories) in Murray Hill, New Jersey in 1954.

In a photovoltaic device, the energy in light is transferred to electrons in the semiconductor when a photon collides with an atom in the material with enough energy to dislodge an electron from a fixed position in the material. A common technique for producing a voltage is by creating an abrupt discontinuity in the conductivity of the cell material (typically silicon) through the addition of dopants. A basic limit on the performance of these devices stems from the fact that light photons lacking the energy needed to lift electrons from the valence to the conduction bands ("band gap" energy) cannot contribute to photovoltaic current, and from the fact that the energy given to electrons which exceeds the minimum excitation threshold cannot be recovered as useful electric current. Most of the photon energy not recovered as electricity is converted to thermal energy in the cell.

Photon energies in the visible light spectrum vary from 1.8 eV (deep red) to 3 eV (violet). In silicon, about 1.1 eV is needed to produce a photovoltaic electron; in gallium arsenide (GaAs), this is about 1.4 eV. Silicon is a comparatively poor absorber of light and consequently silicon cells must be from 100 to 200 micrometers thick to capture an acceptable fraction of the incident light. This places limitations on crystal grain size and thus, with present technology, single crystals must be used. Polycrystalline materials may alter this problem favorably and much research is being directed toward developing polycrystalline materials and, in general, for finding methods to minimize the impact of grain boundaries.

Thin films of gallium arsenide (GaAs) and cadmium sulfide/copper sulfide (CdS/Cu_2S) show potential because they are better absorbers of light and can be made thinner than crystalline silicon. Smaller crystal grains can be tolerated better than with crystalline silicon. See also **Thin Films**. These can be spray- or vapor-deposited, thus simplifying manufacturing. One possible drawback of the CdS and GaAs materials is their toxicity, particularly hazardous during manufacturing operations.

Where solar cells are used in *concentrated* sunlight, efficiency becomes of particular importance because of its effect upon total collector area needed, this being a major cost component of a solar energy system. A number of ingenious collector configurations have been developed. Further, there is the concept of the *thermophotovoltaic cell*, which may be able to achieve efficiencies as high as 30–50% through shifting the spectrum of light reaching the cell to a range where most of the photons are close to the minimum excitation threshold for silicon cells. High efficiencies in intense radiation can be achieved, for example, with GaAs cells by covering them with a layer of $Ga_xAl_{1-x}As$, a material that reduces surface and contact losses. Clearly the interface between cell and solar radiation is of as great importance as development of new cell materials per se.

So-called *wet solar cells* show promise, particularly because of their relative ease of fabrication. In this type of photovoltaic cell, the junction is formed between a semiconductor and a liquid electrolyte. No doping is required because a junction forms spontaneously when a suitable semiconductor, such as GaAs, is contacted with a suitable electrolyte. Three knotty problems (accelerated oxidation of surface of semiconductor; exchange of ions between semiconductor and electrolyte forming a blocking layer; and deposition of ions of impurities on the surface of the semiconductor) all have been solved and thus the concept now appears technically viable.

Over a number of years, the photovoltaic cell developers received large financial incentives from the U.S. government. For example, the National Photovoltaics Act of 1978 was passed by the U.S. Congress, which authorized an expenditure of $1.5 billion for research, development, and demonstration of solar cell systems for converting sunlight into electric power. Also, in connection with the Federal Non-Nuclear Energy Research and Development Act of 1974, which established the concept of "net energy"—that is, the effect of new devices and systems on the overall energy balance. Projects were evaluated on the basis of their "potential for production of net energy." Although there have been some breakthroughs of particular significance to scientists and a gradually expanding market for photovoltaics in addition to use in space, particularly in various consumer products, the long awaited and ultimate application (generation of electric power in impressive amounts at competitive prices) has remained elusive. Scores of analyses have been made and forecasts range from very pessimistic to quite optimistic. The era of practically achieving this goal on the part of the photovoltaic cell community tends to be progressively shifted outward into the future. Forecasts usually are based upon numerous assumptions that are subject to periodic change and their reporting is best left to the periodicals and thus are not detailed here.

It is in order, however, to sum up the observations of the Electric Power Research Institute (EPRI): Photovoltaics need significant additional research to reduce cost and increase efficiency of the cells as well as their support systems (tracking and D.C.-to-A.C. power conversion) before they can be competitive with conventional electricity supply technologies. Current manufacturing costs for flat-panel arrays of interconnected, encapsulated cells are approximately $5000 per peak kW, and balance-of-plant costs double the effective system cost to $10,000 per peak kW. This compares roughly with $300 per kW for combustion turbines; $1400/kW for pulverized coal plants; and $2500/kW for nuclear plants. Two classes of photovoltaic converters that appear to show the most promise for producing large amounts of power are (1) the inexpensive, flat-plate, thin-film devices with target prices of less than $1500 per peak kW and efficiencies of 15%, compared with their current costs of $5000 per peak kW and efficiencies of about 10%; and (2) very high-efficiency, high-concentration devices with target prices less than $1500 per peak kW and efficiencies of 25%, compared with their current costs of $7000 per peak kW and efficiencies to utilities (largely subsidized or experimental programs).

Some authorities estimate that photovoltaic utility capacity could range from 0.6 to 16 GW by the year 2010, provided that needed technical performance is achieved. See also **Photovoltaic Cells**.

Satellite Energy Collectors

Having proven their value in connection with relatively small space satellites, probes, etc., a huge satellite energy collector was first proposed in the late 1960s and, largely on the basis of national concerns with energy supplies precipitated by the oil embargo of the 1970s, considerable attention was given at the design level and in the literature to a solar power satellite (SPS). One proposal called for a space-based array requiring about 90 square kilometers (55 square miles)! That is about the size of Manhattan Island. The satellite would be in a geosynchronous orbit some 36,000 kilometers (22,000 miles) above Earth. Because nearly all authorities now consider such a project very "futuristic," no further details are reported here.

SOL–GEL TECHNOLOGY. The goal of sol–gel technology is to use low temperature chemical processes to produce net-shape, net-surface objects, films, fibers, particulates, or composites that can be used commercially after a minimum of additional processing steps. See also **Thin Films**. Sol–gel processing can provide control of microstructures in the nanometer size range, i.e., 1–100 nm (0.001–0.1 μm), which approaches the molecular level. These materials often have unique physical and chemical characteristics. See also **Nanotechnology (Molecular)**.

Sols are dispersions of colloidal particles in a liquid. *Colloids* are nanoscaled entities dispersed in a fluid. *Gels* are viscoelastic bodies that have interconnected pores of submicrometric dimensions. A gel typically consists of at least two phases, a solid network that entraps a liquid phase. *Sol–gel technology* is the preparation of ceramic, glass, or composite materials by the preparation of a sol, gelation of the sol, and removal of the solvent.

Compositions

Nucleation of particles in a very short time followed by growth without supersaturation yields monodispersed colloidal particles that resist agglomeration. A large range of colloidal powders having controlled size and morphologies have been produced using these concepts. Materials include oxides, hydroxides, carbonates, sulfides, as well as various mixed phases or composites and coated particles. Controlled hydrolysis of alkoxides has also been used to produce submicrometer TiO_2, doped TiO_2, ZrO_2, doped ZrO_2, doped SiO_2, $SrTiO_3$, and even cordierite powders. Emulsions have been employed to produce spherical powders of mixed cation oxides, such as yttrium aluminum garnets (YAG), and many other systems. Sol–gel powder processes have also been applied to fissile elements. Spray-formed sols of UO_2 and UO_2–PuO_2 were formed as rigid gel spheres during passage through a column of heated liquid. Abrasive grains based on sol–gel-derived mixed alumina are important commercial products. Powders for superconductors and magnetic ceramics were also developed using the sol–gel technology. See also **Magnetic Materials**.

Glass and polycrystalline ceramic fibers have been prepared using the sol–gel method.

Sol–Gel Process Steps

Overview. Three approaches are used to make most sol–gel products: method 1 involves gelation of a dispersion of colloidal particles; method 2 employs hydrolysis and polycondensation of alkoxide or metal salts precursors followed by supercritical drying of gels; and method 3 involves hydrolysis and polycondensation of alkoxide precursors followed by aging and drying under ambient atmospheres.

Production of net-shape silica components serves as an example of sol–gel processing methods. A silica gel may be formed by network growth from an array of discrete colloidal particles (method 1) or by formation of an interconnected three-dimensional network by the simultaneous hydrolysis and polycondensation of a chemical precursor (methods 2 and 3). When the pore liquid is removed as a gas phase from the interconnected solid gel network under supercritical conditions (critical-point drying, method 2), the solid network does not collapse and a low density aerogel is produced. Aerogels can have pore volumes as large as 98% and densities as low as 80 kg/m^3.

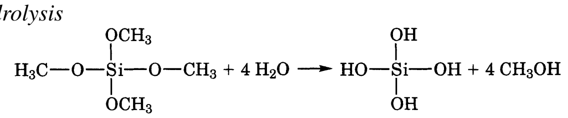
When the pore liquid is removed at or near ambient pressure by thermal evaporation, i.e., by drying (methods 1 and 3), shrinkage occurs and the monolith is termed a xerogel. If the pore liquid is primarily alcohol-based, the monolith is often termed an alcogel. The generic term gel is usually applied to either xerogels or alcogels, whereas aerogels are usually specified as such. A gel is defined as dried when the physically adsorbed solvent is completely evacuated. This occurs between 100 and 180°C.

A dried gel still contains a very large concentration of chemisorbed hydroxyls on the surface of the pores. Thermal treatment in the range of 500–800°C desorbs the hydroxyls and thereby decreases the contact angle and the sensitivity of the gel to rehydration stresses, resulting in a stabilized gel. Heat treatment of a gel at elevated temperatures substantially reduces the number of pores and their connectivity owing to viscous phase sintering. This is termed *densification*. The density of the material increases and the volume fraction of porosity decreases during sintering. The porous gel is transformed to a dense glass when all pores are eliminated. Densification is complete at 1250–1500°C for silica gels made by method 1 and as low as 1000°C for gels made by method 3. The densification temperature decreases as the pore radius decreases and surface area of the gels increases. Silica glass made by densification of porous silica gel is amorphous and nearly equivalent in structure and density to vitreous silica made by fusing quartz crystals or sintering of SiO_2 powders made by chemical vapor deposition (CVD) of $SiCl_4$.

Seven processing steps are involved to various degrees in making sol–gel-derived silica monoliths by methods 1, 2, and 3. The emphasis herein is primarily on net-shape sol–gel-derived silica monoliths made by the alkoxide process (method 3) prepared under ambient pressures.

In method 1, a suspension of colloidal powders, or sol, is formed by mechanical *mixing* of colloidal particles in water at a pH that prevents precipitation. In method 2 or 3, a liquid alkoxide precursor such as $(SiOR)_4$, where R is CH_3 (TMOS), C_2H_5 (TEOS), or C_3H_7, is hydrolyzed by mixing with water (eq. 1).

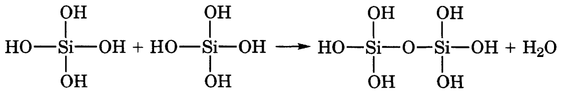
Hydrolysis



(1)

As soon as any hydrolyzed species is present, condensation proceeds. The hydrated silica tetrahedra interact in a condensation reaction (eq. 2), forming ≡ Si–O–Si ≡ bonds.

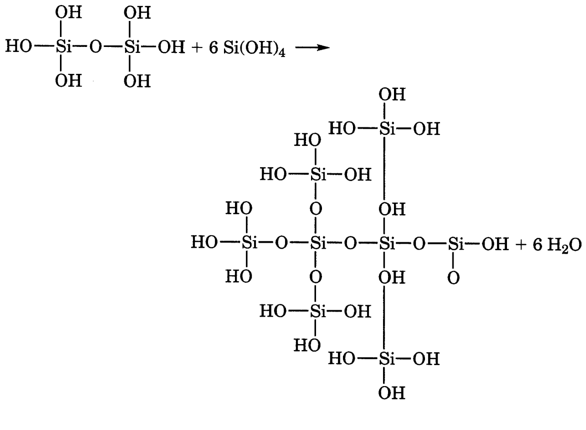
Condensation



(2)

Linkage of additional ≡ Si–OH tetrahedra occurs as a polycondensation reaction (eq. 3) and eventually results in a SiO_2 network. The H_2O and alcohol expelled from the reaction remain in the pores of the network.

Polycondensation



(3)

The hydrolysis and polycondensation reactions initiate at numerous sites within the TMOS/H_2O solution as mixing occurs. When sufficient interconnected Si–O–Si bonds are formed in a region, the material responds cooperatively as colloidal (submicrometer) particles or a sol. The size of the sol particles and the cross-linking within the particles, i.e., the density, depends on the pH and R ratio, where $R = [H_2O]/[Si(OR)_4]$.

Because the sol is a low viscosity liquid, it can be *cast* into a mold.

After some time the colloidal particles and condensed silica species link together to become a three-dimensional network. The physical characteristics of the gel network depend greatly on the size of particles and extent of cross-linking prior to *gelation*. At gelation, the viscosity increases sharply, and a solid object results in the shape of the mold.

The process that involves a continuous change in structure and properties of a completely immersed gel in liquid after the gel point is called *aging*. The shrinkage of the gel and the resulting expulsion of liquid from the pores during aging is called syneresis. During aging, polycondensation continues along with localized solution and reprecipitation of the gel network, which increases the thickness of interparticle necks and decreases the porosity.

During *drying*, the liquid is removed from the interconnected pore network. Large capillary stresses can develop during drying when the pores are small (< 20 nm). These stresses can cause gels to crack catastrophically unless the drying process is controlled by either decreasing the liquid surface energy by addition of surfactants, elimination of very small pores (method 1), supercritical evaporation which avoids the vapor–liquid interface (method 2), or producing a homogenous structure free of defects by controlling the rates of hydrolysis and condensation (method 3).

Dehydration or chemical stabilization, the removal of surface silanol (Si–OH) bonds from the pore network, results in a chemically stable ultraporous solid. Porous gel–silica made in this manner by method 3 is optically transparent, having both interconnected porosity and sufficient strength to be used as unique optical components when impregnated with optically active polymers, such as fluors, wavelength shifters, dyes, or nonlinear polymers.

Heating the porous gel at high temperatures causes *densification*. The pores are eliminated and the density ultimately becomes equivalent to quartz or fused silica.

Hydrolysis and Polycondensation. At gel time, events related to the growth of polymeric chains and interaction between colloids slow down considerably and the structure of the material is frozen. Post-gelation treatments (aging, drying, stabilization, and densification) alter the structure of the original gel, but the resultant structures all depend on the initial structure. Relative rates of hydrolysis (eq. 1) and condensation (eq. 2) determine the structure of the gel. Many factors influence the kinetics of hydrolysis and condensation, because both processes often occur simultaneously. The most important variables are temperature, nature and concentration of electrolyte, nature of solvents, and type of alkoxide precursor. Pressure also influences the gelation process. Condensation may result in a spectrum of structures ranging from molecular networks to colloidal particles. Under acidic conditions, more linear structures are formed prior to gelation. Under basic conditions, the distribution of polysilicate species is much broader and characteristic of branched polymers having a high degree of cross-linking, whereas for acidic conditions there is a lower degree cross-linking. Thus, the shape and size of polymeric structural units are determined by the relative values of the rate constants for hydrolysis and polycondensation reactions.

Gelation. A sol becomes a gel when it can support a stress elastically, defined as the gelation point or gelation time, t_g. A sharp increase in viscosity accompanies gelation. A sol freezes in a particular polymer structure at the gelation point. This frozen-in structure may change appreciably with time, depending on the temperature, solvent, and pH conditions or on removal of solvent.

The time of gelation changes significantly with sol–gel chemistry. One method of measuring t_g determines the viscoelastic response of the gel as a function of shear rate.

The system evolves from a sol, where individual particles interact more or less weakly with each other, to a gel, which is a continuous network occupying the entire volume. The techniques available to follow structural evolution at the nanometer scale of sol–gel networks include small-angle x-ray scattering (saxs), neutron scattering, light scattering, and transmission electron microscopy. Scattering studies show that acid-catalyzed sols develop a more linear structure with less branching, whereas base-catalyzed systems have highly ramified structures.

The classical or mean field theory of polymerization is useful for visualizing the conditions for gelation. This model yields a degree of reaction, p_c, of one-third at the time of gelation for chemical species having functionality equal to four. Two-thirds of the possible connections are still available and therefore may play a role in subsequent processing. This value is lower than the experimental evidence but represents the minimum degree of reaction before gelation can occur. Experimental results indicate that $0.6 < p_c \leq 0.84$ for silica sol–gel systems. Percolation theory is also used to represent gelation.

Aging. When a gel is maintained in its pore liquid, the structure and properties continue to change long after the gel point. This process is called aging. Four aging mechanisms can occur, singly or simultaneously: polycondensation, syneresis, coarsening, and phase transformation. Polycondensation reactions (eqs. 2 and 3), continue to occur within the gel network as long as neighboring silanols are close enough to react. This increases the connectivity of the network and its fractal dimension. Syneresis is the spontaneous shrinkage of the gel and resulting expulsion of liquid from the pores. Coarsening is the irreversible decrease in surface area through dissolution and reprecipitation processes.

During aging, there are changes in most textural and physical properties of the gel. Inorganic gels are viscoelastic materials responding to a load with an instantaneous elastic strain and a continuous viscous deformation. Because the condensation reaction creates additional bridging bonds, the stiffness of the gel network increases, as does the elastic modulus, the viscosity, and the modulus of rupture.

Drying. For porous systems, there are three stages of drying. During the first stage of drying the decrease in volume of the gel is equal to the volume of liquid lost by evaporation. The compliant gel network is deformed by the large capillary forces that cause shrinkage of the object. Changes in pore size during drying as well as a shift in composition of pore liquid can affect the rate of drying in stage 1. For large-or small-pore gels the greatest changes in volume, weight, density, and structure occur during stage-1 drying. Stage 1 ends when shrinkage ceases. The second stage begins when the critical point is reached. The critical point occurs when the strength of the network has increased owing to the greater packing density of the solid phase, which is sufficient to resist further shrinkage. In stage 2, liquid transport occurs by flow through the surface films that cover partially empty pores. The liquid flows to the surface where evaporation takes place. The flow is driven by the gradient in capillary stress. Because the rate of evaporation decreases in stage 2, this is termed the first falling rate period. The third stage of drying is reached when the pores have substantially emptied and surface films along the pores cannot be sustained. The remaining liquid can escape only by evaporation from within the pores and diffusion of vapor to the surface. During this stage, called the second falling rate period, there are no further dimensional changes, only a slow progressive loss of weight until equilibrium is reached, which is determined by the ambient temperature and partial pressure of water.

When gels crack, they do so at distinct points within the drying sequence. Cracking during stage 1 is rare but can occur when the gel has had insufficient aging and strength, and therefore does not possess the dimensional stability to withstand the increasing compressive stress. Most failures occur during the early part of stage 2, the point at which the gel stops shrinking. Cracking during stage 3 seldom occurs.

Stabilization. A critical step in preparing sol–gel products and especially Type VI silica optical components is stabilization of the porous structure. Both thermal and chemical stabilization is required in order for the material to be used in an ambient environment. The reason for the stabilization treatment is the large concentration of hydroxyls on the surface of the pores of these high (> 400 m^2/g) surface area materials. *Chemical stabilization* involves removing the concentration of surface hydroxyls and surface defects, such as metastable three-membered rings, below a critical level so that the surface is not stressed by rehydroxylation in use. Thermal stabilization involves reducing the surface area sufficiently to enable the material to be used at a given temperature without reversible structural changes. The mechanisms of thermal and chemical stabilization are interrelated because of the extreme effects that surface hydroxyls and chemisorbed water have on structural changes. Full densification of gels, such as the transformation of gel–silica to a glass, is nearly impossible without dehydration of the surface prior to pore closure. *Dehydration* of a gel requires removal of two forms of water: free water within the ultraporous gel structure, i.e., physisorbed water, and hydroxyl groups associated with the gel surface, i.e., chemisorbed water. The amount of physisorbed water adsorbed

to the silica particles is directly related to the number of hydroxyl groups existing on the surface. When a silica gel has been completely dehydrated, there are no surface hydroxyl groups to adsorb the free water, and the surface is hydrophobic. It is the realization of this critical point that is the focus for making stable gel products.

Densification. Densification, the final treatment process of gels, occurs between 1000–1700°C, depending on the radii of the pores and the surface area. Controlling the gel–glass or gel–ceramic transition to retain the initial shape of the starting material is difficult. It is essential to eliminate volatile species prior to pore closure and density gradients owing to nonuniform thermal or atmosphere gradients Using appropriate successful stabilization treatments, it is possible to produce monolithic, dense, gel-derived glasses without pressure or heating to temperatures above the melting point. There are at least four mechanisms responsible for the shrinkage and densification of gels: capillary contraction, condensation, structural relaxation, and viscous sintering. It is likely that several mechanisms operate at the same time, e.g., condensation and viscous sintering.

Alumina Derived from Sol–Gel

Aluminum oxide (alumina), Al_2O_3, has high technological value. Sol–gel processing of alumina has created novel applications and improved some of its properties. Products such as catalyst carriers, abrasives, fibers, films for electronic applications, aerogels, and membranes for molecular filtration have been developed based on sol–gel processing. See also **Alumina Adsorption (Process)**; and **Bauxite**; **Aluminum**; and **Aluminum Alloys and Engineered Materials**.

Hydrolysis and Condensation Reactions of Aluminum Alkoxides. Aluminum is less electronegative than silicon, causing it to be more electrophilic and thus less stable toward hydrolysis. These features are responsible for the greater rates of hydrolysis and condensation of aluminum alkoxides when compared to the rates of silicon alkoxide reactions. Hydrolysis and condensation reactions probably occur by nucleophilic addition, followed by proton transfer and elimination of either alcohol or water under neutral conditions. Both reactions are catalyzed by the addition of acid or base. When acids are added, they protonate organic or hydroxyl groups, creating reactive species and eliminating the requirement for proton transfer as an intermediate step. Bases deprotonate water or OH groups, leading to the formation of strong nucleophiles.

Peptization. Aggregation of small inorganic polymeric chains and clusters produced from hydrolysis and condensation reactions of aluminum alkoxides forms macroparticles and nonuniform aggregate. These aggregates that are broken during the peptization step effect the formation of a clear sol having a narrow distribution of particle size. Another mechanism associated with peptization is the production of surface charges on the colloids that eventually leads to either gelation or dispersion.

Gelation. Mechanisms of gelation of alumina sols derived from alkoxides differ from gelation of silicon alkoxide sols. Whereas the sol–gel transition for silica sols is basically a consequence of interactions between long inorganic chains, the gel transition in alumina sols results from colloidal growth by dissolution and reprecipitation processes (Ostwald ripening), followed by formation of linkages between particles. These linkages are initialized by physical–chemical interactions between surface-charged colloids that eventually produce a three-dimensional network, formed by interconnected colloids. The initial contact points between colloids are responsible for neck formation by a coarsening process, followed by particle reshaping and densification. Gelation can be induced either by eliminating excess of water added during hydrolysis or by adding electrolytes to the peptize sol prepared in temperatures above 60°C that leads to sol flocculation.

Drying of Gels. Drying of alumina gels prepared using high temperatures of hydrolysis consists of two steps: sol concentration and pore liquor removal. The rate of sol concentration can dictate some gel properties. High rates of sol concentration lead to less efficiency in packing of colloids. Transparent monolit's can be prepared by drying high density gels.

Applications

Sol–Gel Processing of Thin Films. The sol–gel method enables the production of ceramic films having thickness from 10–1000 nm. See also **Thin Films**. The rheological characteristics of the sol allow the deposition of a film by several procedures: dip coating, spin coating, electrophoresis, thermophoresis, and settling. Dip and spin coating are the most frequently used procedures. Dip coating can be divided into five stages: immersion, startup, deposition, drainage, and evaporation. The fluid mechanical boundary layer, which is pulled with the substrate, splits into two. The inner layer moves upward with the substrate, while the outer layer is returned to the bath. The thickness where the split occurs is responsible for the thickness of the film. The spin coating process can be divided into four stages: deposition, spinup, spinoff, and evaporation. In the first stage, an excess of liquid is distributed along the surface that is to undergo deposition. The spinup stage is related to flow of liquid along all the surface, driven by centrifugal force. In the spinoff stage, the excess of liquid flows to the perimeter and is eliminated as droplets. The solvent is eliminated in the fourth stage by evaporation, which leads to the thinning of the film.

Sol–Gel Fibers. During sol-to-gel evolution, changes in the rheology of the sol can be used to allow fiber pulling. Formation of elongated polymers in a solution is a requirement for spinnability, i.e., the ability to form fibers. Reduced viscosity for solutions of chain-like or spherical polymers is independent of concentration, whereas linear polymers give a direct relation between reduced viscosity and concentration. Acidic pHs and low values for the molar ratio between water and alkoxide result in the production of linear polymers that exhibit spinnability.

Organic–Inorganic Hybrids. Ceramics and polymers have been combined into high performance composites. The association between high modulus and high strength ceramic fibers, such as glass, carbon, and boron fibers, having the inherent ductility and toughness of some polymers, enables the fabrication of materials having special properties. The integration of different types of materials is restricted by the high temperature processing conditions usually employed in ceramic fabrication. The sol–gel method enables preparation of ceramic materials in a temperature range compatible with organic polymer stability, and involves mechanisms of network formation such as hydrolysis and polycondensation reactions, that are similar to the polymerization reactions of polymers. Thus, sol–gel can be used to produce new types of composites involving ceramics and polymers. These are called organic–inorganic hybrids or ceramers.

Several types of organic–inorganic hybrids have been prepared by using different polymers coupled with TEOS. The basic procedure involves dissolution of the polymer in THF (20 wt %) followed by addition of TEOS with an acidic water solution. Some of the polymers, i.e., poly(methyl methacrylate), poly(vinyl acetate), poly(vinyl pyrrolidone), and poly(*N,N*-dimethylamide), yielded transparent films, this demonstrating the absence of macrophase separation. Polycarbonate, poly(acrylic acid), and Nylon trogamid lead to the production of opaque films. Extensive work has been done in terms of combining nanometric clay particles using either Nylon or polyimide. Montmorillonite has been modified by cation exchange using aminolauric acid, and the new groups attached on the surface of the clay bonded to the polymer by initiation of polymerization.

Sol–Gel Bioactive Glasses. Bioactive glasses and ceramics bond to both soft and hard tissue. The chemical bond formed between the implant and tissue can provide the desired adhesion required in many medical and dental applications. Two types of sol–gel processing yield bioactive materials in the $SiO_2{-}CaO{-}P_2O_5$ system having high bioactivity index. The bioactivity of the gel-derived materials is equivalent or greater than melt-derived glasses. See also **Glass**

SOLID. Matter in its most highly concentrated form, i.e., the atoms or molecules are much more closely packed than in gases or liquids and thus more resistant to deformation. The normal condition of the solid state is crystalline structure—the orderly arrangement of the constituent atoms of a substance in a frame work called a lattice. See also **Crystal**. Crystals are of many types and normally have defects and impurities that profoundly affect their applications, as in semiconductors. The geometric structure of

solids is determined by X-rays that are reflected at characteristic angles from the crystalline lattices, which act as diffraction gratings.

Some materials that are physically rigid, such as glass, are regarded as highly viscous liquids because they lack crystalline structure. All solids can be melted (i.e., the attractive forces acting between the crystals are disrupted) by heat and are thus converted to liquids. For ice, this occurs at 0°C; for some metals the melting point may be as high as 3300°C. Some solids convert by sublimation directly to a gas.

SOLID-STATE CHEMISTRY. Study of the exact arrangement of atoms in solids, especially crystals, with particular emphasis on imperfections and irregularities in the electronic and atomic patterns in a crystal and the effects of these on electrical and chemical properties.

See also **Crystal**; and **Semiconductors**.

SOLID-STATE PHYSICS. The study of the physical properties (crystallographic, electrical and electronic, magnetic, acoustic, optical, thermal, mechanical, etc.) of substances in the solid phase.

In years past, much emphasis has been given to crystalline solids and this continues, but there has been a growing shift of interest to polymeric and amorphous substances as well. Much attention in the past has been given to metals and this also continues apace, but other substances are now under very serious investigation, including the ceramics, glasses, and organics. Interest in the solid state, of course, was given a tremendous boost by the discovery of semiconductors in the 1940s. During the intervening years, this interest has been spurred by other electronic and electrical materials, including dielectrics, piezoelectrics, ferroelectrics, conductors and superconductors, electrodes, insulators, contacts, and polymers and macromolecular materials, notably those that are electroactive. Interest outside the electronics field, notably in the science of ceramics, glasses, and entirely new materials, such as composites, also has been adding to the body of knowledge of the solid state. However, because of the great need for solid materials with special properties for a host of applications, solid-state theory has tended to lag practice.

Nevertheless, solid-state theory has made excellent progress during the past decade. Just a few examples would include:

Excitonic Matter

The interaction of light with solid matter is a phenomenon of fundamental importance for exploring the quantum mechanics of materials. This field dates back to Einstein's finding that light energy is carried by quantized packets of radiation (photons). More recently, it has been found that a conduction electron can combine with a positively charged "hole" in a semiconductor to create an *exciton*, which, in turn, can form molecules and liquids. Some authorities consider the exciton as a new phase of matter. It was learned several years ago that the energy of incident photons can be converted inside a crystal into what might be termed short-lived neutral entities, i.e., excitons. As reported in an excellent paper by Wolfe and Mysyrowicz (1984), the exciton resembles the hydrogen atom. It consists of two oppositely charged carriers bound together by electrostatic attraction. In the hydrogen atom, the positive charge is a proton, which is surrounded by the negatively charged electron. In the exciton, the positive charge has a mass of an estimated $\frac{1}{1000}$th that of the proton. In the Wolfe/Mysyrowicz paper (details far beyond the scope of this encyclopedia), the investigators address several interesting questions. Can the exciton propagate freely through the crystal like a free hydrogen atom in a gas? Can two or more excitons combine to form a molecule? Can the excitonic "atoms" or the molecules made up of them form liquid or solid phases? Can more exotic phases of condensed excitonic matter come into being? How are excitons created by light in a crystal? Why does a crystal absorb light at all?

Electron Transport in Solids

It is well established (elucidated in several articles in this encyclopedia) that the production of integrated circuits (ICs) requires manufacturing techniques of extreme precision and sophistication. The purity of materials used is also far higher than experienced by most other materials-processing industries. It has been observed by Howard, Jackel, Mankiewich, and Skocpol (AT&T Bell Laboratories), in a 1986 paper, that a single-crystal silicon wafer 15 cm or more in diameter can be obtained with concentrations of undesired dopants at less than 1 part in 10 billion and with only about one defect per square centimeter. Accuracy in recent years is in terms of a few nanometers, and feature sizes in commercial circuits are down to 1 micrometer (micron) and getting smaller. Thus, it is no surprise that the silicon transistor can serve as a model for investigating numerous areas of the solid state. Using new patterning techniques, devices almost $\frac{1}{100}$th the size of commercial ICs can be made, making it possible to study transport physics in microstructures only a few hundred atoms across.

In 1985, two research institutions (IBM and AT&T Bell Laboratories) reported that electrons can travel through a semiconductor without being slowed by collisions (*ballistically*). The report was based upon experimental data showing a ballistic peak in the electron energy spectra of gallium arsenide (GaAs) test devices. This is reported in more detail in article on **Arsenic**.

Electroactive Polymers and Macromolecular Electronics

Electro active polymers are of particular interest in connection with their use in fabricating improved electronic microstructures. Scientists at AT&T Bell Laboratories have been active in the investigation and development of electroactive polymers notably for electrodes. As reported by Chidsey and Murray (1986), electrodes can be coated with electrochemically reactive polymers in several microstructural formats called sandwich, array, bilayer, micro-, and ion-gate electrodes. These microstructures can be used to study the transport of electrons and ions through the polymers as a function of the polymer oxidation state, which is essential for understanding the conductivity properties of these new chemical materials. The microstructures also exhibit potentially useful electrical and optical responses, including current rectification, charge storage and amplification, electron-hole pair separation, and gates for ion flow. In their well-illustrated paper, the investigators explore the three broad categories of electroactive polymers: (1) pi-conjugated, electronically conducting polymers; (2) polymers with covalently linked redox groups (redox polymers); and (3) ion-exchange polymers. In summary, the authors observe that although macromolecular electronics is still at a rudimentary level, the concepts involved are quite novel and with continued development may lead to practical applications. See also entry in this encyclopedia, **Molecular and Supermolecular Electronics**.

Quantized Hall Effect

In 1980, at the Max Planck Institute, Klaus von Klitzing discovered the quantized Hall effect, a phenomenon that occurs in certain semiconductor devices at low temperatures in very strong magnetic fields. As pointed out by Halperin (1986), the quantized Hall effect is observed in artificial structures known as two-dimensional electron systems. The conduction electrons in these systems are trapped in a very thin layer, such that the electronic motion perpendicular to the layer is frozen into its lowest quantum mechanical stage and thus plays no role in the conductivity of the device. In his experiment, Klitzing worked with a silicon field effect transistor (MOSFET). Electrons are trapped in what is called an inversion layer near the surface of a silicon crystal that is covered with a film of insulating silicon oxide, on top of which is deposited a metal gate electrode, used to control the density of conduction electrons in the inversion layer. This effect had been predicted as early as 1975 by Japanese investigators. Considerable detail pertaining to von Klitzing's experimental apparatus is given in the Halperin paper.

Surface Physics

Closely allied with solid state physics is the discipline of surface science. Investigations in this area have been quite intense during the past decade, notably in connection with catalysts. A catalyst is a species that changes the rate of a reaction and yet is regenerated by that reaction so that it seems to be unchanged in the net reaction. Although there are enzyme catalysts, for example, the majority of industrially interesting catalysts are found among the metals, the surfaces of which serve to catalyze reactions. The first catalytic phenomena were observed as early as 1835 by Berzelius and later better quantified by Ostwald in 1894. Aided by the great volume of catalysts used industrially ($ billions/year), the incentive for research is large. See articles on **Catalysis**; **Scanning Tunneling Microscope**; and **Silicon**.

Extremely High-Pressure Research

The invention and refinement of the modern diamond anvil cell (Carnegie Institution) occurred in the mid-1980s. This is a tool par excellence for optical, infrared and Raman spectroscopy and enables the researcher to study the changes in the electronic structure and chemical binding caused by the application of high pressure. Phase transitions, which involve changes in the atomic architecture can be determined with the diamond cell using the x-ray diffraction technique. Studies with the diamond anvil cell have been particularly valuable for obtaining geophysical information—for example,

the state of silicate minerals and oxides in the mantle region right up to the core-mantle boundary to provide a view of the earth's interior, where high pressure and high temperature conditions exist. In solid-state physics, there is the fascinating challenge of making metallic hydrogen under ultrahigh pressure. This extraordinary change from a very good insulating to a metallic state in hydrogen is predicted to occur near 3 to 4 million atmospheres. See article on **Diamond Anvil High Pressure Cell**.

The foregoing examples are but a few to indicate the continuing vigorous research into the nature of the solid state. See also **Superconductivity**.

Concepts of Solids Simplified

The atoms that comprise a solid can be considered for many purposes to be hard balls which rest against each other in a regular repetitive pattern called the crystal structure. Most elements have relatively simple crystal structures of high symmetry, but many compounds have complex crystal structures of low symmetry. The determination of crystal structures, of atom location in the crystal, and of the dependence of many physical properties upon the inherent characteristics of the perfect solid is an absorbing study, one that has occupied the lives of numerous geologists, mineralogists, physicists, and other scientists for many years.

The rigid, hard-ball model is not adequate to explain many properties of solids. To begin with, solids can be deformed by finite forces, thus solids must not be completely rigid. Furthermore, atoms in a solid possess vibrational energy, so the atoms must not be precisely fixed to mathematically defined lattice points. This deformability of solids is built into the model by the assignment of deformable bonds (springs) between nearest atom neighbors. This ball-and-spring model has many successes; one important early use was that of Einstein to devise a reasonably successful theory of specific heats. Later incorporation by Debye of coupled motion of groups of atoms led to an even more successful theory.

Several measures exist of the strength of these bonds. One is the size of the elastic constants—for most solids, Young's modulus is about 10^{11} newtons per square meter. The other is the frequency of vibration of the atoms—values around 10^{13} to 10^{14} Hz are found.

The lack of perfection occasioned by elastic deformation of solids is but one of many kinds of crystalline imperfections. Defects are frequently found in crystals, produced in nature and in the laboratory. These defects may be characterized by three principal parameters—their geometry, size, and energy of formation.

All real crystals have atoms which occupy external surface sites and which do not possess the correct number of nearest neighbors as a consequence. Thus, a surface is a seat of energy and is characterized by surface tension. Furthermore, internal surfaces exist, grain boundaries and twin boundaries across which atoms are incorrectly positioned. In a crystal of reasonable size—say 1 cubic centimeter, these two-dimensional defects, called *surface defects*, contain only about 1 atom in 106, a rather small fraction. Even so, surfaces are important attributes of solids.

Some defects have extent in only one dimension—*line defects*. The most prominent of these, the dislocation, is a line in the crystal along which atoms have either an incorrect number of neighbors or neighbors which have not the correct distance or angle. In 1 cubic centimeter of a real crystal, one might find a wide variation of length of dislocations present—from near zero to perhaps 10^{11} centimeters.

Defects which have extent of only about an atomic diameter also exist in crystals—the *point defects*. Vacant lattice sites may occur—*vacancies*. Extra atoms—*interstitials*—may be inserted between regular crystal atoms. Atoms of the wrong chemical species—*impurities*—also may be present.

The properties of defects are intimately related to their energy of formation. A standard against which this energy can be compared is provided by the energy of sublimation—the energy necessary to separate the ions of a solid into neutral, noninteracting atoms. This energy is about 81,000 calories per mole for a typical metal, copper, at room temperature, about 3.5 eV per atom. Energies of surfaces, both free surfaces and grain boundaries, are about 1000 ergs per square centimeter, about 1 eV per surface atom. Dislocation energies are of similar size per atom length of dislocation, about 1 to 5 eV, so the energy of a dislocation is about 10^{-4} erg per centimeter of length. Point defects, too, possess an inherent energy of about 1 eV each. Vacancies in copper have an energy of about 1 eV; self-interstitials, 2 or 3 eV.

The energies per atom of these various defects, surface, line, and point, are all much larger than the average thermal energy per atom in a solid at reasonable temperatures. This thermal energy kT is only about $\frac{1}{40}$ eV at room temperature. Thus, defects can be produced only by conditions which exist during manufacturing (artificial and natural) by external means, such as plastic deformation or particle bombardment; or by large local fluctuations in thermal energy away from the average.

The total amount of energy bound up in ordinary concentrations of these defects is not large as compared to the total thermal energy of a solid at normal temperatures. All the vacancies in equilibrium in copper, even at the melting point, comprise less than 10 calories of energy per mole, much less than the enthalpy at 1357 K (the melting point) of more than 7000 calories per mole. In a material with very heavy dislocation density, 10^{12} centimeters per cubic centimeter, the total dislocation energy is only a few calories per mole. And the total energy of a free surface of a compact block of 1 mole of copper is even less: about 10^{-3} calorie. Thus, the inherent energy of these defects is not large; even so they are immensely important in controlling many phenomena in crystals—as in the case of semiconductor devices.

Crystallographic defects need not remain stationary in the crystal; they may move about with time. Some of these movements may reduce the overall free energy of the solid; others (these are chiefly movement of the point defects) may simply be the wandering of random walk. Since these movements require larger than kT, the motion of defects depends upon rather large local fluctuations in energy. Consequently, their rate of motion depends upon temperature through a Boltzmann factor exp $(-\Delta H/RT)$, where ΔH is the enthalpy increase necessary to move the defect from the lowest-energy site to the top of the barrier.

A convenient description of the crystalline structure of solids is thus seen to consist of successive stages of approximation. First, the mathematically perfect geometrical model is described; then departures from this perfect regularity are permitted. The deformability of solids is allowed for by letting the force constants between adjacent atoms be finite, not infinite. Then, misplacement of atoms is permitted and a variety of crystalline irregularities, called defects, is described. Some of these defects have intrinsic features which affect properties of the crystal; other affect the properties by their motion from site to site in the crystal. In spite of their relatively small number, defects are of immense importance.

Electronic Structure of Solids

In principle, the electronic structure of solids is determined by the electronic structure of the *free atoms* of which the solid is composed. Since the free atom structure is known rather well, especially for atoms of lower atomic number, the electronic structure of solids should be subject to determination by calculation. This is not the case. A wide variety of interactions occur between the electrons on adjacent atoms as they approach the equilibrium distance characteristic of solids. These interactions are of such complex nature that they tend to defy concise definition and involve such a host of charged particles, electrons, and ion cores, that only approximate calculations can usually be made. Nevertheless, the use of approximate models allows many general features of the electronic structure to be deduced, especially when close interplay between theory and experiment is established. As for the crystalline structure of solids, two stages are useful in understanding the electronic structure. First, the perfect electronic structure is defined. Then, irregularities in this structure, again termed defects, are described. Although both the geometry and energy of crystalline defects are defined, description of the geometry of the charge distribution of many of the electron defects is difficult, and one must generally be content with description of the formation energy of the defect.

The nuclei of the atoms in a solid and the inner electrons form ion cores with energy levels little different from corresponding levels in free atoms. The characteristics of the valence electrons are modified greatly, however. The state functions of these outer electrons greatly overlap those of neighboring atoms. Restrictions of the Pauli Exclusion Principle and the Uncertainty Principle force modification of the state functions, and the development of a set of split energy levels becomes a quasi-continuous band of levels of width, which are several electron volts for most solids. Importantly, unoccupied levels of the atoms are also split into bands. The electronic characteristics of solids are determined by the relative position in energy of the occupied and unoccupied levels as well as by the characteristics of the electrons within a band.

Metals. The solid is called a *metal* if excitation of electrons from the highest filled levels to the lowest unoccupied levels can occur with infinitesimal expenditure of energy. Thus, excitation can occur by means of many external forces, such as electric fields, heat, light, radio waves. Metals are, therefore, good conductors of electricity and of heat; they are opaque to light and they reflect radio waves.

Insulators. Some solids have wide spacing between the occupied and the unoccupied energy states—2 eV or more. Such solids are called *insulators* since normal electric fields cannot cause extensive motion of the electrons. Examples are diamond, sodium chloride, sulfur, quartz, mica. They are poor conductors of electricity and heat and are usually transparent to light (when not filled with impurities or defects).

Semiconductors. Solids with conductivity properties intermediate bet ween those of metals and insulators are called *semiconductors*. For them, the excitation energy lies in the range 0.1 to about 2 eV. Thermal fluctuations are sufficient to excite a small, but significant, fraction of electrons from the occupied levels (the valence band) into the unoccupied levels (the conductance band). Both the excited electrons and the empty states in the valence band (aptly called *holes*) may move under the influence of an electric field, providing a means for conduction of current. Such electron-hole pairs may be produced not only by thermal energy, but also by incident light, providing photo-effects. The inverse process, emission of light by annihilation of electrons and holes in suitably prepared materials, provides a highly efficient light source (example, light-emitting diodes).

Crystallographic defects, in general, are also electronic defects. In metals, they provide scattering centers for electrons, increasing the resistance to charge flow. The resistance wire in many electric heaters consists of an ordinary metal, such as iron with additional alloying elements such as nickel or chromium providing scattering centers for electrons. In semiconductors and insulators, however, alloying elements and defects provide an even greater variety of effects, since they can change the electron-hole concentrations drastically in addition to providing scattering centers. This is the basis of semiconductor technology. See also **Semiconductors**.

Interactions of Solids with Light. Solids are useful because of their interaction with external forces or stimuli, such as electric and magnetic fields, heat, and mechanical forces. Yet among these interactions, probably the most important I s the interrelation between matter and light. This interaction, important to all photosynthetic phenomena and the production of food; to the artificial generation of light; to the use of phosphors in cathode-ray tubes—is also the basis of spectroscopy and its use in the study of solids. In this field, first came investigation of emission and absorption of radiation from free atoms. Later investigations included emission and absorption of radiation by atoms in solids—giving rise to maser and laser phenomena, Mossbauer spectroscopy, nuclear magnetic resonance, X-ray diffraction, infrared spectroscopy, fluorescence, the Raman effect, microwave emission and absorption, among many other useful effects.

Band Theory of Solids

The success of the simple free electron theory of metals was so striking that it was natural to ask how the same ideas could be applied to other types of solids, such as semiconductors and insulators. The basic assumption of the free electron theory is that the atoms may be stripped of their outer electrons, the resulting ions arranged in the crystalline lattice, and the electrons then poured into the space between.

The free electron model results from the neglect of the interaction of the various atoms and of the periodic variation of the potential in which the electrons move, i.e., as their distance from the nearest metallic ion changes. When the former is taken into account, it is found that each energy eigenstate of an isolated atom is split into N non-degenerate states, where N is the number of atoms in the crystal. The group of levels that result from a single atomic state form an *allowed band*. If we start from the free electron picture and consider the effect of the periodic variations of potential, the Bloch theorem leads to the conclusion that there will be discontinuities in the plot of energy vs. momentum whenever the wave vector **k** has magnitude and direction such that it satisfies the Bragg law for reflection, in which λ may be set equal to $1/\mathbf{k}$ to give $\mathbf{k} \cdot \mathbf{d} = n$. Here **k** is the wave vector, **d** is the vector separation of two atomic planes in the crystal, and n is an integer equal to the scalar product. As with the atomic interaction model, the number of eigenstates between two energy breaks is equal to the number of atoms in the crystal. Thus, either approach leads to the existence of a manifold of energy levels occurring in groups of N closely spaced levels, the groups being separated by energies that are often very large compared with the spacing of levels within a group, somewhat as shown in Fig. 1. Each group of levels is known as an *allowed band*; the energies between groups are said to be in a *forbidden band*. Because these levels depend on the properties of the body as a whole, the entire macroscopic crystal may be considered to be a single giant molecule. The electrical, mechanical, and thermal properties of the crystal are then largely determined by the electrons in the energy levels within the highest occupied bands.

Because electrons obey the Pauli Exclusion Principle, not more than two of them (with oppositely directed spin) can exist in any single energy level. In thermal equilibrium at the zero of absolute temperature, than, all of the levels up to some particular energy, determined by the number of electrons present, will be occupied and all above this energy will be vacant. This highest level is known as the *Fermi level*. At higher temperatures there will not be a sharp discontinuity in occupancy—some of the levels below the Fermi level will be vacant and some above it will be occupied. The *Fermi level* is then defined as the energy of the state that has a 50% chance of being occupied.

The Fermi level is determined by the number of electrons present, and the properties of the material are therefore dependent on whether this energy falls near the bottom, top, or middle of an allowed band. If the number of electrons is such as to exactly fill certain bands, with a wide gap above them, the material will be an insulator (m). If the gap is very narrow, or if there are impurities present to create extra levels, the substance may be semiconducting (o). See Fig. 2. In these cases, it is difficult to supply sufficient thermal energy to an electron to promote it into the conduction band above the gap, where alone it is free to carry an electric current. In a metal (n), however, there is always a partially filled band, in which the electrons behave in many respects as if they were free. The existence of the partially filled band may be due either to the fact that each atom contains an odd number of electrons or to the overlapping of two allowed bands, each of which will be partly filled. Direct evidence for the existence of bands is provided by the soft X-ray emission spectra, but the importance of the theory is not so much its correctness in detail as the simplicity of the band scheme by which the energy relations between various phenomena may be shown on a single diagram.

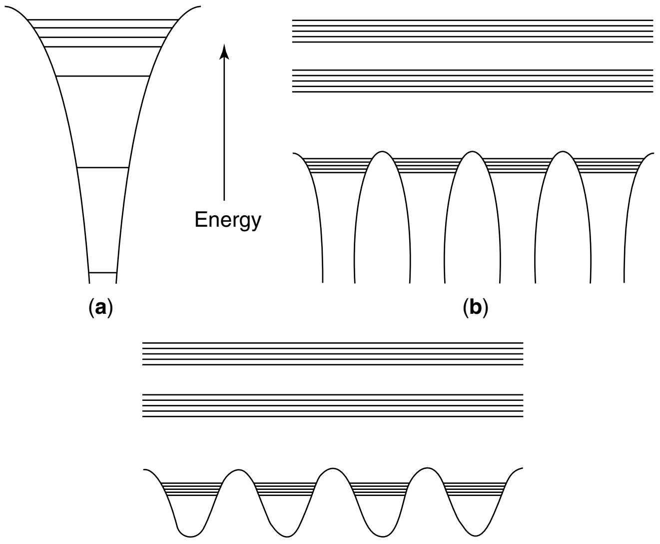

Fig. 1. Origin of the energy levels in a crystalline solid. The curves represent potential energy versus distance. At (**a**), the potential energy is that of an isolated ion; the energy levels, represented by the horizontal lines, are sharp. At (**b**), the overlap of the fields of the ions lowers the potential energy curve between the atomic positions and results in a splitting of each atomic level into a band of allowed levels. At (**c**), the model is derived from one in which the electrons are free, subject only to a periodic potential resulting from the ionic fields

SOLIDUS CURVE. A curve representing the equilibrium between the solid phase and the liquid phase in a condensed system of two components. The relationship is reduced to a two-dimensional curve by disregarding the influence of the vapor phase. The points on the solidus curve are obtained by plotting the temperature at which the last of the liquid phase solidifies, against the composition, usually in terms of the percentage composition of one of the two components.

SOLID WASTES. See **Wastes and Pollution**; **Water Pollution**

SOLION. A small electrochemical oxidation-reduction cell consisting of a small cylinder containing a solution and divided into sections by platinum gauze, porous ceramics, or other materials. A type of solion for detecting sound waves consists of a potassium iodide-iodine solution in which the iodide ions are oxidized to triiodide ions at the anode, and the reverse process occurs at the cathode. The cell is constructed so that the sound waves cause agitation of the solution between the electrodes, and thus change the current. In addition to detection of sound, solions can be designed to detect changes in other conditions, such as temperature, pressure, and acceleration.

SOLUBILITY. A property of a substance by virtue of which it forms mixtures with other substances which are chemically and physically homogeneous throughout. The degree of solubility is the concentration of a solute in a saturated solution at any given temperature. The degree of solubility of most substances increases with a rise in temperature, but there are cases (notably the organic salts of calcium) where a substance is more soluble in cold than in hot solvents.

SOLUBILITY PRODUCT. A numerical quantity dependent upon the temperature and the solvent, characteristic of electrolytes. It is the product of the concentrations of ions in a saturated solution and defines the degree of solubility of the substance. When the product of the ion concentrations exceeds the solubility product, precipitation commonly results. Strictly speaking, the product of the activities of the ions should be used to determine the solubility product, but in many cases the results obtained using concentrations, as suggested by Nernst, are correct.

SOLUBILIZATION. Defined loosely, solubilization is the enhancement of the solubility of one substance, the solubilizate, by another substance, the solubilizing agent or solubilizer. More strictly, it is a process occurring in the presence of a solvent, whereby one species, the solubilizing agent, diminishes the activity coefficient of another species, the solubilizate, and both species are soluble thereafter, J. W. McBain, who coined this term, used it to denote the dissolution of an otherwise insoluble material brought about by interaction with micelles, a type of colloid, present in the solvent. The definition given here, however, is more inclusive than his original concept, and could be extended logically to systems whose characteristics are remote or completely apart from colloidal behavior. Practice nevertheless limits the term to usage in which there is either a close or a marginal relationship to micelles, and the literature of solubilization refers chiefly to systems in which the solubilizers are micelle formers. For example, potassium laurate solubilizes hydrocarbons in water, and calcium xenylstearate solubilizes water in hydrocarbons because of the micelle-forming nature of the respective solubilizing agents. However, the striking similarity among interactions between various agents and both soluble and insoluble species makes it undesirably arbitrary to restrict the term solubilization rigidly to its original usage.

Because absolute insolubility does not exist in nature, insolubility must be considered a matter of degree. Consequently, if an *apparently* insoluble species, in unlimited excess, is in contact with a solvent it must have a finite concentration and activity in the solvent at equilibrium. A solubilizing agent added to the system may interact with this species by coordination, hydrogen bonding, dipole interaction, complex formation, or in some other manner. In any case, the interaction results in a decrease of the effective concentration, or activity, of this species. Accordingly, more of the solubilizate progressively dissolves until its activity returns to the initial equilibrium value in the pure solvent, whereupon the activity coefficient is correspondingly less. If a species is freely soluble, or even infinitely miscible with a solvent, an interaction causes no *apparent* increase in the solubility of the species, but its activity, as evidenced by its osmotic behavior, nevertheless similarly decreases. The activity represents the tendency of the species to escape from the solution. Since solubility depends upon a balance between the opposing tendencies to enter and to leave the solution, the decreased activity is in effect equivalent to increased solubility. Solubilization is said to occur then, regardless of the independent solubility or insolubility in the pure solvent.

The salts of high-molecular weight organic acids are particularly important solubilizing agents. In nonpolar solvents such as hydrocarbons, they form colloidal aggregates known as association micelles. Most frequently such a micelle constitutes a limited number of salt monomers associated into a spheroidal cluster, with the polar ends of the salt monomers oriented toward the interior, and the nonpolar hydrocarbon ends at the periphery. Other polar species such as water, alcohol, acids, and dyes can be solubilized by these micelles in a variety of ways. In benzene solution, for example, zinc dinonylnaphthalene sulfonate can solubilize at least six moles of water for each equivalent weight of the salt present. The solution remains transparent, and no phase separation is observed. During the progressive addition of six moles of water per gram-equivalent

of salt, the micelles expand to aggregations containing ten acid residues per unit, whereas the water-free micelles contain only seven. The water molecules are believed to be held in the polar core of the micelle where the environment is favorable to their retention.

Methanol, on the other hand, decreases the size of magnesium phenylstearate micelles. As methanol is solubilized by this salt in toluene solution, the micelle size decreases progressively from 23 salt monomers per aggregate to as little as 2 at a methanol concentration of 2% by weight. Each of these dimers is then associated with ten molecules of the alcohol. The partial pressure of methanol over the solution is demonstrably less than that over the salt-free methanol-toluene solution of equal methanol concentration. Rhodamine B dissolves very sparingly in pure benzene as the colorless and nonfluorescent base form. It is converted to the brilliantly fluorescent colored form by the addition of any of numerous micelle-forming solubilizers. No major changes in micelle size are believed to result from this solubilization, and it is postulated that a dye molecule replaces a monomer of the solubilizing agent in the matrix of the micelle.

In aqueous solutions, salts of high-molecular weight acids from micelles whose orientations are the reverse of those in nonpolar solvents. The hydrocarbon portions of the monomers, being insoluble in water, are oriented inward, whereas the ionic, or polar ends are oriented outward. Solubilization by these agents is complicated by dissociation of cations from surfaces of the aggregates and by the resulting surface charges developed. Both polar and nonpolar species such as hydrocarbons, dyes, alcohols, fats, organic acids, and a wide variety of soluble and insoluble species are solubilized in aqueous micellar solutions. Micelle enlargement is frequently said to follow from solubilization by these salts in aqueous solution, although the possibility of reduction of micelle size should not be excluded from consideration.

A nonpolar solubilizate such as hexane penetrates deeply into such a micelle, and is held in the nonpolar interior hydrocarbon environment, while a solubilizate such as an alcohol, which has both polar and nonpolar ends, usually penetrates less, with its polar end at or near the polar surface of the micelle. The vapor pressure of hexane in aqueous solution is diminished by the presence of sodium oleate in a manner analogous to that cited above for systems in nonpolar solvents. A 5% aqueous solution of potassium oleate dissolves more than twice the volume of propylene at a given pressure than does pure water. Dimethylaminoazobenzene, a water-insoluble dye, is solubilized to the extent of 125 mg per liter by a 0.05 *M* aqueous solution of potassium myristate. Bile salts solubilize fatty acids, and this fact is considered important physiologically. Cetyl pyridinium chloride, a cationic salt, is also a solubilizing agent, and 100 ml of its *N*/10 solution solubilizes about 1 g of methyl ethyl-butyl either in aqueous solution.

Among other species that are good solubilizing agents are the nonionic compounds such as the polyethylene oxide-fatty acid condensates and the fatty esters of polyalcohols. A wide variety of nonionic solubilizing agents is possible, but most of those available are of variable composition. They can be effective in both aqueous and nonaqueous solutions.

The colloidal nature of some systems can disappear completely as solubilization proceeds. For instance, when methanol is solubilized by magnesium and sodium dinonylnaphthalene sulfonates, the aggregates decrease in size to a degree beyond which they can be considered micelles. In toluene solutions, micelles of these salts dissociate progressively on the addition of methanol increments until each of the particles in these solutions contains only one salt monomer when the methanol concentration reaches about 2% by weight. Probably the properties of some species which cause them to aggregate are those which make them good solubilizing agents, but it is evident that micelles are not a necessary condition for solubilization.

Accordingly, it is logical for solubilization to occur in systems which show no colloidal behavior, although frequently the effect in these cases is described by other proper terminology. Usually the term "solubilization" is applied in cases where the solubilizing agent is effective in small quantities, but arbitrary limitations of quantity might confuse the basic concept of solubilization. The terms cosolvency, hydrotropy, and "salting in" are used sometimes to describe effects which may be considered within the broad general scope of solubilization.

Applications of solubilization, although not always completely understood, range widely. A solubilizing agent can be used to bring an otherwise insoluble substance into solution where it is needed for a specific use, or it can be incorporated in a formulation to suppress the activity of an unwanted species which otherwise cannot be eliminated or prevented from occurring. In the pharmaceutical industry, drugs which are insoluble in pure water are solubilized by suitable agents to form homogeneous solutions. Dyes are solubilized for more efficient penetration and uniform coloring of fabrics. Soaps and detergents in aqueous solution are effective cleansing agents because they solubilize oily and greasy residues which may be flushed away from contaminated surfaces, although other effects may be equally important in the process. Removal of silver halides from photographic papers and films by aqueous fixing solutions may be considered solubilization by noncolloidal solubilizers. Certain oil-soluble salts dissolved in dry cleaning fluids can solubilize water. The water, which is solubilized in the micelles can in turn solubilize inorganic salts. The salts are then retained in the polar cores of the micelles where the water is held. This effect is referred to as secondary solubilization. In automotive fuels and lubricating oils, nonaqueous detergents are used to maintain engine cleanliness by solubilizing products of oxidation and combustion which tend to form sludges and gums, and to suppress the destructive effects of acids and other species generated in operation. Other solubilizing agents are used in these fluids to incorporate otherwise insoluble additives for oxidation and corrosion inhibition.

SOLUTIONS. The equilibrium of a saturated solution represents a balance between the potentials and entropies of the molecules present in the two phases. These depend upon pressure, temperature, and the kind and strength of the attractions between the molecules. The attractions may be classified as interactions between ions, dipoles, metallic atoms, and the "electron clouds" of nonpolar molecules, differing among themselves in kind, in range, and in strength. The potential energy of the molecules of a nonpolar liquid is measured appropriately for the purpose of solubility relations by its energy of vaporization per cc, called its "cohesive energy density." The square root of this quantity will be used below as a "solubility parameter" δ.

We consider, first, the mutual solubility of two nonpolar liquids, whose molecules have practically equal sizes, and equal attractive and repulsive forces. When they are brought into contact, thermal agitation will cause mutual diffusion until the two species are uniformly distributed. The mixing process has produced maximum molecular disorder, and therefore entropy, which is given by the expression, for 1 mole of solution,

$$\Delta S^M = -R(x \ln x_1 + x_2 \ln x_2), \tag{1}$$

where R is the gas constant and x_1 and x_2 the respective mole fractions. The partial molal entropies of transfer of 1 mole from pure liquid to solution are

$$\overline{s}_1 - \overline{s}_1^0 = -R \ln x_1, \tag{2}$$

for component 1, and with subscript 2, for the other component.

The partial molal free energies of transfer are related to the *fugacities* in pure liquid, f^0 (vapor pressure corrected for deviation from the perfect gas law), and in solution, by the equations,

$$\overline{F}_1 - \overline{F}_1^0 = -R \ln(f_1/f_1^0). \tag{3}$$

and its counterpart.

Liquids such as are here postulated mix with no heat effect; therefore $F_1 - F_1^0 = -T(s_1 - s^0)$, etc.; therefore

$$f_1/f_1^0 = x_1 \quad \text{and} \quad f_2/f_2^0 = x_2 \tag{4}$$

which is Raoult's law, and defines the *ideal* solution.

If one of the components of an ideal solution, e.g., component 2, is a solid, its fugacity, f_2^s, is less than the fugacity of the pure, supercooled liquid, and limits the amount that can dissolve to $x_2 = f_2^s/f_1^0$. The ratio f_2^s/f_2^0, can be calculated from its melting point and heat of fusion.

Most solutions deviate from Raoult's law. The curved lines in Fig. 1 represent positive deviations, with $f_1/f_1^0 > x$. The ratio f_1/f_1^0 is called *activity*, and

$$f_1/f_1^0 = a, \quad \text{and} \quad a_1/x_1 = \gamma, \tag{5}$$

the *activity coefficient*.

Regular Solutions

The internal forces of a pair of liquids are seldom so nearly alike as to permit their mixture to obey Raoult's law very closely throughout the whole range of composition. In the absence of chemical interaction, the attraction between two different molecular species, provided their dipole moments are zero or small, is approximately the geometric mean of the attractions between the like molecules. Since a geometric mean is less than an arithmetic mean, the mixing is accompanied by expansion and absorption of heat. The partial molal heat of transfer per mole from pure liquid to solution is given with fair accuracy for many systems by the equation,

$$H_2 - H_2^0 = \nu_2 \phi_1^2 (\delta_2 - \delta_1)^2 \qquad (6)$$

and its cognate. where $\nu \equiv$ molal volume, δ is a *solubility parameter*, the square root of the energy of vaporization per em^3, and ϕ_2 is volume fraction.

Thermal agitation, except in the liquid-liquid critical region, suffices to give essentially maximum randomness of mixing, especially when one component is dilute, so that the entropy of mixing may be practically ideal, although the heat of mixing is not, and the partial molal free energy can be computed by combining the entropy and the heat terms, Eqs. (2), (5), and (6),

$$RT \ln a_2^s / x_2 = \nu_2 \phi_1^2 (\delta_1 - \delta_2)^2 \qquad (7)$$

This equation neglects the effects of expansion upon both the heat and the entropy, but the errors largely cancel when combined in Eq. (7).

A plot of a_2 vs. x_2 for symmetrical systems (i.e., $\nu_1 \approx \nu_2$) is shown in Fig. 1 for a series of values of the heat term. It shows how the partial vapor pressure of a component of a binary solution deviates positively from Raoult's law more and more as the components become more unlike in their molecular attractive forces. Second, the place of T in the equation shows that the deviation is less the higher the temperature. Third, when the heat term becomes sufficiently large, there are three values of x_2 for the same value of a_2. This is like the three roots of the van der Waals equation, and corresponds to two liquid phases in equilibrium with each other. The criterion is that at the critical point the first and second partial differentials of a_2 and a_1 are all zero.

The presence of a dipole in one component adds a temperature-dependent component to its self-attraction and also induces a dipole in the other component. The effect can often by allowed for, for practical purposes, by an empirical adjustment of its solubility parameter.

If the dipole is hydrogen bonding, then this component is "associated," and it mixes less readily with a nonpolar second component.

If the components are, respectively, electron-donor and acceptor, or basic and acidic in the generalized sense of Gilbert Lewis, negative deviations from Raoult's law occur, with enhancement of solubility.

The effects of these various factors are well illustrated by solutions of iodine, I_2. In Fig. 2 are plotted the saturation values of $\log x_2$ for iodine against log T. The slopes of the lines, when multiplied by R, give the entropy of transfer of iodine from solid to saturated solution. The solid lines are for violet solutions, from which chemical equilibria are absent. The positions of the lines are determined by the solubility parameters: how well is seen in the accompanying table, where δ-values are given for iodine in a spread of solvents calculated by means of Eq. (7) from the measured values of x_2. The broken lines indicate nonviolet solutions.

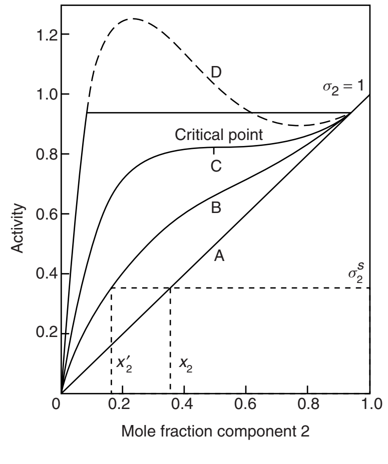

Fig. 1. Activity versus mole fraction for varying deviations from Raoult's law

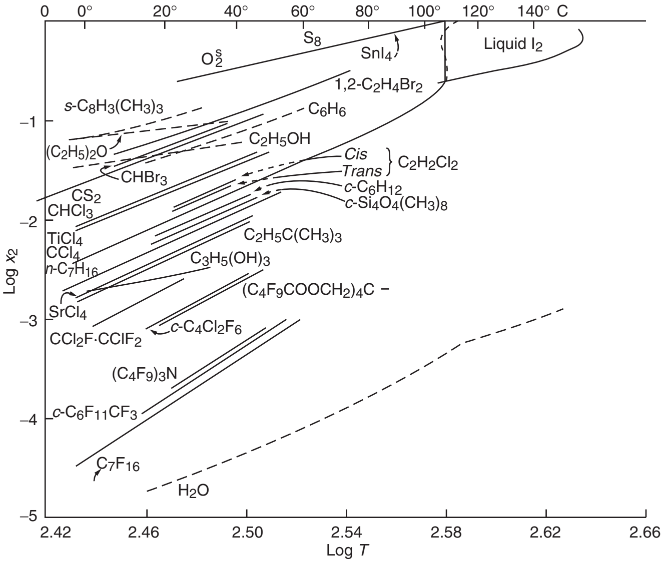

Fig. 2. Solubility of iodine

The factors that cause solutions of iodine to deviate from the behavior of regular solutions are illustrated in Fig. 3, in which values of the left hand member of Eq. (7) are plotted against those of the right for iodine solutions at 25°C; a_2^s is the activity of solid iodine; x_2 denotes measured solubility; ν_2 is the extrapolated molal volume of liquid iodine, 59 cm^3; ϕ_1 is the volume fraction of the solvent, $\sim$1.0; $\delta_2 = 14.1$; δ_1 is the solubility parameter of the solvent. Illustrative values of x_2 and δ_1 are given in accompanying table.

The points on line A are all for regular solutions, conforming to Eq. (7) over large ranges of x_2. Line B starts with a point for iodine in cycyohexane, next a point for methylcyclohexane, followed by one for dimethylcyclohexane. The point below is for ethylcyclohexane. Line C is for normal alkanes, from $C_{16}H_{34}$ to C_5H_{12}; groups D and E are for branched alkanes. Displacements from line A increase with increasing ratios of $-CH_3$ to $-CH_2$. The reason for this is not clear.

Line F contains points for aromatics, from benzene at the top to mesitylene at the bottom. All complex with iodine, altering its color. Group G consists of CH_2Cl_2 and 1,1- and 1,2- $C_2H_4Cl_2$, with strong dipoles, which enhance energy of vaporization without increasing solvent power for iodine.

Gases

Gas solubilities may be expressed as (1) volume of gas dissolved in unit volume of solvent, known as the *Ostwald coefficient*, designated by γ; (2) the volume of gas reduced to 0°C and 1 atmosphere dissolved in unit volume of solvent, known as the Bunsen coefficient, designated α; (3) the mole fraction, x; or (4) the moles per liter, c, dissolved at 1 atmosphere partial pressure. Henry's law, that the amount of gas dissolved is proportional to its partial pressure, holds rather well at moderate pressures in the basence of a chemical equilibrium. The fact that a substance is a gas at 1 atmosphere and ordinary temperatures indicates that its attractive forces are low and that consequently its solubility will be greater in solvents with low δ-values; also that solubility of different gases in the same solvent will be higher the higher the critical temperature of the gas.

δ-VALUES FOR I_2, 25°C

Solvent	Molal Vol. CC.	δ_1	100_{x_2}
n-C_7F_{16}	227.0	5.7	.0185
$SiCl_4$	115.3	7.6	.499

The solubility of a number of gases at 1 atmosphere partial pressure and 25°C expressed as $RT \ln x_2$ is plotted in Fig. 4 against the squares of the solubility parameters of a number of solvents. A high amount of regularity is evident for all except the gases SF_6 and CF_4, whose molecules attract molecules of the solvents very selectively. Similar irregularity is evident in the case of the solvent $(C_4F_9)_3N$. In all other cases the positions of missing points could be predicted with confidence.

Variations of solubility with temperature are illustrated in Fig. 4 for 10 gases in cyclohexane. The slopes of the lines times the gas constant R give values for the entropy of solution. In decending from C_2H_6 to He the

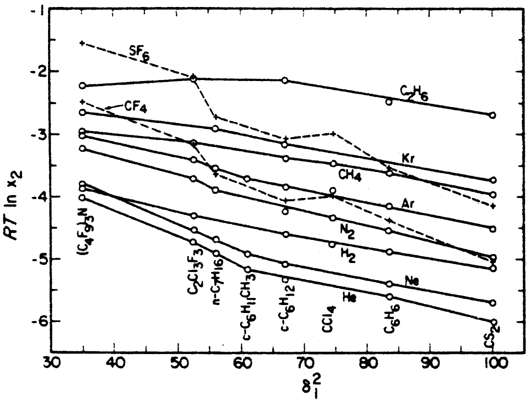

Fig. 4. Solubility of gases, $\log x_2$ at 25°C and 1 atm versus square of solubility parameter of solvents

entropy increases from −8.7 cal/deg mole to +8.1 partly from increases in entropy of dilution, $-R \ln x_2$, but also because the successive gases attract the surrounding solvent molecules less and less strongly, but since they have the same kinetic energy they finally almost blow bubbles permitting more freedom of motion to adjacent molecules of solvent.

The foregoing interesting phenomena are treated at length in "Regular and Related Solutions," by J. H. Hildebrand, J. M. Prausnitz, and R. L. Scott, Van Nostrand Reinhold, New York, 1970.

Solid Solutions

The formation of a solid solution requires not only attractive forces which are not too different, but also identical crystal structures. The latter condition is found most frequently among solids whose molecules are rotating, giving highly symmetrical crystals. See **Crystal**.

Metallic Solutions

In the absence of compounds, these follow the foregoing rules to a fair extent, but with added complications on account of the states of their electrons. The metals have a wide range of solubility parameters and exhibit many cases of incomplete miscibility in the liquid state.

Salt Solutions

The most obvious requirement necessary in a solvent for a salt is that it shall have a high dielectric constant, as is the case with water, liquid ammonia, hydrogen fluoride, and, in a smaller degree, methyl alcohol, in order to weaken the coulombic attraction of its ions for one another. It is possible to formulate the equilibrium between a solid salt and a solution of its ions by considering the changes in energy and entropy involved in vaporization of the solid to gaseous ions, and hydration of the ions. This would be relatively simple if the lattice energy of the solid and the hydration of the ions were solely electrostatic; but the process involves also van der Waals forces, polarization, covalent forces, hydrogen bonding, and entropy changes, which, in the case of water, are considerable, by reason of the ice structure persisting in water and the different structure of water of hydration. Consequently, such a breakdown of the problem, while it may serve to suggest comparisons, is better for explanation than for prediction.

The Periodic System offers the most useful guide by virtue of the trends it reveals; e.g., the decreasing solubility in water of the sulfates and the increasing solubility of the hydroxides of the elements of Group II in descending the group.

Liquid ammonia, because of its lower dielectric constant, is in general a much poorer solvent for salts than water; but this is offset to some extent toward salts of electron-acceptor, Lewis acid cations by its greater basic, electron-donor character.

Insight into the nature of electrolytes in water solutions is afforded by their effects in varying concentration upon the freezing point of water, Δt, at varying concentrations, m moles per 1000 grams. In Fig. 5 $\Delta t/m$ is plotted against m on a logarithmic scale.

The molal lowering of nonelectrolytes is illustrated by sucrose and H_2O_2. These enter so easily into the hydrogen bonded structure of water that they give the theoretical lowering, 1.86° up to 0.1 M in the case of sucrose and to 10 M by H_2O_2.

Binary electrolytes, such as KCl, although completely ionized, even in the solid state, lower the freezing point less than 2 × 1.86°, even when as dilute as $10^{-3}M$. This was at first attributed to incomplete ionization but is now explained by the long range of electrostatic forces. Note that Mg^{++} and SO_4^{-} are less independent than K^+ and $Cl^- \cdot AgNO_3$, unlike KCl, etc., is a weak salt, and undissociated molecules increase rapidly with concentration. The ions nearer to an ion of one sign are those of opposite sign, therefore electric conductivity is less than the sum of ionic conductivities extrapolated to zero concentration.

This effect has been formalized in the concept of *ionic strength*, expressed as

$$I = \tfrac{1}{2}(m_1 z_1^2 + m_2 z_2^2 + m_3 z_3^2 + \cdots)$$

where z is the ionic charge. Applied to solutions of KCl, K_2SO_4 and $MgSO_4$ the values of I are respectively, 0.01, 0.03, and 0.04. Ionic strength is significant for dealing with the equilibrium and kinetic properties of an ion in mixtures of electrolytes.

Concentrated solutions are strongly affected by ionic hydration. Its strength depends upon ionic radius and charge, therefore it is in general stronger for cations than anions. K_2SO_4 and $MgSO_4$ both yield 3 ions,

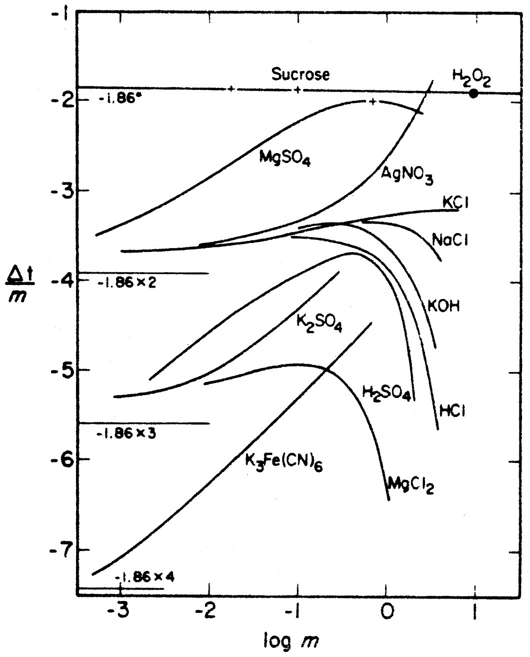

Fig. 5. Molal lowering of freezing points at different concentrations

but the hydration is stronger for Mg^{++} than K^+, Na^+ than K^+, Na^+ than Ag^+. The line for K_2SO_4 ascends whereas the one for $MgSO_4$ plunges downward, (a) because the strong hydration of Mg^{++} diminishes the coulombic attraction of SO_4^- and (b) because it ties up molecules of water, decreasing the amount of solvent.

SOLVENT. The term solvent generally denotes a liquid that dissolves another compound to form a homogeneous liquid mixture in one phase. More broadly, the term is used to mean that component of a liquid, gaseous, or solid mixture which is present in excess over all other components of the system. A *chemical solvent* is the term used for solvents in those instances where the process of solution is attended by a chemical reaction between the solvent and the solute. In contrast, a *physical solvent* is one that does not react with the solute. A *dissociating solvent* is one in which solutes that associate in many other solvents enter into solution as single molecules. For instance, various carboxylic acids associate and thus give abnormal elevations of the boiling point, abnormal depressions of the freezing point, etc., in many organic solvents; but in water, however, they do not associate. For this reason water is called a dissociating solvent for such solutes. A liquid that dissolves or extracts a substance from solution in another solvent without itself being very soluble in that other solvent is termed an *immiscible solvent.* A solvent whose constituent molecules do not possess permanent dipole moments and do not form ionized solutions, is termed a *nonpolar solvent. Polar solvents*, on the other hand, consist of polar molecules, that is, molecules that exert local electrical forces. In such solvents, acids, bases, and salts, that is, electrolytes, in general, dissociate into ions and form electrically conducting solutions. Water, ammonia, and sulfur dioxide are typical polar solvents. A *normal solvent* is one that does not undergo chemical association, namely, the formation of complexes between its molecules.

A *leveling solvent* is a solvent in which the acidity or basicity of a solute is limited (or leveled) by the acidity or basicity of the solvent itself. For example, the strongest acid that can exist in water is oxonium ion, H_3O^+. Consequently, even though HCl (for example) is intrinsically a much stronger acid than H_3O^+, its acidity in aqueous solution is "leveled" to that of H_3O^+ through the reaction $HCl + H_2O \rightleftharpoons H_3O^+ + Cl^-$. Likewise the very strong base KNH_2 is leveled in water to the basicity of OH^-

$$KNH_2 + H_2O \rightleftharpoons K^+ + OH^- + NH_3$$

The solvents that are leveling to both acids and bases are self-ionized solvents, e.g., water, ammonia, alcohols, carboxylic acids, nitric acid, etc. Basic non-protonic solvents are leveling to acids, but not to bases (i.e., they are differentiating toward bases), e.g., pyridine, ethers, ketones, etc., since the strongest acid attainable is the protonated solvent molecule (e.g., $C_5H_5N + HCl \rightleftharpoons C_5H_5NH^+ + Cl^-$), whereas there is no corresponding basic species derived from the solvent. Though solvents leveling to bases but not to acids are in principle much more difficult to find, in practice, very strong acids like H_2SO_4 and $HClO_4^-$ are limiting to bases because the species HSO_4^- and ClO_4^-, which will be formed by almost any basic substance, are the strongest bases attainable in these solvents—$B^- + HClO_4 \rightleftharpoons HB + ClO_4^-$—whereas practically no other acid is capable of producing the cations $H_3SO_4^+$ and $H_2ClO_4^+$ in these solvents (i.e., they are differentiating toward acids).

Differentiating solvents are solvents in which neither the acidity of acids nor the basicity of bases is limited by the nature of the solvent. These solvents are not self-ionized. The aliphatic hydrocarbons and the halogenated hydrocarbons are such solvents.

In industry it is generally understood that solvents are simple or complex, pure or impure, compounds or mixtures of compounds (either natural or synthetic), which dissolve many water-insoluble products like fats, waxes, resins, etc., forming homogeneous solutions; that such organic solvents dissolve these water-insoluble products in various proportions depending on the solvent power of the solvent, the degree of solubility of the solute, and the temperature; and that the solute can be recovered with its original properties by the removal of the solvent from the solution. It is also understood in industry that there is a much more limited number of solvents which do not have the properties given above but which nevertheless are of considerable importance; they are the inorganic solvents like water, liquid ammonia, liquid metals, and the like.

Solvents have been classified on various arbitrary bases: (1) boiling point, (2) evaporation rate, (3) polarity, (4) industrial applications, (5) chemical composition, (6) proton donor and proton acceptor relationships, and (7) behavior toward a dye, Magdala Red. Thus on the basis of industrial application one can classify solvents as those for (1) acetyl-cellulose, (2) pyroxylin, (3) resins and rubber, (4) cellulose ether, (5) chlorinated rubber, (6) synthetic resins, and (7) solvents and blending agents for cellulose ester lacquers. Solvents classified according to chemical composition are noted below.

The term *solvent action* is understood to mean any process of making substances water-soluble; but in a broader interpretation the term is understood to be the phenomenon of making a substance soluble in a solvent. Solvent power, diluting power, solvency and similar expressions indicate the property of solvents to disperse the molecules of a solute or vehicle thereby causing a decrease in viscosity.

The most common solvent is water. Water dissolves a great many gases, liquids, and solids, and is much used for this purpose. Other liquids similarly dissolve many substances without reacting chemically with them. Important considerations in connection with the choice of solvent for a given case are (1) vapor pressure and boiling point, (2) solvent power under stated conditions of temperature, (3) ease and completeness of recoverability by evaporation and condensation, and completeness of separation from dissolved material by evaporation, (4) heat of vaporization, (5) miscibility with water or other liquid, if present, (6) inertness to chemical reaction with the materials present, and with the apparatus, (7) inflammability and explosiveness, (8) odor and toxicity; (9) cost of solvent, loss in process, cost of recovering.

See also **Pollution (Air)**.

Colligative Properties of Solutions

When solute is added to a pure solvent, thus forming a solution, properties of the solvent are altered, including (1) osmotic pressure; (2) vapor pressure (lowered); (3) melting point (lowered); and (4) boiling point (elevated). These properties bear a relationship to the number of solute molecules in solution and not to the nature of the molecules. These phenomena are explained by enhanced tension in the solvent. Complete explanation of these changes is beyond the scope of this book, but reference is suggested to H.T. Hammel's article on "Colligative Properties of a Solution" (*Science*, **192**, 748–756, 1976).

SOLVENT EXTRACTION. A separation operation that may involve three types of mixture:

- A mixture composed of two or more solids, such as a metallic ore.

- A mixture composed of a solid and a liquid.
- A mixture of two or more liquids.

One or more components of such mixture are removed (extracted) by exposing the mixture to the action of a solvent in which the component to be removed is soluble. If the mixture consists of two or more solids, extraction is performed by percolation of an appropriate solvent through it. This procedure is also called leaching, especially if the solvent is water; coffee making is and example. Synthetic fuels can be made from coal by extraction with a coal-derived solvent followed by hydrogenation.

In liquid-liquid extraction one or more components are removed from a liquid mixture by intimate contact with a second liquid that is itself nearly insoluble in the first liquid and dissolves the impurities and not the substance that is to be purified. In other cases, the second liquid may dissolve i.e., extract from the first liquid, the component that is to be purified, and leave associated impurities in the first liquid. Liquid-liquid extraction may be carried out by simply mixing the two liquids with agitation and then allowing them to separate by standing. It is often economical to use counter-current extraction, in which the two immiscible liquids are caused to flow past or through one another in opposite directions. Thus fine droplets of heavier liquid can be caused to pass downward through the higher liquid in a vertical tube or tower.

The solvents used vary with the nature of the products involved. Widely used are water, hexane, acetone, isopropyl alcohol, furfural, xylene, liquid sulfur dioxide, and tributyl phosphate. Solvent extraction is an important method of both producing and purifying such products as lubrication and vegetable oils, pharmaceuticals, and nonferrous metals.

SOLVOLYSIS. A generalized conception of the relation between a solvent and a solute (i.e., a relation between two components of a single-phase homogeneous system) whereby new compounds are produced. In most instances, the solvent molecule donates a proton to, or accepts a proton from a molecule of solute, or both, forming one or more different molecules. A particular case of special interest occurs when water is used as solvent, in which case the interaction between solute and solvent is called *hydrolysis*.

SOMMELET REACTION. Preparation of aldehydes from aralkyl or alkyl halides by reaction with hexamethylenetetramine followed by mild hydrolysis of the formed quaternary salt.

SONN-MULLER METHOED. Preparation of aromatic aldehydes from anilides by conversion of an acid anilide with phosphorus pentachloride to an imido chloride, reduction of the imido chloride with stannous chloride, and hydrolysis of the obtained anil.

SONOCHEMISTRY. Ultrasonic irradiation of liquids causes high energy chemical reactions to occur, often with the emission of light. The origin of sonochemistry and sonoluminescence is acoustic cavitation: the formation, growth, and implosive collapse of bubbles in liquids irradiated with high intensity sound. The collapse of bubbles caused by cavitation produces intense local heating and high pressures, with very short lifetimes. In clouds of cavitating bubbles, these hot-spots have equivalent temperatures of roughly 5000 K, pressures of about 1000 atmospheres, and heating and cooling rates above 10^{10} K/s. In single-bubble cavitation, conditions may be even more extreme. Thus, cavitation can create extraordinary physical and chemical conditions in otherwise cold liquids. Sonoluminescence in general may be considered a special case of homogeneous sonochemistry; however, recent discoveries in this field have heightened interest in the phenomenon in and by itself. See also **Ultrasonics**.

Acoustic Cavitation

The chemical effects of ultrasound do not arise from a direct interaction with molecular species. Ultrasound spans the frequencies of roughly 15 kHz to 1 GHz. With sound velocities in liquids typically about 1500 m/s, acoustic wavelengths range from roughly 10 to 10^{-4} cm. These are not molecular dimensions. Consequently, no direct coupling of the acoustic field with chemical species on a molecular level can account for sonochemistry or sonoluminescence. Instead, sonochemistry and sonoluminescence derive principally from acoustic cavitation, which serves as an effective means of concentrating the diffuse energy of sound. Compression of a gas generates heat. The compression of bubbles during cavitation is more rapid than thermal transport, which generates a short-lived, localized hot-spot.

If the acoustic pressure amplitude of a propagating acoustic wave is relatively large (greater than ≈0.5 MPa), local inhomogeneities in the liquid (e.g., gas-filled crevices in particulates) can give rise to the explosive growth of a nucleation site into a cavity of macroscopic dimensions, primarily filled with vapor. Such a bubble is inherently unstable, and its subsequent collapse can result in an enormous concentration of energy. This violent cavitation event has been termed “transient cavitation”. A normal consequence of this unstable growth and subsequent collapse is that the cavitation bubble itself is destroyed. Gas-filled remnants from the collapse, however, may give rise to reinitiation of the process. The generally accepted explanation for the origin of sonochemistry and sonoluminescence is the hot-spot theory, in which the potential energy given the bubble as it expands to maximum size is concentrated into a heated gas core as the bubble implodes.

Two-Site Model of Sonochemical Reactivity

The transient nature of the cavitation event precludes conventional measurement of the conditions generated during bubble collapse. Chemical reactions themselves, however, can be used to probe reaction conditions. The effective temperature realized by the collapse of clouds of cavitating bubbles can be determined by the use of competing unimolecular reactions whose rate dependencies on temperature have already been measured. The sonochemical ligand substitutions of volatile metal carbonyls were used as these comparative rate probes (eq. 1), where the symbol $\xrightarrow{)))}$ represents ultrasonic irradiation of a solution, and L represents a substituting ligand. These kinetic studies revealed that there were in fact

$$M(CO)_x \xrightarrow{)))} M(CO)_{x-n} + n\ CO \xrightarrow{L} M(CO)_{x-n}(L)_n$$

$$\text{where } M = \text{Fe, Cr, Mo, W} \qquad (1)$$

two sonochemical reaction sites: the first (and dominant site) is the bubble’s interior gas-phase while the second is an *initially* liquid phase. The latter corresponds either to heating of a shell of liquid around the collapsing bubble or to droplets of liquid ejected into the hot-spot by surface wave distortions of the collapsing bubble.

Microjet Formation during Cavitation at Liquid–Solid Interfaces

A very different phenomenon arises when cavitation occurs near extended liquid–solid interfaces. There are two proposed mechanisms for the effects of cavitation near surfaces: microjet impact and shockwave damage. Whenever a cavitation bubble is produced near a boundary, the asymmetry of the liquid particle motion during cavity collapse can induce a strong deformation in the cavity. The potential energy of the expanded bubble is converted into kinetic energy of a liquid jet that extends through the bubble’s interior and penetrates the opposite bubble wall. Because most of the available energy is transferred to the accelerating jet, rather than the bubble wall itself, this jet can reach velocities of hundreds of meters per second. Because of the induced asymmetry, the jet often impacts the solid boundary and can deposit enormous energy densities at the site of impact. Such energy concentration can result in severe damage to the boundary surface. The second mechanism of cavitation-induced surface damage invokes shockwaves created by cavity collapse in the liquid. The impingement of microjets and shockwaves on the surface creates the localized erosion responsible for much of ultrasonic cleaning and many of the sonochemical effects on heterogeneous reactions. In this process, the erosion of metals by cavitation generates newly exposed, highly heated surfaces that are highly reactive.

Sonoluminescence

In addition to driving chemical reactions, ultrasonic irradiation of liquids can also produce light. As with sonochemistry, sonoluminescence derives from acoustic cavitation. There are two separate forms of sonoluminescence: multiple-bubble sonoluminescence (MBSL) and single-bubble sonoluminescence (SBSL). Since cavitation is a nucleated process and liquids generally contain large numbers particulates that serve as nuclei, the cavitation field generated by a propagating or standing acoustic wave typically consists of very large numbers of interacting bubbles, distributed over an extended region of the liquid. If this cavitation is sufficiently intense to produce sonoluminescence, then this phenomenon is called multiple-bubble sonoluminescence (MBSL).

Under the appropriate conditions, the acoustic force on a bubble can be used to balance against its buoyancy, holding the single bubble isolated in the liquid by acoustic levitation. This permits examination of the dynamic characteristics of the bubble in considerable detail, from both a theoretical and an experimental perspective. Such a bubble is typically quite small, compared to an acoustic wavelength (e.g., at 20 kHz, the resonance size is approximately 150 μm). For rather specialized but easily obtainable conditions, a single, stable, oscillating gas bubble can be forced into such large amplitude pulsations that it produces sonoluminescence emissions on each (and every) acoustic cycle. This phenomenon is called single-bubble sonoluminescence.

Sonochemistry

In a fundamental sense, chemistry is the interaction of energy and matter. In large part, the properties of a specific energy source determine the course of a chemical reaction. Ultrasonic irradiation differs from traditional energy sources (such as heat, light, or ionizing radiation) in duration, pressure, and energy per molecule. The immense local temperatures and pressures and the extraordinary heating and cooling rates generated by cavitation bubble collapse mean that ultrasound provides an unusual mechanism for generating high energy chemistry. Furthermore, sonochemistry has a high-pressure component, which suggests that one might be able to produce on a microscopic scale the same macroscopic conditions of high temperature–pressure "bomb" reactions or explosive shockwave synthesis in solids.

Experimental Design. A variety of devices have been used for ultrasonic irradiation of solutions. There are three general designs in use presently: the ultrasonic cleaning bath, the direct immersion ultrasonic horn, and flow reactors. The originating source of the ultrasound is generally a piezoelectric material, usually a lead zirconate titanate ceramic (PZT), which is subjected to a high a-c voltage with an ultrasonic frequency (typically 15 to 50 kHz).

The ultrasonic cleaning bath has been used successfully for a variety of liquid–solid heterogeneous sonochemical studies. Lower acoustic intensities can often be used in liquid–solid heterogeneous systems, because of the reduced liquid tensile strength at the liquid–solid interface. The low intensity available in these devices (≈ 1 W/cm^2), however, can prove limiting. The most intense and reliable source of ultrasound generally used in the chemical laboratory is the direct immersion ultrasonic horn (50 to 500 W/cm^2) which can be used for work under either inert or reactive atmospheres or at moderate pressures (<10 atmospheres). Commercially available flow-through reaction chambers which will attach to these horns allow the processing of multiliter volumes. Homogeneous sonochemistry typically is not a very energy efficient process (although it can be more efficient than photochemistry), whereas heterogeneous sonochemistry is several orders of magnitude better. Unlike photochemistry, whose energy inefficiency is inherent in the production of photons, ultrasound can be produced with nearly perfect efficiency from electric power. A primary limitation of sonochemistry remains the small fraction of the acoustic power actually involved in the cavitation events. Sonochemistry is strongly affected by a variety of external variables, including acoustic frequency, acoustic intensity, bulk temperature, static pressure, ambient gas, and solvent. The frequency of the sound field is not a commonly altered variable in most sonochemistry. Changing sonic frequency alters the resonant size of the cavitation event and to some extent, the lifetime of the bubble collapse, but the overall process remains unchanged.

Acoustic intensity has a dramatic influence on the observed rates of sonochemical reactions. Below a threshold value, the amplitude of the sound field is too small to induce nucleation or bubble growth. Above the cavitation threshold, increased intensity of irradiation (from an immersion horn, for example) will increase the effective volume of the zone of liquid which will cavitate, and thus, increase the observed sonochemical rate.

The effect of the bulk solution temperature lies primarily in its influence on the bubble content before collapse. With increasing temperature, in general, sonochemical reaction rates are *slower*. This reflects the dramatic influence which solvent vapor pressure has on the cavitation event: the greater the solvent vapor pressure found within a bubble prior to collapse, the less effective the collapse. Increases in the applied static pressure increase the acoustic intensity necessary for cavitation, but if equal numbers of cavitation events occur, the collapse should be more intense. In contrast, as the ambient pressure is reduced, eventually the gas-filled crevices of particulate matter which serve as nucleation sites for the formation of cavitation in even "pure" liquids, will be deactivated, and therefore the observed sonochemistry will be diminished.

The choice of ambient gas will also have a major impact on sonochemical reactivity. Monatomic gases give much more heating than diatomic, which are much better than polyatomic gases (including solvent vapor). The choice of the solvent also has a profound influence on the observed sonochemistry. In addition to vapor pressure, other liquid properties, such as surface tension and viscosity, will alter the threshold of cavitation. The chemical reactivity of the solvent is often much more important. No solvent is inert under the high temperature conditions of cavitation.

Homogeneous Sonochemistry: Bond Breaking and Radical Formation. The primary products of ultrasound in aqueous solutions are H_2 and H_2O_2; there is strong evidence for various high-energy intermediates, including HO_2, H·, OH·, and perhaps $e^-_{(aq)}$. The sonolysis of water, which produces both strong reductants and oxidants, is capable of causing secondary oxidation and reduction reactions.

Suslick and co-workers established that virtually all organic liquids will generate free radicals upon ultrasonic irradiation, as long as the total vapor pressure is low enough to allow effective bubble collapse. The sonalysis of sample hydrocarbons, (e.g., *n*-alkanes) creates the same kinds of products associated with very high temperature pyrolysis.

Applications of Sonochemistry to Materials Synthesis. Of special interest is the development of sonochemistry as a synthetic tool for the creation of unusual inorganic materials. More generally, ultrasound has proved extremely useful in the synthesis of a wide range of nanostructured materials, including high surface area transition metals, alloys, carbides, oxides and colloids. Sonochemical decomposition of volatile organometallic precursors in high boiling solvents produces nanostructured materials in various forms with high catalytic activities. Nanometer colloids, nanoporous high surface area aggregates, and nanostructured oxide supported catalysts can all be prepared by this general route. Sonochemistry has important applications with polymeric materials. Substantial work has been accomplished in the sonochemical initiation of polymerization and in the modification of polymers after synthesis.

Another important application has been the sonochemical preparation of biomaterials, most notably protein microspheres. Using high intensity ultrasound and simple protein solutions, a remarkably easy method to make both air-filled microbubbles and nonaqueous liquid-filled microcapsules has been developed. These microspheres are stable for months, and being slightly smaller than erythrocytes, can be intravenously injected to pass unimpeded through the circulatory system. The mechanism responsible for microsphere formation is a combination of *two* acoustic phenomena: emulsification and cavitation. Ultrasonic emulsification creates the microscopic dispersion of the protein solution necessary to form the proteinaceous microspheres. The long life of these microspheres comes from a sonochemical crosslinking of the protein shell. These protein microspheres, have a wide range of biomedical applications.

Heterogeneous Sonochemistry: Reactions of Solids and Liquids. The use of ultrasound to accelerate chemical reactions in heterogeneous systems has become increasingly widespread. The use of high intensity ultrasound to enhance the reactivity of reactive metals as stoichiometric reagents has become an especially routine synthetic technique for many heterogeneous organic and organometallic reactions. Applications of ultrasound to electrochemistry have also seen substantial recent progress. Another important application for sonoelectrochemistry is the electroreductive synthesis of sub-micrometer powders of transition metals.

Sonocatalysis. Ultrasound has potentially important applications in both homogeneous and heterogeneous catalytic systems. The inherent advantages of sonocatalysis include *(1)* the use of low ambient temperatures to preserve thermally sensitive substrates and to enhance selectivity; *(2)* the ability to generate high energy species difficult to obtain from photolysis or simple pyrolysis; and *(3)* the mimicry of high temperature and pressure conditions on a microscopic scale. Homogeneous catalysis of various reactions often uses organometallic compounds that are often catalytically inactive until loss of metal-bonded ligands (such as carbon monoxide) from the metal. Ultrasound can induce ligand dissociation, permitting initiation of homogeneous catalysis by ultrasound. Heterogeneous catalysts often require rare and expensive metals. The use of ultrasound may permit activating less reactive, but also less costly, metals.

SPACE CHEMISTRY. Experiments carried out on the space shuttle in the early 1980s indicate that unique types of chemical reactions occur in outer space, and the actual products may result that are not achievable under the terrestrial environment. Several factors are believed to account for this, primarily zero gravity, through absence of oxygen and enhanced magnetic effects may also play a part. Several encouraging results have already been obtained. Among projects that have that have been carried out or are contemplated are the following:

- Uniform polymer microspheres that are over twice as large as possible on earth have been made due to zero gravity.
- More effective electrophoresis reactions for making biological materials have been discovered, probably also because of zero gravity.
- Possibilities exist for (a) making unique alloys in space that are not possible on earth, for example lead-copper, lead-zinc, and aluminum indium (b) purer crystals for microelectronics; (c) better glass for fiber optics; (d) new drugs and pharmaceuticals.

Future experiments will involve human cells, enzymes, and hormones. See also **Space Processing**.

SPACE PROCESSING. Because the residual accelerations resulting from atmospheric drag and gravity gradient effects in low earth orbit are typically on the order of 10^{-6} times earth-gravity, the term microgravity generally is used to describe this acceleration environment. Because by the mid-1990s the space shuttle had been operational for more than a decade, a large number of microgravity experiments were conducted on various flights. Several microgravity-emphasis missions, in which the shuttle was flown in an attitude that minimized acceleration disturbances, were also flown to accommodate experiments that were exceptionally sensitive to accelerations. The more academically oriented experiments designed to address fundamental issues of materials processing are sponsored by the NASA Office of Microgravity Science and Applications; experiments designed to address issues of more direct interest to industrial research are sponsored by the NASA Office of Space Access and Technology (formerly the Office of Commercial Programs).

Materials Experiments in Space

Protein Crystal Growth. By the mid-1990s, the protein crystal growth experiments produced the most spectacular results of all the space processing experiments. The importance of x-ray crystallography as a mechanism for determining three-dimensional structure of complex macromolecules has placed new demands on the ability to grow large (ca 0.5 mm on a side), highly ordered crystals of a vast variety of biological macromolecules in order to obtain high resolution x-ray diffraction data. There are numerous difficulties encountered in attempts to grow macromolecular crystals of biological interest, and the ability to grow such crystals of sufficient size and quality has become an important step for advancement in this field. The difficulties encountered prompted some investigators to consider growing protein crystals in reduced gravity. The first protein growth experiment in reduced gravity was carried out in 1983 on Spacelab 1; crystals of lysozyme and β-galactosidase grew substantially larger in space than in ground control experiments.

The first U.S. protein crystal growth experiment under reasonably well-controlled conditions was carried out in September 1988 on a space transportation system (STS-26), the first shuttle flight after the Challenger accident. The γ-interferon sample and the porcine elastase sample grew much larger than the ground control samples. The isocitrate lyase sample grew as discrete prisms, whereas the ground control crystals always grew dendritically. Crystals of all three of these proteins exhibited significantly higher x-ray diffraction resolution than any produced on Earth. This was true even when some of the smaller space-grown crystals were compared with larger Earth-grown crystals.

Following STS-26, there have been many other attempts to grow a variety of protein crystals in space. Considered as a whole, these experiments have produced a mixed set of results. In some cases the space experiments yielded no crystals or produced crystals that were inferior to those grown on Earth. However, there have been a number of cases in which the space-grown crystals were larger and better ordered than the best ever grown on the earth.

Solution Growth of Small-Molecule Crystals. At least some of the advantages obtained from growth of macromolecular crystals in microgravity appear to carry over to the growth of small-molecule crystals. Triglycine sulfate (TGS) crystals were grown from solution on Spacelab-3 and again on IML-1 using a novel cooled sting method. Supersaturation was maintained by extracting heat through the seed, which was mounted on a small heat pipe, and in turn was attached to a thermoelectric device. By growing under diffusion-controlled transport conditions, it was hoped it would be possible to avoid liquid–vapor inclusions. These inclusions are the most common types of defect in solution-grown crystals and are believed to be caused by unsteady growth conditions resulting from convective flows.

Typically, TGS crystals are grown on ⟨001⟩ oriented seeds, because growth on the ⟨010⟩ face tends to be nonuniform and multifaceted. However, in the absence of convection, growth on the ⟨001⟩ seeds on Spacelab-3 was mostly around the periphery of the seed. Therefore, seeds with a natural ⟨010⟩ face were cut from a polyhedral TGS crystal for the experiments on IML-1. The crystal was grown in space with a 4°C undercooling, which produced a growth rate of 1.6 mm/d. Even though this is somewhat larger than typical growth rates (because of the limited time available) the quality of the space-grown crystal was extremely good. Growth was very uniform and the usual growth defects in the vicinity of the seed that form during the transition from dissolution to growth, known as ghost of the seed, were notably absent.

Vapor Crystal Growth. For materials that lend themselves to physical or chemical vapor transport, growth from the vapor offers some attractive alternatives to growth from the melt. Growth can take place at temperatures considerably lower than the melting point, thus avoiding some of the higher temperature problems associated with melt growth. Several crystal growth experiments on the shuttle have produced provocative results that are not at all understood, e.g., growth of unseeded GeSe crystals by physical vapor transport using an inert noble gas as a buffer in a closed tube on STS-7. In the ground control experiment, many small crystallites formed a crust inside the growth ampul at the cold end. The flight experiment produced dramatically different results; the crystals apparently nucleated away from the walls and grew as thin platelets that eventually became entwined with one another, forming a web that was loosely contained by the ampul. Even more striking was the appearance of the surfaces of the space-grown crystals. These were mirror-like and almost featureless, exhibiting only a few widely spaced growth terraces. By contrast, the crystallites in the ground control experiments conducted under identical thermal conditions had many pits and irregular closely spaced growth terraces.

Test of Dendritic Growth Models. The microgravity environment provides an excellent opportunity to carry out critical tests of fundamental theories of solidification without the complicating effects introduced by buoyancy-driven flows. This advantage was used to carry out a series of experiments to elucidate dendrite growth kinetics under well-characterized diffusion-controlled conditions in pure succinonitrile (SCN). Dendrite tip velocities were measured as a function of undercooling over a range from 0.05–1.5 K. Comparing these measurements with ground-based measurements, it was possible to show that effects of convection are more significant at the smaller undercoolings and are still important up to undercoolings as large as 1.3 K. Even in microgravity, a slight departure in the data was noted at the smallest undercooling, which was attributed to the residual acceleration of the spacecraft. These data also allow the determination of the scaling constant important in the selection of the dynamic operating state, which the present theories have been unable to provide.

Electrodeposition. Electrodeposition experiments in reduced gravity have produced some intriguing results. An early experiment on the German TEXUS rocket, using higher current densities than can normally be used on Earth, reported the deposition of amorphous Ni on Au substrates. In a series of experiments on the Consort Rocket, it was possible to repeat this result.

SPECIFIC GRAVITY. For a given liquid, the specific gravity may be defined as the ratio of the density of the liquid to the density of water. Because the density of water varies, particularly with changes in temperature, the temperature of the water to which a specific gravity measurement is referred should be stated. In exacting, scientific observations, the reference may be to pure (double-distilled) water at 4°C (39.2°F). In engineering practice, the reference frequently is to pure water at 15.6°C (60°F). A value of unity is established for water. Thus, liquids with a specific gravity less than 1 are lighter than water; those with a specific gravity greater than 1 are heavier than water. From a practical standpoint, it usually is more meaningful to express the specific gravity of gases with reference to pure air rather than to pure water. Thus, for a given gas, the specific gravity may be defined as the ratio of the density of the gas to the density of air. Since the density of air varies markedly with both temperature and pressure, exacting observations should reflect both conditions. Common reference conditions are 0°C and 1 atmosphere pressure (760 torr; 760 millimeters Hg; 29.92 inches Hg).

Specific Gravity Scales

Arising essentially from a lack of communication between various scientific and industrial communities, a number of different specific gravity scales were formulated in earlier times. Because so much data and experience have been accumulated in terms of these scales, several methods of expressing specific gravity persist in common use. The most important of these scales are defined here.

API Scale—This scale was selected in 1921 by the American Petroleum Institute, the U.S. Bureau of Mines, and the National Bureau of Standards (Washington, DC) as the standard for petroleum products in the United States.

$$\text{Degrees hydrometer scale (at }15^\circ\text{C; }60^\circ\text{F)} = \frac{141.5}{\text{sp gr}} - 131.5$$

Balling Scale—This scale is used mainly in the brewing industry to estimate percent wort but also is used to indicate percent by weight of either dissolved solids or sugar liquors. Hydrometers are graduated in percent weight at 60°F or 17.5°C.

Barkometer Scale—This scale is used essentially in the tanning and tanning-extract industry. Water equals zero. Each scale degree equals a change of 0.001 in specific gravity. The following formula applies:

$$\text{Sp gr} = 1.000 \pm 0.001 \times \text{(degrees Barkometer)}$$

Baumé Scale—This scale is used widely in connection with the measurement of acids and light and heavy liquids, such as syrups. The scale originally was proposed by Antoine Baumé, a French chemist, in 1768. The scale has been widely accepted because of the simplicity of the numbers which represent liquid specific gravity. Two scales are in use:

$$\text{For light liquids, }^\circ\text{Be} = \frac{140}{\text{sp gr}} - 130$$

$$\text{For heavy liquids, }^\circ\text{Be} = 145 - \frac{145}{\text{sp gr}}$$

The standard temperature for these formulas is 15.6°C (60°F).

To calibrate his instrument for heavy liquids, Baumé prepared a solution of 15 parts by weight of sodium chloride in water. On his hydrometer, Baumé marked zero at the point to which the float submerged in pure water; and he marked the scale 15 at the point to which the float submerged in the salt solution. He then divided the distance between the two marks into 15 equal spaces (or degrees as he termed them). In connection with liquids lighter than water, Baumé prepared a 10% sodium chloride solution. In this case, he marked the scale zero at the point to which the float submerged in the salt solution; and he marked the scale 10 at the point to which the float submerged in pure water. Thus, he created a scale which provided increasing numbers with decreases in density.

Users of the Baumé method found that the scale generally read 66 when the float was submerged in oil of vitriol. Thus, early manufacturers of hydrometers calibrated the instruments by this method. There were variations in the Baumé scale, however, because of lack of standardization in hydrometer calibration. Consequently, in 1904, the National Bureau of Standards made a careful survey and finally adopted the scales previously given for light and for heavy liquids.

Brix Scale—This scale is used almost exclusively by the sugar industry. Degrees on the scale represent percent pure sucrose by weight at 17.5°C (63.5°F).

Quevenne Scale—This scale is used for milk testing and essentially represents an abbreviation of specific gravity. For example, 20° Quevenne indicates a specific gravity of 1.020; 40° Quevenne, a specific gravity of 1.040, and so on. One lactometer unit approximates 0.29° Quevenne.

Richter, Sikes, and Tralles Scales—These are alcoholometer scales, which indicate directly in percent ethyl alcohol by weight in water.

Twaddle Scale—This scale is the result of attempting to simplify the measurement of industrial liquids heavier than water. The range of specific gravity from 1.000 to 2.000 is divided into 200 equal parts. Thus, 1° Twaddle equals 0.005 sp gr.

An abridged compilation of specific gravity conversions is given in Table 1. The specific gravities of numerous materials are given throughout this volume.

Determination of Specific Gravity. The principal means for measuring specific gravity (and density) of liquids and gases are listed in Table 2.

Hand Hydrometer. This instrument consists essentially of a long, slender glass float weighted at the lower end and provided with a scale so graduated that the depth to which the instrument sinks in the liquid indicates the specific gravity by direct reading of the scale. See Fig. 1. The numbering of the scale increases from the top downward. The instrument sometimes is proportioned so that the numbering begins with unity at the top, being applicable only to liquids heavier than water; in others, it increases from the top to unity at the lower end and is for use with liquids lighter than water; in still other designs, unity is marked at the middle of the scale and thus the instrument may be used for both light and heavy liquids. To be sensitive, the stem carrying the scale must be slender. It may be observed that the scale intervals corresponding to equal increments

of density cannot be equal where the stem is of uniform diameter. These intervals, in fact, are inversely proportional to the square of the density, being much smaller at the lower than at the upper end of the scale. To

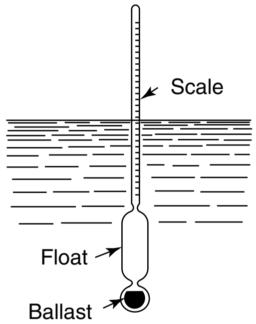

Fig. 1. Hydrometer for liquids

avoid this, some hydrometers are graduated with an arbitrary scale having uniform spacing, as in the case of the Baumé scale, the readings of which may be converted into density by reference to tables. Nicholson devised a hydrometer for measuring the densities of small solids, the specimen being placed on the hydrometer, first above and then below the surface of the water in which the instrument floats, and its volume deduced from the resulting alteration in buoyant force. See Fig. 2. Hand hydrometers are used extensively where automatic, continuous, and remote readings of specific gravity or density are not required. However, a simple hydrometer can be used in a standpipe, equipped with an overflow at reading level, thus allowing for visual observations of a continuously flowing liquid.

Automated Hydrometers. One form of hydrometer utilizes an opaque stem which, as the stem rises and falls, effects the amount of light which passes through a slit to a photocell. In this way, the photocell output is proportional to specific gravity and may be recorded by an electric instrument. In another industrial version, designed for remote transmission, the hydrometer is contained within a metal cylinder. A rod connects the bottom portion of the float to an armature, which moves vertically between inductance coils. Changes in inductance are transmitted by cable to a central instrument panel receiving instrument.

Chain-balanced Float. In this device, a submerged plummet, which is self-centering and operates essentially without friction, moves up or down with changes in specific gravity. A section of chain is fastened to the bottom of the plummet to provide a counter-buoyancy force. The effective chain weight varies as the plummet moves up and down. For each value of density or specific gravity, the plummet assumes a specific point of equilibrium. By means of a differential transformer, readings may be transmitted to a receiving instrument. A resistance thermometer bridge may be used where compensation for density changes with temperature is required. See Fig. 3.

Balanced-flow Vessel. In this method of specific gravity measurement, a vessel with a fixed-volume is weighed automatically by means of a scale, spring, or use of a pneumatic force-balance system. The liquid being measured flows continuously into and out of the vessel by way of flexible connections. Accuracy of the system is very good.

Displacement-type Meter. In this instrument, the liquid being measured flows continuously through a chamber. A displacer element, usually a hollow metal sphere or cylinder containing air, is submerged fully in the liquid. The buoyant force on the displacer is measured, often by a pneumatic force-balance system, and any variations in this force reflect changes in the specific gravity or density of the liquid. The system can be compensated for changes in liquid temperature by thermostatically heating the chamber.

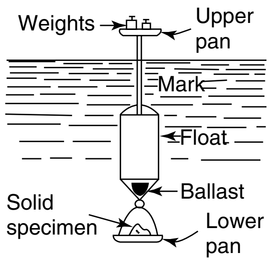

Fig. 2. Nicholson's hydrometer for small solids

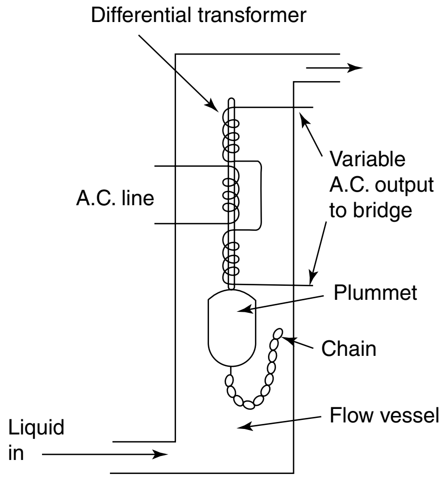

Fig. 3. Chain-balanced float or plummet-type specific gravity or density meter

Differential-pressure Method

As shown in Fig. 4, two bubbler tubes, the exit of one being lower than the other, are installed in a vessel containing the liquid being measured. Air is bubbled into the liquid through these tubes. The difference in pressure required by each tube represents the weight of a constant-height column of the liquid equal to the difference in level of the ends of the two tubes. Thus, the instrument can be calibrated directly in terms of specific gravity or density. The accuracy ranges from 0.3 to 1% and provides a good approach for liquids that do not tend to crystallize in the measuring pipes. The system is used extensively in the pulp and paper industry for the measurement of white liquor, light black liquor, and bleach. There are several variations of the air-bubbler method, including the use of a reference column and a system with range suppression.

Boiling-point Rise System

For certain liquids, the temperature of a boiling solution of the unknown may be compared with that of boiling water at the same pressure. For a given solution, the boiling-point elevation may be calibrated in terms of specific gravity at standard temperature. Usually two resistance thermometers are used. The system finds use in the control of evaporators to determine the endpoint of evaporation. Good accuracy is achieved in the determination of one dissolved component, or of mixtures of fixed composition.

Nuclear-type Density Meters

As illustrated in Fig. 5, a radioisotope source is placed on one side of a pipeline while a detector is placed on the opposite side. Transmitted radiation is in proportion to the density of the material within the pipeline. Standard radiation detectors and associated electrical instrumentation can be used. An A.C. type amplifier is used for accurate determinations when the measurement spans are narrow. For wider spans, D.C. amplifiers may be used. A compensating cell may be used for zero suppression. This essentially eliminates zero drift rate that results from radioisotope source decay. The method is particularly attractive for the density and specific gravity determination of slurries. See also **Radioactivity**.

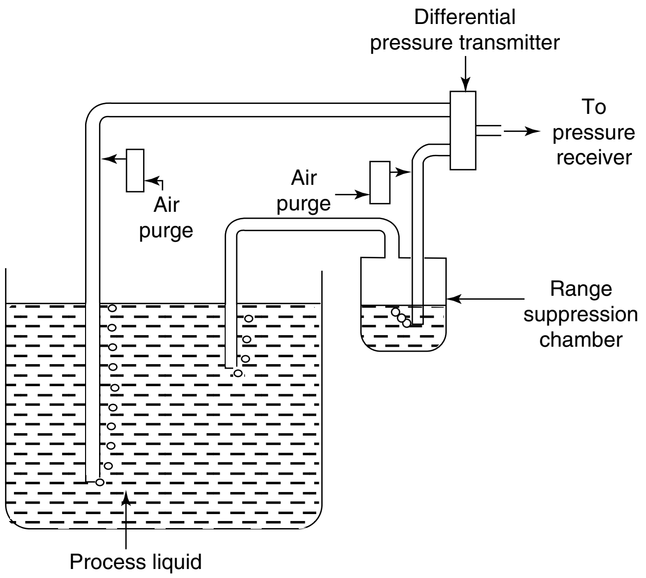

Fig. 4. Differential-pressure method for specific gravity measurement

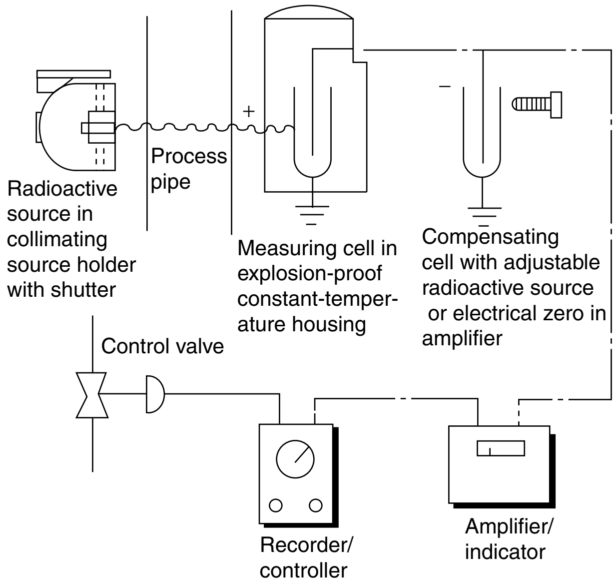

Fig. 5. Nuclear radiation-type density meter

Gas Density Measurements

In the gas specific gravity balance, a tall column of gas is weighed by the floating bottom of the vessel. This weight measurement is converted to the motion of an indicating pointer or recording pen over a graduated scale, calibrated in units of density or specific gravity. In a viscous-drag type of instrument, one set of impellers is driven in a chamber containing a standard reference gas, and the power required to achieve rotation is measured. A matching set of nonrotating impellers is located in a chamber containing the gas under test. The sets of impellers are connected by a linkage and measure the relative drag shown by the tendency of the impellers to rotate in the test gas. The balance point is a function of relative gas density. In the buoyancy gas balance, a displacer is mounted on a balance beam in the vessel containing the test gas. A reading of the air pressure required to maintain the displacer at a perfectly horizontal position (observed through a window in the chamber) is read from a manometer. Then, the air is displaced in the chamber by the gas under test. The foregoing procedure is repeated. The ratio of pressure with air to pressure with the gas provides a measure of the density of the gas relative to air. This is primarily a laboratory type measurement.

SPECIFIC HEAT. Sometimes called specific heat capacity. The quantity of heat required to raise the temperature of unit mass of a substance by one degree of temperature. The units commonly used for its expression are the unit mass of one gram, the unit quantity of heat in terms of the calorie. See also **Heat**.

Specific Heat at Constant Pressure

The amount of heat required to raise unit mass of a substance through one degree of temperature without change of pressure. Usually denoted by C_p, when the mole is the unit of mass, and c_p when the gram is the unit of mass.

Specific Heat at Constant Volume

The amount of heat required to raise unit mass of a substance through one degree of temperature without change of volume. Usually denoted by C_v, when the mole is the unit of mass, and c_v when the gram is the unit of mass.

SPECIFIC VOLUME. The volume of a substance or entity per unit mass, obtained by dividing the volume by the mass; and expressed in units of length to the third power and reciprocal units of mass. Reciprocal of the density.

See also **Density**.

SPECTROCHEMICAL ANALYSIS (Visible). Chemical systems that exhibit a selective light absorptive capacity are colored. Hence, the terms *colorimetric analysis* and *colorimetry* often are used to designate the measurement of such systems when the objective is to determine the concentration of the constituent responsible for the color. The use of the term *colorimetry* in this respect is not to be confused with the use of the same term in physics where the term refers strictly to the measurement of color. See also **Colorimetry**.

Visible spectrometry may be used to determine a constituent constituting the major part of a sample, but it also may be applied to the determination of trace quantities. Some methods are applicable to amounts of a few parts per million, with some tests sensitive to 0.01 ppm or less.

Like other areas of spectroscopy, visible spectrometry has a wide range of applications. Included are most of the elements, many anions, functional groups, and innumerable compounds.

The main practical problems in the methodology of visible spectrometry are: (1) to prepare a suitable colored solution; and (2) to measure the light absorptive capacity of this solution, or to compare it with that of a colored solution of known concentration.

Visual spectrochemical analysis has largely been displaced by other, more automated instrumental methods.

SPECTRO INSTRUMENTS. *Spectro* is used as a prefix for a wide assortment of analytical instruments. *Spectro* is derived from *spectrum*, which originally referred to the component colors that make up visible light, the so-called rainbow colors of violet, indigo, blue, green, yellow, orange, and red. A very simple device made up of a glass prism to break up sunlight into color bands is referred to as a *spectroscope*. Much more sophisticated instruments are available for manual manipulation and observation, which still rely on this basic, simple principle; these are termed visual spectroscopes, and the field is called visual spectroscopy.

Over the years, the term *spectrum* has increased in application and meaning and now embraces the total electromagnetic radiation span—no longer being confined to the visible portion. Concurrently, the term *spectroscope* has broadened in meaning so that mention of spectroscope no longer signifies an instrument which operates in the visible region. This situation gave rise to the need for modifying words for use with the term *spectroscope* to signify the portion of the electromagnetic spectrum with which the instrument is concerned. Thus, there are infrared spectroscopes, x-ray spectroscopes, ultraviolet spectroscopes, microwave spectroscopes, and so on. Further, the term *spectrum* has widened to include practically any orderly array of phenomena. For example, a mass spectrometer sorts atoms or radicals by their atomic weight—over a spectrum of values. Other spectrometers analyze the decay "spectra" of radioactive isotopes.

In terms of what is measured or observed, there are (1) portions of the electromagnetic spectrum: gamma-ray, cosmic ray, x-ray, ultraviolet, infrared, far-infrared, microwave, and radiowave instruments; (2) regions pertaining to the energies of particles: beta ray (electrons), protons, neutrons, and mass associated instruments; and (3) instruments dealing with other "spectra" such as radioactive decay and Mossbauer effects.

The suffix *scope* was ample when spectro instruments were essentially manual and confined to visual observations with the unaided eye. As the functions of these instruments increased, new suffixes were required to completely describe the instruments. Thus, if the instrument provides a record of the measurement, either by means of photographic film or by pen recording on a chart, the suffix *graph* is used. Where a meter is utilized to display the information detected by a device such as a bolometer, thermocouple, or thermistor, and so on, the suffix *meter* may be used. In cases where an instrument is designed to measure the intensity of various portions of spectra (again not confined to visible light), the suffix *photometer* may be used. Thus, there are spectrographs (spectrography), spectrometers (spectrometry), and spectrophotometers (spectrophotometry).

But, with increasing complications of instrument design and flexibility of use, the foregoing terms still are not sufficient to fully describe many instruments. Although some instruments display a continuous spectrum of what is being measured, other instruments filter out, for example, certain incident radiation. In other words, certain radiation may be absorbed, giving rise to the terms *absorption spectrometer* or *absorption spectrograph*. In some cases, the energy level of the specimen under analysis must be raised, as by means of flame heating or a spark discharge. Instruments in this category are of the emission type—and hence such terms as *flame photometer* and *optical emission spectrometer*. The names of spectro instruments can be complicated further where some special function may be incorporated in the title. A few examples are:

Spectroheliograph: a spectrograph designed for use with a telescope and for making photographs of the sun, in which the radiation of a particular element in the radiation of the sun may be recorded.

Ultraviolet-visible Spectropolarimeter: an instrument for measuring the rotation of the plane of polarization in accordance with wavelength and light intensity.

Spectrophotofluorometer: an instrument which provides means for both controlling the exciting wavelength and for identifying and measuring light output of a fluorescing sample. If the term *fluorometer* alone were used, it could indicate an instrument with a filtered light input that will measure the fluorescent light from a sample, usually by wavelength.

See also **Spectroscopy (Instrumental Analysis)**.

SPECTROSCOPE. Several types of instruments for producing 0and viewing spectra are included under this term. Variations in form are due, not only to differences in principle, but also to the type of radiation or phenomena to be examined. Terminology employed in this field of instrumentation is described under **Spectro Instruments**.

The earlier spectroscopes, developed by Fraunhofer, Ångström, and others in the early part of the last century, adapted Newton's discovery of the dispersion of light by a prism. The essential features shown in Fig. 1 are a slit, S, a collimator, C, for rendering the light from the slit parallel before entering the prism, one or more dispersing prisms, P, and a telescope, T (or a camera), for forming images of the slit in the various wavelengths and thus providing a method for viewing or photographing the spectrum. The light passes through these in the order named, being deviated by the prism through various angles according to the wavelength. When a spectroscope is provided with a graduated circle for measuring deviations, it is called a "spectrometer." The "direct-vision" or nondeviation spectroscope, employing an Amici prism, is a compact instrument for qualitative purposes. The photographic spectroscope, known as a "spectrograph," is now almost universally used in spectral research.

Many modern spectroscopes employ the diffraction grating instead of the prism. In the concave grating spectroscope, developed by Rowland, the collimating lens and telescope or camera objective are unnecessary because of the focusing effect of the grating itself. See Fig. 2.

The growth of the importance of infrared spectrography and spectrophotometry in determining the structure of compounds and the composition of substances has led to the development of many infrared spectroscopes and other instruments. Most infrared spectroscopes and spectrophotometers employ front-surface mirrors instead of lenses. This eliminates the necessity for energy to pass through glass, quartz, or similar material. Furthermore,

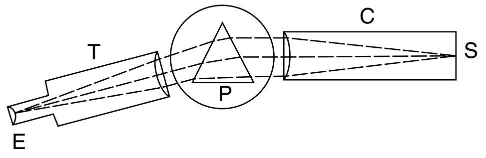

Fig. 1. Simple prism spectroscope: Collimator, C; slit, S; prism, P; telescope, T; and eyepiece for viewing spectrum, E

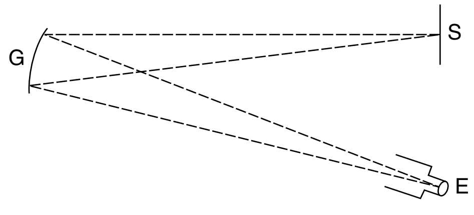

Fig. 2. Concave grating spectroscope: Slit, S; grating, G, eyepiece or plate-holder, E

it would be difficult or impossible to make lenses that would bring rays of the widely varying wavelengths in the infrared region to focus at one point. Occasionally a rock salt lens will be found in an infrared spectrophotometer, but such lenses are usually not essential optical components. Parabolic mirrors bring energy of all wavelengths to focus at one point. Reflection from most metallic surfaces is generally very efficient in the infrared region. Both gratings and prisms can be used for dispersing the energy, but prisms seem to be more common, perhaps because energy in the infrared region is at a premium and none can be wasted in higher order spectra. The materials most suitable in the infrared region are quartz, calcium fluoride, sodium chloride, and sodium bromide, all in the form of single crystals.

The energy source for an infrared spectroscope or spectrophotometer is a Nernst glower or a Globar. The receiving element for the infrared radiation must be a bolometer, Golay cell or thermistor since photocells are not sensitive in this region of the spectrum. Indeed, the thermoelectric element chosen must be extremely sensitive, since the average energy in the dispersed beam is very small.

Most available infrared instruments use the Littrow mount for the prism, the beam being reflected from a plane mirror behind the prism and thus returning it through the prism a second time. This doubles the dispersion produced. Actually, a double-pass system is also used so that the beam goes through the prism four times. Other design modifications include those with single beam and double monochromator, double beam and double monochromator, and related combinations. See also **Infrared Radiation**.

Check alphabetical index for a wide range of spectroscopic instruments that are based upon numerous materials-energy relations. Also see **Analysis (Chemical)**.

SPECTROSCOPY (Instrumental Analysis). A branch of analytical chemistry devoted to identification of elements and elucidation of atomic and molecular structure by measurement of the radiant energy absorbed or emitted by a substance in any of the wavelength of the electromagnetic spectrum in response to excitation by an external energy source. The types of absorption and emission spectroscopy are usually identified by the wavelength involved, γ-ray, X-ray, UV, visible infrared, microwave, and radiofrequency. The technique or spectroscopic analysis was originated by Fraunhofer who in 1814 discovered certain dark (D) lines in the solar spectrum, which were later identified as characterizing the element sodium. In 8161 Kirchoff and Bunsen produced emission spectra and showed their relationship to Fraunhofer lines X-ray spectroscopy was utilized by Moseley (1912) to determine the precise location of elements in the periodic system. Since then, a number of sophisticated and highly specialized techniques have been developed including the Raman spectroscopy, nuclear magnetic resonance, nuclear quadrupole resonance, dynamic reflectance spectroscopy, laser, microwave, and γ-ray spectroscopy, and electron paramagnetic resonance.

See also **Spectrochemical Analysis (Visible)**; **Spectro Instruments**; **Spectroscope**; and **Raman Spectrometry**.

SPECTRUM. The radiant energy emitted by a substance as a characteristic band of wavelengths by which it can be identified.

See also **Spectroscope**; and **Radiation**.

SPERRYLITE. A mineral diarsenide of platinum, $PtAs_2$. Crystallizes in the isometric system. Hardness, 6–7; specific gravity, 10.58; color, white; opaque. Named after Francis L. Sperry, Sudbury, Ontario.

SPERRY PROCESS. An electrolytic process for the manufacture of lead carbonate, basic (white lead) from desiliverized lead containing, some bismuth. The impure lead forms the anode. A diaphragm separates anode and cathode compartments, and carbon dioxide is passed into the solution. Impurities, including bismuth, remain on the anode as a slime blanket.

SPHALERITE BLENDE. Also known as zinc blende, this mineral is zinc sulfide, (Zn, Fe)S, practically always containing some iron, crystallizing in the isometric system frequently as tetrahedrons, sometimes as cubes or dodecahedrons, but usually massive with easy cleavage, which is dodecahedral. It is a brittle mineral with a conchoidal fracture; hardness, 2.5–4; specific gravity, 3.9–4.1; luster, adamantine to resinous, commonly the latter. It is usually some shade of yellow brown or brownish-black, less often red, green, whitish, or colorless; streak, yellowish or brownish, sometimes white; transparent to translucent. Certain varieties are phosphorescent or fluorescent. Sphalerite is the commonest of the zinc-bearing minerals, and is found associated with galena, chalcopyrite, tetrahedrite, barite, and fluorite, as a result of contact metamorphism, and as replacements and vein deposits.

There are very many European localities, including Saxony; Bohemia; Switzerland; Cornwall, in England; Spain; Sweden; Japan; and elsewhere. In the United States, sphalerite is found in Arkansas, Iowa, Wisconsin, Illinois, Colorado, New Jersey, Pennsylvania, Ohio, and especially in the area that includes parts of Kansas, Missouri, and Oklahoma. The word sphalerite is derived from the Greek, meaning treacherous, and its older name, blende, meaning blind or deceiving, refers to the fact that it was often mistaken for lead ore.

SPHENE. This mineral occurs as a yellow, green, gray, or brown calcium titanosilicate, corresponding to formula $CaTiSiO_2$, crystallizing in the monoclinic system. Fracture conchoidal to uneven; brittle; habit usually wedge-shaped and flattened crystals, also massive and lamellar; luster, resinous to adamantine; transparent to opaque; hardness, 5–5.5; specific gravity, 3.45–3.55.

Sphene is an accessory mineral of widespread occurrence in igneous rocks, and calcium-rich schists and gneisses of metamorphic origin, and very common in nepheline-syenites. In the United States sphene is found in Arkansas, California, New Jersey, New York; in Ontario and Quebec in Canada; and from Greenland, Brazil, Norway, France, Austria, Finland, Russia, Madagascar and New Zealand, as well as many other world localities.

SPINEL. The mineral spinel is one of a group of minerals which crystallize in the isometric system with an octahedral habit, and whose chemical compositions are analogous. These minerals are combinations of bivalent and trivalent oxides of magnesium, zinc, iron, manganese, aluminum, and chromium, the general formula being represented as $R''O \cdot R''_2O_3$. The bivalent oxides may be MgO, ZnO, FeO, and MnO, and the trivalent oxides Al_2O_3, Fe_2O_3, Mn_2O_3, and Cr_2O_3. The more important members of the spinel group are spinel, $MgAl_2O_4$; gahnite, zinc spinel, $ZnAl_2O_4$, franklinite (Zn, Mn^{2+}, Fe^{2+}) (Fe^{3+}, Mn^{3+})$_2O_4$, and chromite, $FeCr_2O_4$. True spinel has long been found in the gem-bearing gravels of Sri Lanka and in limestones of Burma and Thailand.

Spinel usually occurs in isometric crystals, octahedrons, often twinned. It has an imperfect octahedral cleavage; conchoidal fracture; is brittle; hardness, 7.5–8; specific gravity, 3.58; luster, vitreous to dull; transparent to opaque; streak white; may be colorless, rarely through various shades of red, blue, green, yellow, brown, or black. These colors are doubtless due to small amounts of impurities. The clear red spinels are called spinel-rubies or balas-rubies and were often confused with genuine rubies in times past. Rubicelle is a yellow spinel. A violet-colored manganese-bearing spinel is called almandine spinel.

Spinel is found as a metamorphic mineral, and also as a primary mineral in basic rocks, because in such magmas the absence of alkalies prevents the formation of feldspars, and any aluminum oxide present will form corundum or combine with magnesia to form spinel. This fact accounts for the finding of both ruby and spinel together. In addition to the localities mentioned above, which yield beautiful specimens, spinel is found in Italy and Sweden and in Madagascar. Also in the United States in Orange County, New York, and in Sussex County, New Jersey, are many well-known spinel localities. Spinel is found also in Macon County, North Carolina, and in Canada in Quebec and Ontario.

The name spinel is derived from the Greek, meaning a spark, in reference to the fire-red color of the sort much used for gems. Balas ruby is derived from Balascia, the ancient name for Badakhshan, a region of central Asia situated in the upper valley of the Kokcha River, one of the principal tributaries of the Oxus.

SPIRO COMPOUND. See **Compound (Chemical)**.

SPODUMENE. The mineral spodumene is a lithium aluminum silicate corresponding to the formula $LiAlSi_2O_6$ and occurs in monoclinic

prismatic crystals, occasionally of very large size. It also occurs massive. Spodumene has a perfect prismatic cleavage often very noticeable; uneven to splintery fracture; brittle; hardness, 6.5–7.5; specific gravity, 3–3.2; luster, vitreous to dull; color, grayish- to greenish-white, green, yellow and purple. Its streak is white; it is transparent to translucent. Spodumene is characteristically a mineral of the pegmatites, and it is found in Sweden, Ireland, Madagascar and Brazil. In the United States it is found especially in the pegmatites of Oxford County, Maine; in the towns of Goshen, Huntington and Chesterfield in western Massachusetts; at Branchville, Connecticut; in North Carolina; in South Dakota in huge crystals and in San Diego and Riverside Counties in California.

The name spodumene is derived from the Greek meaning ash-colored, particularly appropriate for the slightly weathered varieties. Hiddenite, the beautiful emerald-green or yellow-green spodumene that is used as a gem, was named for W.E. Hidden. Kunzite, named in honor of George F. Kunz, is a transparent lilac to rose-colored spodumene from Madagascar and California, and recently as magnificent, large gem crystals of both purple and yellow color from the Hindu-Kush Mountains, Nuristan Province in Afghanistan. Beautiful gem stones are cut from such crystals, but its easy cleavage discourages its use as a wearable gem. Spodumene alters rather readily to a mass of albite and muscovite. The commercial use of spodumene is chiefly as a source of lithium compounds.

SPRAY DRYING. A process used in the production of numerous chemical and food products. It is widely used in connection with the production of powdered milk and instant coffee preparations. The spray drying is unique among dryers in that it dries a finely divided droplet by direct contact with the drying medium (usually air) in an extremely short retention time (3 to 30 seconds). This short contact time results in minimum heat degradation of the dried product, a feature that led to the popularity of the spray dryer in the food and dairy industries during its early development. In the case of coffee extract, water in the feed will range from 50 to 70%.

Atomization

In as much as the spray dryer operates by drying a finely divided droplet, the feed to the dryer must be capable of being atomized sufficiently to ensure that the largest droplet produced will be dried within the retention time provided. There are different requirements on the degree of atomization needed to result in the desired product. These factors including minimizing the fine and/or coarse fractions, controlling particle dryness, and controlling bulk density. All commercial atomizers, whether of the centrifugal-wheel, pressure-nozzle, or other types, will produce a particle-size distribution that follows a probability curve. As the total energy input increases, the average particle size will decrease and the particle-size distribution will improve, i.e., the spread between the largest and smallest particles will be less.

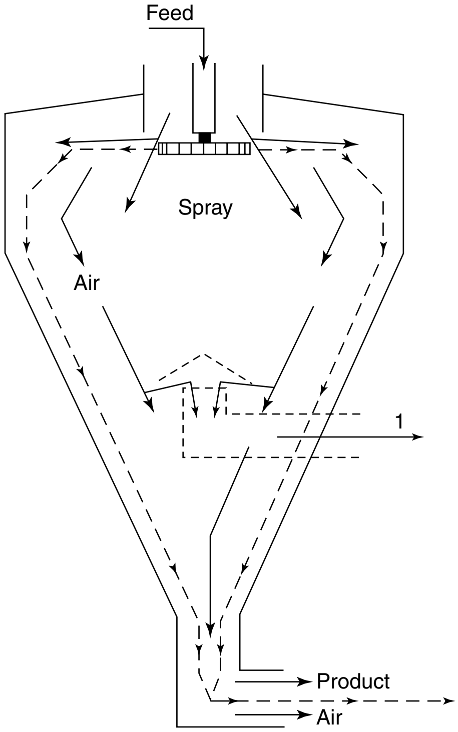

Fig. 1. Spray dryer with wheel atomizer: (1) Air outlet when drying chamber is used for initial separation

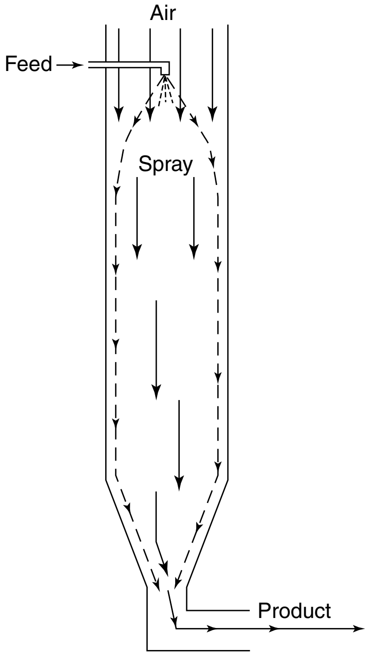

Fig. 2. Spray dryer featuring parallel flow

Centrifugal-wheel Atomizers

The wheel consists of a disk, which is rotated at very high speed (1700–50,000 revolutions per minute). See Fig. 1. Feed generally is introduced to the center, with centrifugal force dispersing the feed and throwing out a thin film to the periphery. As the film leaves the disk, it breaks up into a thread, which in turn forms droplets. The disk is located in the hot-air stream so that even though droplets are thrown toward the wall of the dryer, the hot air travels cocurrently and dries the particle sufficiently to prevent wall build-up upon contact. A spray dryer with a wheel atomizer must be relatively large in diameter and shorter than a dryer with pressure nozzles.

Pressure-Nozzle Atomizers

This system consists of an orifice placed after a fixed mechanism, called a core, swirl chamber, or whizzer, depending upon the manufacturer. A

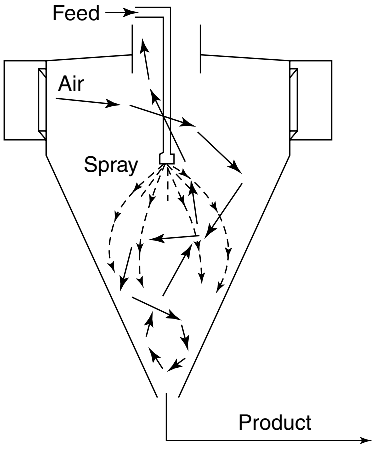

Fig. 3. Mixed-flow spray dryer

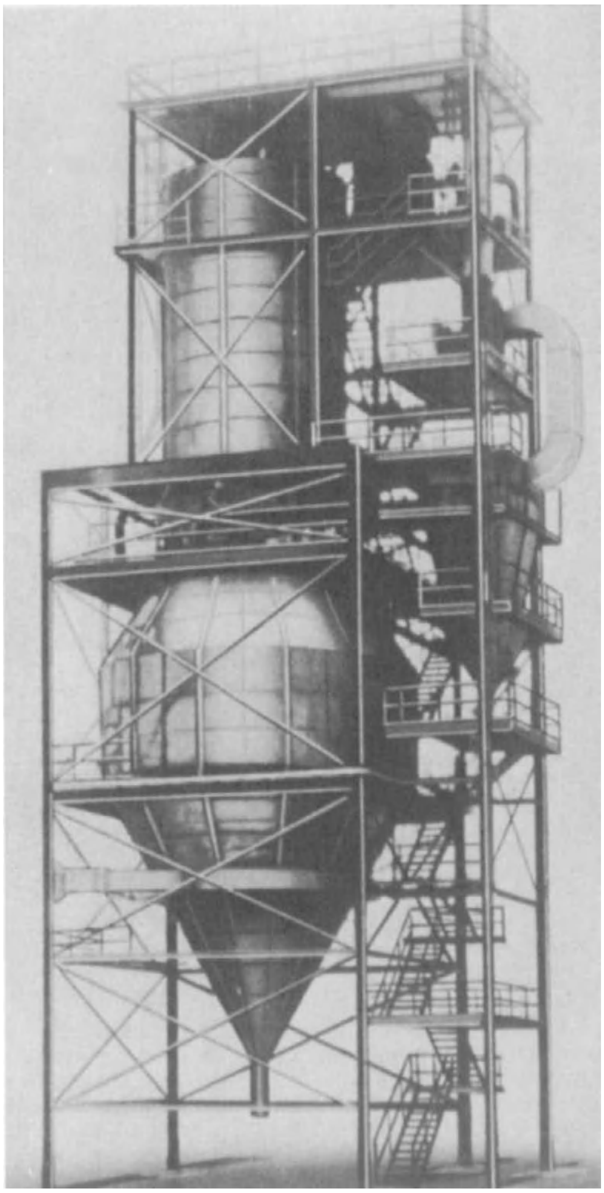

Fig. 4. Tall-form chamber employing nozzle atomization. System is particularly suited for dense particles requiring high-pressure atomization. (*Stork-Bowen*)

high-pressure pump moves the feed to the nozzle body at a pressure of from 250 to 8000 pounds per square inch (17 to 544 atmospheres). The feed slurry is pumped through high-pressure piping to the whizzer, where a spin is imparted to the fluid before it enters the nozzle orifices. This results in a hollow-cone spray which throws droplets either cocurrent or countercurrent to the air flow.

The flow pattern is such that a cocurrent spray dryer must be relatively long and small in diameter (Fig. 2), whereas a countercurrent dryer is shorter and larger in diameter. A third type, sometimes referred to as a mixed-flow dryer (Fig. 3), uses an air pattern similar to a cyclone collector, i.e., the spray is introduced at the upcoming air stream (countercurrent) and the particles transfer to the air sweeping the wall (cocurrent).

A multistory, tall-form dryer chamber using nozzle atomization is shown in Fig. 4.

SPRAYS. A spray comprises a cloud of liquid droplets randomly dispersed in a gas phase. Depending on the application, sprays may be produced in many different ways. The purposes of most sprays are *(1)* creation of a spectrum of droplet sizes to increase the liquid surface-to-volume ratio, *(2)* metering or control of the liquid throughput, *(3)* dispersion of the liquid in a certain pattern, or *(4)* generation of droplet velocity and momentum. The mechanical devices designed to generate sprays are commonly called atomizers. In the past, the design of atomizers and spray processes was based on traditional fluid dynamic principles and empirical methods. The technology of spraying has advanced rapidly through computer-aided design, mathematical modeling, and sophisticated instrumentation.

Liquid Atomizers

The transformation of bulk liquid to sprays can be achieved in many different ways. Basic techniques include applying hydraulic pressure, electrical, acoustic, or mechanical energy to overcome the cohesive forces within the liquid. Atomizers can be classified according to the energy source used to achieve liquid breakup. Table 1 provides a summary of various atomizers.

Physics of Liquid Atomization

Liquid atomization involves a series of complicated physical processes. These processes can generally be divided into three different flow regimes: internal flow, breakup, and droplet dispersion. The internal flow regime extends from the atomizer inlets to the discharge orifice where liquid emerges. The liquid breakup regime starts at the atomizer exit plane and ends at a certain distance downstream where primary atomization is complete. The final process of atomization is the dispersion regime where spherical droplets gradually evolve into a particular spray pattern.

Droplet Dispersion. The primary feature of the dispersed flow regime is that the spray contains generally spherical droplets. In most practical sprays, the volume fraction of the liquid droplets in the dispersed region is relatively small compared with the continuous gas phase. Depending on the gas-phase conditions, liquid droplets can encounter acceleration, deceleration, collision, coalescence, evaporation, and secondary breakup during their evolution. Through droplet and gas-phase interaction, turbulence plays a significant role in the redistribution of droplets and spray characteristics.

After breakup, droplets continue to interact with the surrounding environment before reaching their final destination. In theory, each

TABLE 1. SUMMARY OF ATOMIZERS BASED ON SOURCE OF ENERGY

Atomizer	Description
air-assisted	pneumatic atomizer in which pressurized air is utilized to enhance atomization produced by pressurized liquid
airblast	pneumatic atomizer that utilizes a relatively large volume of low pressure air
centrifugal	rotating solid surface is the primary source of energy utilized to produce spray
electrostatic	electric charge is the primary source of energy utilized to produce spray
piloted airblast	airblast atomizer combined with a lower capacity pressure atomizer
pneumatic (twin-fluid)	movement of gas/vapor is primary source of energy utilized to produce spray
pressure	pressurized liquid is primary source of energy utilized to produce spray
sonic	pneumatic or vibratory atomizer in which energy is imparted (frequencies > 20 KHz) to liquid
ultrasonic	pneumatic or vibratory atomizer in which energy is imparted at high frequency to liquid
vibratory (piezoelectric)	oscillating solid surface is primary source of energy

droplet group produced during primary breakup can be traced by using a Lagrangian calculation procedure. Droplet size and velocity can be determined as a function of spatial locations.

Spray Characteristics

Spray characteristics are those fluid dynamic parameters that can be observed or measured during liquid breakup and dispersal. They are used to identify and quantify the features of sprays for the purpose of evaluating atomizer and system performance, for establishing practical correlations, and for verifying computer model predictions. Spray characteristics provide information that is of value in understanding the fundamental physical laws that govern liquid atomization.

Spray Parameters. There are several common spray parameters.

Droplet Size Distribution. Most sprays comprise a wide range of droplet sizes. Some knowledge of the size distribution is usually required, particularly when evaluating the overall atomizer performance.

Mean Diameters. Several mean diameters are frequently used to represent the statistical properties of droplets produced by liquid automizers. These mean diameters include volume mean and Sauter mean diameters.

Median Diameter. The median droplet diameter is the diameter that divides the spray into two equal portions by number, length, surface area, or volume. Median diameters may be easily determined from cumulative distribution curves.

Number Density and Volume Flux. The determination of number density and volume flux requires accurate information on the sample volume cross-sectional area, droplet size and velocity, as well as the number of droplets passing through the sample volume at any given instant of time. Volume flux is the volume contained by the droplets passing through a unit cross-sectional area per unit interval of time.

Cone Angle. The spray cone angle is one of the most important parameters in the specification of atomizers. A common method of defining the spray cone angle is to draw two tangent lines originating at the orifice and extending to the outermost spray edges at a specified axial distance.

Patternation. The spray pattern provides important information for many spray applications. It is directly related to the atomizer performance. The pattern information must be able to reveal characteristics such as skewness, degree of pattern hollowness, and the uniformity of liquid flux over the entire cross-sectional area.

Spray Dynamic Structure. Detailed measurements of spray dynamic parameters are necessary to understand the process of droplet dispersion. Improvements in phase Doppler particle analyzers (PDPA) permit *in situ* measurements of droplet size, velocity, number density, and liquid flux, as well as detailed turbulence characteristics for very small regions within the spray.

Spray Correlations. One of the most important aspects of spray characterization is the development of meaningful correlations between spray parameters and atomizer performance. The parameters can be presented as mathematical expressions that involve liquid properties, physical dimensions of the atomizer, as well as operating and ambient conditions that are likely to affect the nature of the dispersion. Empirical correlations provide useful information for designing and assessing the performance of atomizers. Dimensional analysis has been widely used to determine nondimensional parameters that are useful in describing sprays.

Spray Instrumentation

An ideal droplet measurement instrument should (*1*) not interfere with the spray pattern or breakup process, (*2*) provide for large representative samples, (*3*) permit rapid sampling or counting, (*4*) have adequate resolution and accuracy over a wide range of droplet sizes, and (*5*) accommodate variations in the liquid and ambient gas properties. Significant advances have been made in the development of laser diagnostic techniques for measuring sprays. Prior to selecting such an instrument, users should have a thorough understanding of its capabilities and limitations. Existing droplet measurement techniques may be classified into three broad categories: (*1*) optical nonimaging techniques; (*2*) imaging techniques; and (*3*) nonoptical methods.

Industrial Applications

Although atomizers are usually small components in many industrial spray applications, they play an important role in determining the

TABLE 2. SUMMARY OF ATOMIZER SPRAYS FOR SPECIFIC APPLICATIONS

Atomizer spray	Special application
cone spray, hollow or solid	aerating water, brine sprays, chemical processing, coil defrosting, dust control, evaporative condensers, evaporative coolers, industrial washers, roof cooling, spray ponds, spray coating, spray drying, gas scrubbing and washing, humidification, gas cooling, cooling towers, coal washing, degreasing, gravel washing, dish washing, foam control, suspensions and slurries for food and chemical products, pollution control, and oil heating
flat spray	asphalt or tar laying, bottle washing, coal and gravel washing, foam control, degreasing, metal cleaning—rinsing, spray coating, vehicle washing and water misting, descaling, roll cooling, quenching, and agricultural spraying
plain jet spray	rocket engines, diesel engines, agitation, mixing of liquids, cataphoresis plants, and cutting
air atomizing spray	chemical processing, continuous casting, cooling casting and molds, curing concrete products, evaporative coolers, foam control, incineration, quenching, spray coating, spray painting, spray drying, flue gas desulfurization, pollution control, gas turbine engines, and medical spray

performance and efficiency of the entire process. It has long been recognized that atomizers must be properly selected to achieve optimum performance. More recently it has become necessary to comply wit stringent environmental regulations to reduce waste and pollution. Though spray requirements differ from one application to another, the spray pattern or shape appears to be a sensible criterion for selectiry liquid atomizers for certain processes. Table 2 lists a variety of applications that are based on the pattern of the spray.

SPUTTERING. In a gas discharge, material is removed, as though by evaporation, from the electrodes, even though they remain cold. This phenomenon is known as sputtering. 2. The term is also used for the corresponding phenomenon when the discharge is through a liquid. In the first case, sputtering is a nuisance that limits the life of a device; in the second case, it is put to work to make colloidal solutions of metals. 3. A result of the disintegration of the metal cathode in a vacuum tube due to bombardment by positive ions. Atoms of the metal are ejected in various directions, leaving the cathode surface in an abraded and roughened condition. The ejected atoms alight upon and cling firmly to the tube walls and other adjacent surfaces, forming a blackish or lustrous metallic film. This effect is often utilized to form very fine-grained coatings of metal upon surfaces of glass, quartz, etc., purposely exposed to the sputtering. Films of different metals can be obtained by using cathodes made of these metals. Glass plates may be thus silvered, or suspension fibers of spun quartz rendered conducting for use in electrometers, etc.

STABLIZER. Any substance that tends to keep a compound, mixture, or solution from changing its form or chemical nature. Stabilizers may retard

a reaction rate, preserve a chemical equilibrium, act as antioxidants, keep pigments and other components in emulsion form, or prevent the particles in a colloidal suspension from precipitating.

STALACTITE AND STALAGMITE. A *stalactite* is a deposit of a mineralized solution, commonly calcium carbonate, which hangs like an icicle from the roof or wall of a limestone cavern. See Fig. 1. The formation of the stalactite usually is quite a slow process. Corresponding columnar structures built upward from the floors of caves beneath the stalactites are called *stalagmites*. Stalactite is derived from the Greek, meaning to fall in drops. Stalagmite, also derived from the Greek, means that which drops. When a stalactite from the top of a cave and a stalagmite from the floor of the cave join, the resulting singular structure is called a *column*.

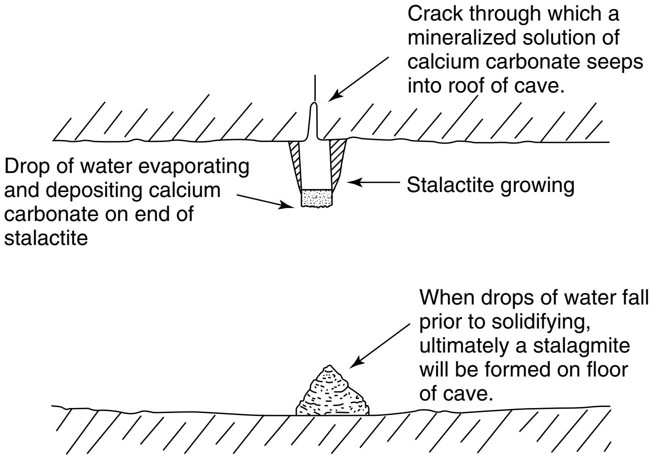

Fig. 1. Formation of stalactite and stalagmite

STANDARD CONDITIONS. Many physical and chemical phenomena and substances are defined in terms of *standard* conditions. In some instances, a temperature commonly prevailing in a chemical laboratory may be selected. Thus, when comparing a number of substances, such as their index of refraction, one may find lists in handbooks that give these values as measured by a given temperature and pressure. The Smithsonian Tables, for example, include such data for scores of substances. The researcher then can seek formulas for converting such values to other temperatures/pressures. Interpolations in some instances can be linear over a wide range of values, or the relationships may be nonlinear.

In the case of gases, properties may be tabulated in terms of their existence at 0°C and 760 mm pressure. To determine the volume of a gas at some different temperature and pressure, corrections derived from known relationships (Charles', Amonton's, Gay-Lussac's, and other laws) must be applied as appropriate. In the case of pH values given at some measured value (standard for comparison), the same situation applies. Commonly, lists of pH values are based upon measurements taken at 25°C. The pH of pure water at 22°C is 7.00; at 25°C, 6.998; and at 100°C, 6.13. Modern pH instruments compensate for temperature differences through application of the Nernst equation.

Standard conditions are not necessarily consistent with standards definitions. The careful researcher will always take note of the conditions stated for determining values in a tabulated list.

STANDARD STATE. The stable form of a substance at unit activity. The stable state for each substance of a gaseous system is the ideal gas at 1 atmosphere pressure; for a solution it is taken at unit mole fraction; and for a solid or liquid element it is taken at 1 atmosphere pressure and ordinary temperature.

STANLEY, WENDELL M. (1904–1971). An American biochemist who won the Nobel prize for chemistry in 1946 along with John H. Northrop and James B. Sumner. His work on virus research resulted in isolation of crystals proving the virus to be proteinaceous. In the 1930s, he was concerned with isolating nucleic acid from crystallized virus, and the reproduction of influenza virus. His doctorate was from the University of Illinois. His many accomplishments included membership in the National Advisory Cancer Council of the United States Public Health Service in the 1950s.

STANNITE (Mineral). This mineral is a sulfo-stannate of copper and iron, sometimes with some zinc, corresponding to the formula, Cu_2FeSnS_4. It is tetragonal; brittle with uneven fracture; hardness, 4; specific gravity, 4.3–4.5; metallic luster; color, gray to black, sometimes tarnished by chalcopyrite; streak, black; opaque. The mineral occurs associated with cassiterite, chalcopyrite, tetrahedrite, and pyrite, probably the result of deposition by hot alkaline solution. Stannite occurs in Bohemia; Cornwall, England; Tasmania; Bolivia; and in the United States in South Dakota. It derives its name from the Latin word for "tin," *stannum*.

STARCH. [CAS: 9005-25-8]. Chemically, starch is a homopolymer of α-D-glucopyranoside of two distinct types. The linear polysaccharide, amylose, has a degree of polymerization on the order of several hundred glucose residues connected by alpha-D-(1 $\rightarrow$ 4)-glucosidic linkages. The branched polymer, amylopectin, has a DP (degree of polymerization) on the order of several hundred thousand glucose residues. The segments between the branched points average about 25 glucose residues linked by alpha-D-(1 $\rightarrow$ 4)-glucosidic bonds, while the branched points are linked by alpha-D-(1 $\rightarrow$ 6)-bonds. See Fig. 1.

Most cereal starches are made up of about 75% amylopectin and 25% amylose molecules. However, root starches are slightly higher in amylopectin, while waxy corn*. and waxy milo starch contain almost 100% amylopectin. At the other extreme, high amylose corn starch and wrinkled pea starches contain 60–80% amylose. The molecules of amylose and amylopectin are synthesized by enzymes inside the living cell in plastids known as amyloplasts and are deposited as starch granules. These granules are microscopic in size, ranging from 3–8 micrometers in diameter for rice starch up to 100 micrometers for the larger potato starch granules. Corn starch usually falls in a range of 5–25 micrometers. An experienced observer usually can identify the genetic origin of a sample of starch by the size and shape of the granules. The granules are insoluble in cold water, but swell rapidly when heated to the gelatinization temperature range for the particular starch involved. As the granules swell, they lose their characteristic cross under polarized light and imbibe water rapidly until they are many times their original size. Upon continued heating or mechanical shear, the swollen granules begin to disintegrate and the viscosity, having reached a maximum, begins to decrease. However, there usually are some granules and some segments of granules that do not completely disperse in aqueous systems even under the most stringent conditions.

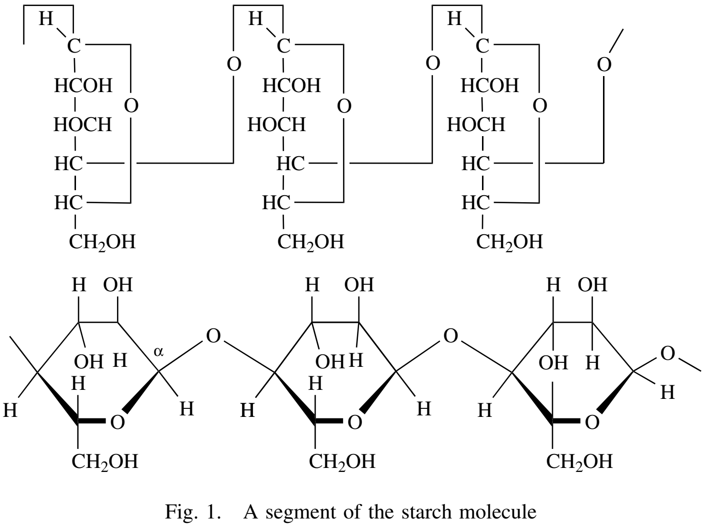

Fig. 1. A segment of the starch molecule

* With exception of North America, where the plant is called *corn*, other English-speaking people call it *maize*. French = *mais*; Spanish = *maiz*

As the partially dissolved paste is cooled, the hydrated molecules and segments of granules begin to precipitate. In a dilute system (approximately 1%), the segments and molecules retrograde or precipitate. At higher concentrations, sufficient intermolecular and intersegment bonds form to fix the entire system into three-dimensional gel. The rigidity of this gel is affected by many factors, but the amylose content is perhaps the most significant. High amylose starches, when thoroughly cooked, form very rigid gels. Waxy corn or waxy milo starch paste form little, if any, gel structure when cooled.

While some wheat and potatoes are processed in the United States, over 90% of all starch is produced from corn in what is called the *corn wet milling industry*. Close to one-quarter of a billion bushels of corn, representing about 5% of the total corn crop, is converted into wet-process products. The corn refining process is illustrated in Fig. 2. Shelled corn is delivered to the wet-milling plant in boxcars containing an average of 2,000 bushels (50.8 metric tons) per car, and unloaded into a grated pit. The corn is elevated to temporary storage bins, and then to scale hoppers for weighing and sampling. The corn passes through mechanical cleaners designed to separate unwanted substances, such as pieces of cobs, sticks, and husks, as well as metal and stones. The cleaners agitate the kernels over a series of perforated metal sheets; the smaller foreign materials drop through the perforations, while a blast of air blows away chaff and dust, and electromagnets draw out nails and bits of metal. Coming out of the storage bins, the corn is given a second cleaning before going into very large "steep" tanks.

At this point, the use of water becomes an essential part of the corn refining process. The cleaned corn is typically moved into large wooden or metal tanks holding 2,000 to 6,000 bushels (50.8 to 152.4 metric tons), and soaked for 36 to 48 hours in circulating warm water 49°C (120°F) containing a small amount of sulfur dioxide to control fermentation and to facilitate softening. At the end of the steeping process, the steepwater contains much of the soluble protein, carbohydrates, and minerals of the corn kernel, and is drawn off as the first by-product of the process. Steepwater, unmodified and modified, is an essential nutrient for production of antibiotic drugs, vitamins, amino acids, and fermentation chemicals. See Fig. 3. It is also an effective growth supplement for animal feeds.

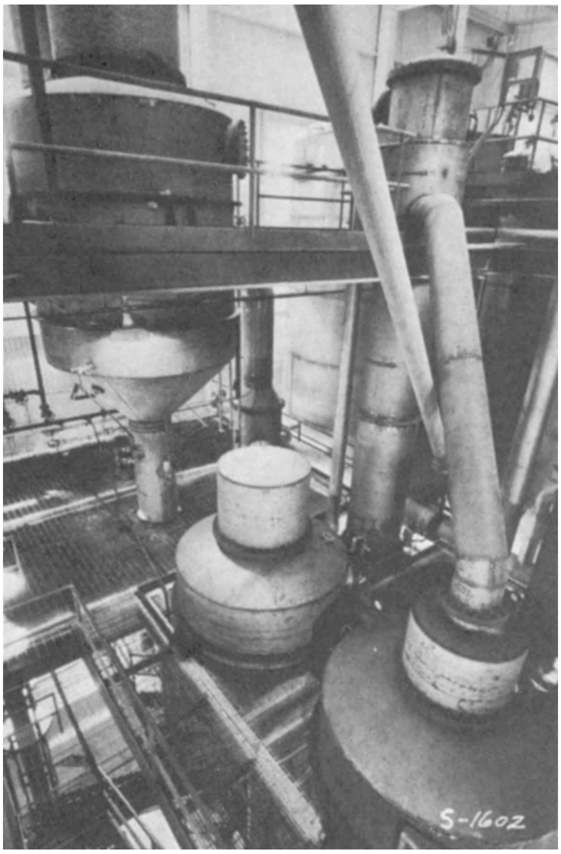

Fig. 3. Triple-effect steepwater evaporator. The third effect (forced circulation) is shown in background; second effect (falling-film, recirculating) is middle unit. The first effect vapor head is shown in foreground. (*Swenson, Whiting Corp*)

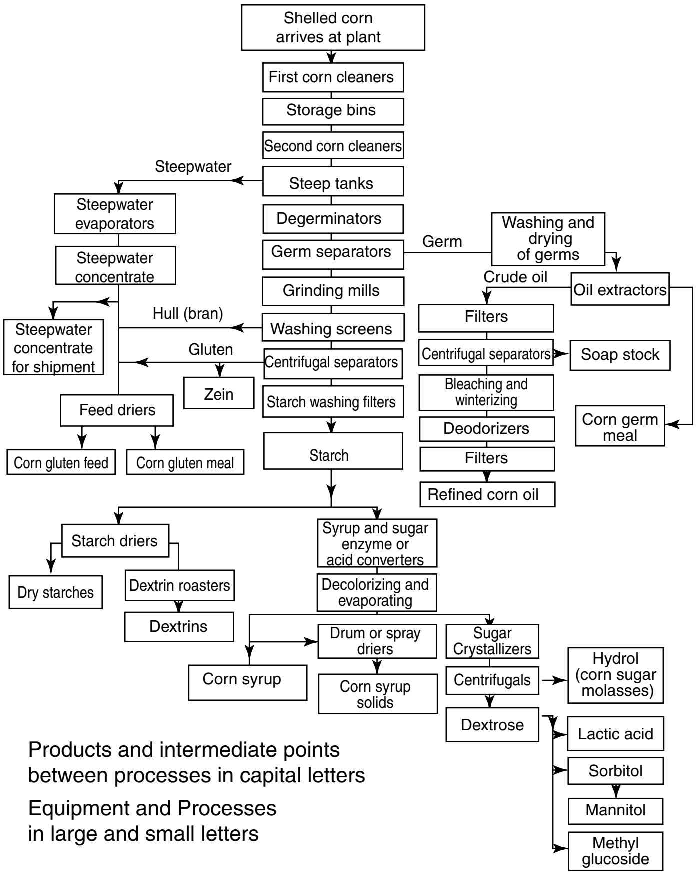

Fig. 2. The corn (maize) refining process. (*Corn Refiners Association, Inc*)

From the steeps, the softened kernels go through degerminating mills, which are designed not for fine grinding, but rather for tearing the soft kernels apart into coarse particles, freeing the rubbery oil-bearing germ without crushing it, and loosening the bran. The wet, macerated kernels then are sluiced into flotation tanks, called germ separators, or centrifugal hydrocyclones. The germs, lighter than the other components of the kernel, float to the surface, and are skimmed off. By oil expellers or extractors (heat and pressure) and by means of solvents, practically all of the oil is removed as another byproduct to be settled, filtered, refined, and otherwise processed into clear, edible oil for salad dressing and frying, and "corn oil foods" or "soap stock" for soap manufacture. The residue of the germ, after oil-extraction, is ground and marketed as corn germ meal, or may become a part of corn gluten feed or meal.

The remaining mixture of starch, gluten, and bran (hull), which is finely ground, is washed through a series of screens to sieve the bran from the starch and gluten. The hull becomes part of corn gluten feed.

The remaining mixture of gluten and starch is pumped from the shakers to high speed centrifugal machines, which, because of the difference in specific gravity, separate the relatively heavier starch from the lighter gluten. After further processing, the protein-rich gluten is marketed as such, or becomes corn gluten meal, or may be mixed with steepwater, corn oil meal, and hulls to become corn gluten feed. Gluten may also be made to yield a highly versatile protein, *zein*; amino acids, such as glumatic acid, leucine, and tyrosine; and xanthophyll oil, for poultry rations.

Having been separated from the kernels, the starch is now ready for washing, drying, or further processing into numerous dry-starch products, or into dextrin, or for conversion into syrup and sugar. From a 56-pound (25 kilograms) bushel of corn, approximately 32 pounds (14.5 kilograms) of starch result, about 14.5 pounds (6.6 kilograms) of feed and feed products, about 2 pounds (0.9 kilogram) of oil, the remainder being water.

Starch Conversion

More than half of the total production of starch is converted into syrup dextrins or dextrose by acid hydrolysis and/or enzyme action or heat treatment.

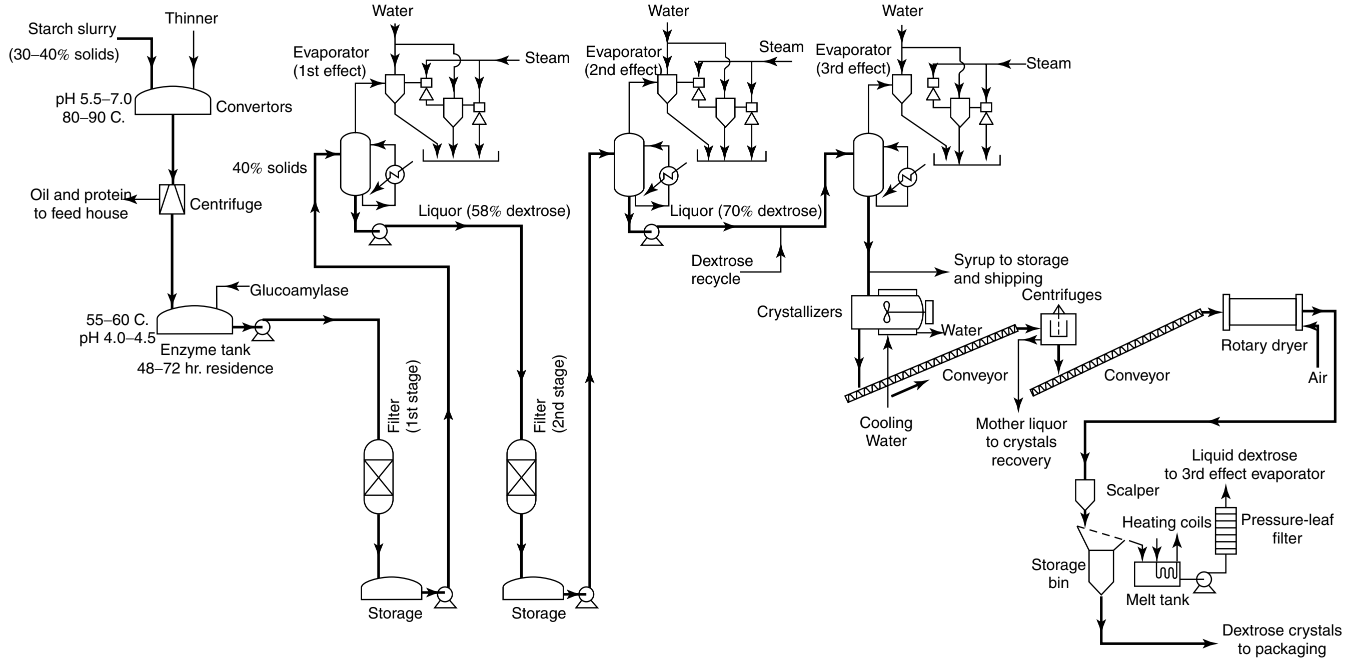

Fig. 4. Enzyme process for converting starch into dextrose. (*A.E. Staley Mfg. Co.*)

Starch, mixed with water, and heated in the presence of weak hydrochloric acid, breaks down chemically by hydrolysis. If the hydrolysis or conversion of corn starch is interrupted before final conversion, a noncrystallizing corn syrup is obtained. Many varieties may be made by supplemental use of enzymes to meet specific functional requirements. The solids content is varied to suit the requirements of the users. Corn syrup is used in a wide variety of food products, including baby foods, breakfast foods, cheese spreads, chewing gum, chocolate products, confectionary, cordials, frostings and icings, peanut butter, sausage, and for numerous industrial products, including adhesives, dyes and inks, explosives, metal plating, plasticizers, polishes, textile finishes, and in leather tanning.

A process for converting starch to dextrose is shown in Fig. 4. The enzyme process shown overcomes flavor and color difficulties of the hydrochloric acid method. The enzyme is obtained by growing a mold (*Aspergillus phoenicis*, a member of the *Aspergillus niger* group). The mold yields the key glucoamylase as well as transglucosylase. The latter must be eliminated because it catalyzes the formation of undesirable glucosidic linkages. Through a special process, almost pure glucoamylase is obtained.

Purified starch slurry (30–40% solids), made from dent corn, is received in the converters from basic processing at the corn plant. A preliminary conversion using alpha-amylase enzyme or acid is carried out at 80–90°C (176–194°F), during which 15–25% of the starch is converted into dextrose. This thins the starch slurry, allowing easier addition of the glucoamylase enzyme. It also prevents formation of unhydrolyzable gelatinous material during the main conversion, and results in increased dextrose yields of from 3–4%. Thinning also reduces evaporation costs because starch concentrations of 30–40% can be handled compared with the 12–20% limit for the acid process. Before the main conversion, the starch-dextrose slurry is centrifuged to remove oil and protein by-products, which are processed for animal feed.

The slurry then goes to a 25,000-gallon (946-hectoliter) enzyme tank where, at pH 4.0–4.5 and 60°C, the major reaction with the glucoamylase takes place. It is a batch operation requiring about 72 hours. When conversion is complete, the batch (97–98.5% dextrose on a dry basis) is passed through a preliminary decolorizing filter of powdered carbon and then pumped on to the first of three evaporators. The remaining operations are evaporation and crystallization, followed by centrifuging, and rotary drying for dextrose crystals; and by a remelting and filtering process for handling of outsize crystals, the resulting liquid being returned to the third effect evaporator for reprocessing.

STARK EFFECT. In 1913, Stark showed that every line in the Balmer series of hydrogen, when excited in a strong electric field of 100 kilovolts per square centimeter or more, is split into several components. If the spectrum is observed perpendicular to the field, some members of the line pattern are plane-polarized with the electric vector parallel to the field (p-components) and the others are polarized with the electric vector normal to the field (s-components). When the spectrum is observed parallel to the field, only unpolarized s-components are observed. A similar splitting of lines is noted in the cathode dark space of a discharge tube. The Stark effect is similar, in many respects, to the Zeeman effect but it is generally more difficult to study experimentally because of the high potential gradients needed in the light source. Its theory is quite different, and the observed spectral pattern varies markedly in character and in number of components as the field intensity increases.

See also **Zeeman Effect**.

STATE. 1. In its fundamental connotation, this term refers to the condition of a substance, as its state of aggregation, which may be solid, liquid, or gaseous—compact or dispersed.

2. As extended to a particle, the state may denote its condition of oxidation, as the state of oxidation of an atom, or the energy level, as the orbital of an electron, or in fact, the energy level of any particle.

3. In quantum mechanics, the word state is used in its most general context to refer to the condition of a system described by a wave function satisfying the Schrödinger equation for the system, when this wave function is simultaneously an eigenfunction of one or more quantum mechanical operators corresponding to one or more dynamical variables. If this set of operators includes all those which will commute with the ones in the set, then the state of the system is as completely specified as the Heisenberg uncertainty principle allows and is characterized by the eigenvalues of these operators. These eigenvalues are the results which will always be found if measurements of the corresponding dynamical variables are made. In its more limited sense, the word state is used to refer to the condition of the system when its wave function is simultaneously an eigenfunction of the Hamiltonian operator. In this case the system is characterized by a definite value of the energy, i.e., the eigenvalue of the Hamiltonian operator, and is said to be an *energy eigenstate*, a *stationary state*, or a definite *energy state*.

STATISTICAL MECHANICS. One major problem of physics involves the prediction of the macroscopic properties of matter in terms of the properties of the molecules of which it is composed. According to the ideas of classical physics, this could have been accomplished by a determination of the detailed motion of each molecule and by a subsequent superposition or summation of their effects. The Heisenberg indeterminacy principle now indicates that this process is impossible, since we cannot acquire sufficient information about the initial state of the molecules. Even if this were not so, the problem would be practically insoluble because of the extremely large numbers of molecules involved in nearly all observations. Many successful predictions can be made, however, by considering only the average, or most probable, behavior of the molecules, rather than the behavior of individuals. This is the method used in statistical mechanics.

In the general approach to classical statistical mechanics, each particle is considered to occupy a point in phase space, i.e., to have a definite position and momentum, at a given instant. The probability that the point corresponding to a particle will fall in any small volume of the phase space is taken proportional to the volume. The probability of a specific arrangement of points is proportional to the number of ways that the total ensemble of molecules could be permuted to achieve the arrangement. When this is done, and it is further required that the number of molecules and their total energy remain constant, one can obtain a description of the most probable distribution of the molecules in phase space. The Maxwell-Boltzmann distribution law results.

When the ideas of symmetry and of microscopic reversibility are combined with those of probability, statistical mechanics can deal with many stationary state nonequilibrium problems as well as with equilibrium distributions. Equations for such properties as viscosity, thermal conductivity, diffusion, and others are derived in this way.

The development of quantum theory, particularly of quantum mechanics, forced certain changes in statistical mechanics. In the development of the resulting quantum statistics, the phase space is divided into cells of volume h^f, where h is the Planck constant and f is the number of degrees of freedom. In considering the permutations of the molecules, it is recognized that the interchange of two identical particles does not lead to a new state. With these two new ideas, one arrives at the Bose-Einstein statistics. These statistics must be further modified for particles, such as electrons, to which the Pauli exclusion principle applies, and the Fermi-Dirac statistics follow.

It is often possible to obtain similar or identical results from statistical mechanics and from thermodynamics, and the assumption that a system will be in a state of maximal probability in equilibrium is equivalent to the law of entropy. The major difference between the two approaches is that thermodynamics starts with macroscopic laws of great generality and its results are independent of any particular molecular model of the system, while statistical methods always depend on some such model.

STAUROLITE. The mineral staurolite is a complex silicate of iron and aluminum corresponding to the formula $(Fe, Mg, Zn)_2Al_9Si_4O_{23}$ (OH) but somewhat varying and may carry magnesium or zinc. It is orthorhombic, prismatic, twins common, often producing cruciform crystals. It is a brittle mineral; fracture, subconchoidal; hardness, 7–7.5; specific gravity, 3.65–3.83; luster, subvitreous to resinous; color, dark brown, sometimes reddish to nearly black; grayish streak; translucent to opaque. Staurolite is a metamorphic mineral usually the result of regional rather than contact metamorphism, and is common in schists, phyllites and gneisses together with garnet, kyanite, and tourmaline.

Well-known European localities are in Switzerland and Brittany; and in the United States this mineral is common in the schists of New England, and those of the southern Alleghenies. Frequently the crystals are found loose in the soil after the disintegration of the country rock. The name staurolite is derived from the Greek meaning a cross, in reference to the twin crystals, the more nearly perfect crosses being somewhat in demand as curios.

STEAM. Steam, gaseous H_2O, is the most important industrially used vapor and, after water, the most common and important fluid used in chemical technology. Steam is generated from water by boiling, flash evaporation, and throttling from high to low pressure. The phase change occurs along the saturation line such that the specific volume of steam is larger than that of the boiling water. Thermal energy, i.e., the heat of evaporation, is absorbed during the process. At the critical and supercritical pressures, the water–steam distinction disappears, and the fluid can go from water-like properties to steam-like properties without an abrupt change in density or enthalpy. Properties of steam can be divided into thermodynamic, transport, physical, and chemical properties.

Physical Properties

Official Properties. The International Association for Properties of Water and Steam (IAPWS), an association of national committees that maintains the official standard properties of steam and water for power cycle use, maintains two formulations of the properties of water and steam. The first is an industrial formulation, the official properties for the calculation of steam power plant cycles. This formulation is appropriate from 0.001 to 100 MPa (0.12–1450 psia) and from 0 to 800°C (32–1472°F) and also from 0.001 to 10 MPa (0.12–145 psia) between 800 and 2000°C (1472–3632°F). This formulation is used in the design of steam turbines and power cycles. IAPWS maintains a second formulation of the properties of water and steam for scientific and general use from 0.01 MPa (extrapolating to ideal gas) at 0°C (1.45 psia at 32°F) to the highest temperatures and pressures for which reliable information is available.

Thermodynamic Properties. Ordinary water contains three isotopes of hydrogen (qv), i.e., ^1H, ^2H, and ^3H, and three of oxygen (qv), i.e., ^{16}O, ^{17}O, and ^{18}O. The bulk of water is composed of ^1H and ^{16}O. Tritium, ^3H, and ^{17}O are present only in extremely minute concentrations, but there is about 200-ppm deuterium, ^2H, and 1000-ppm ^{18}O in water and steam. See **Deuterium** and **Tritium**. The thermodynamic properties of heavy water are subtly different from those of ordinary water. The properties given herein are for ordinary water having the usual mix of isotopes.

Vapor pressure is one of the most fundamental properties of steam. Figure 1 shows the vapor pressure as a function of temperature for temperatures between the melting point of water and the critical point. This line is called the saturation line. Liquid at the saturation line is called saturated liquid; liquid below the saturation line is called subcooled. Similarly, steam at the saturation line is saturated steam; steam at higher temperature is superheated. Properties of the liquid and vapor converge at the critical point, such that at temperatures above the critical point, there is only one fluid. Along the saturation line, the fraction of the fluid that is vapor is defined by its quality, which ranges from 0 to 100% steam.

The density of saturated water and steam is a function of temperature. As the temperature approaches the critical point, the densities of the liquid and vapor phase approach each other. This fact is crucial to boiler construction and steam purity, because the efficiency of separation of water from steam depends on the density difference.

The enthalpies and internal energies of steam and water also converge at the critical point. The heat capacity at constant pressure, C_p, is defined as the derivative of enthalpy with respect to temperature. The value of C_p becomes very large in the vicinity of the critical point. The variation is much smaller for the heat capacity at constant volume, C_v.

Transport Properties. Viscosity, thermal conductivity, the speed of sound, and various combinations of these with other properties are called steam transport properties, which are important in engineering calculations. The speed of sound is important to choking phenomena, where the flow of steam is no longer simply related to the difference in pressure. Thermal conductivity is important to the design of heat-transfer apparatus. See **Heat-exchange Technology**. Sharp declines in each of these properties occur at the transition from liquid to gas phase, i.e., from water to steam.

Miscellaneous Properties. The dielectric constant is a physical property having great importance to the chemical properties of hot water and steam.

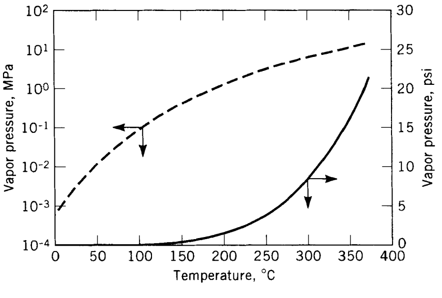

Fig. 1. Vapor pressure of ordinary water, where (___) represents linear and (— — —) logarithmic scale. To convert MPa to psi, multiply

Along the saturation line, the steam and water values converge at the critical point. The ability of water to dissolve salts results from the high dielectric constant. The precipitous drop in water dielectric constant in the region of the critical point is very important to the solubility of salts in water near the critical temperature. Many salts exhibit declining solubilities as the critical temperature is approached and then exceeded. The drop in dielectric constant is largely a result of the decline in density.

The ion product of water is the product of the molality of the hydrogen and hydroxide ions, $K_w = m_{H+}m_{OH^-}$. The ion product increases with temperature to 250°C and then declines. The initial increase is the temperature effect, and the later decline is on account of the decline in the dielectric constant of water. This variation means that neutral pH, which is the square root of the ion product, varies with temperature.

Chemical Properties

Molecular Nature of Steam. The molecular structure of steam is not as well known as that of ice or water. There are indications that in the steam phase some H_2O molecules are associated in small clusters of two or more molecules.

Solvent. The solvent properties of water and steam are a consequence of the dielectric constant. At 25°C, the dielectric constant of water is 78.4, which enables ready dissolution of salts. As the temperature increases, the dielectric constant decreases. The solubility of many salts declines at high temperatures. As a consequence, steam is a poor solvent for salts. Although the solubility of salts in steam is small, it has great significance to corrosion of steam system components, particularly steam turbines. At the critical point and above, water is a good solvent for organic molecules.

Reactant. Steam can behave as an oxidant. Steam reacts with salts so that the salts dissociate into the respective hydroxide and acid. For sodium salts, the sodium hydroxide is largely in a liquid solution and the acid is volatile. STEARIC ACID AND STEARATES. [CAS: 57-11-4]. Stearic acid $H \cdot C_{18}H_{35}O_2$ or $C_{17}H_{35} \cdot COOH$ or $CH_3(CH_2)_{16} \cdot COOH$ is a white solid, melting point 69°C, boiling point 383°C, insoluble in water, slightly soluble in alcohol, soluble in ether. Stearic acid may be obtained from glyceryl tristearate, present in many solid fats such as tallow, and in smaller percentage in semisolid fats (lard) and liquid vegetable oils (cottonseed oil, corn oil), by hydrolysis. The crude stearic acid, after separation of the water solution of glycerol, is cooled to fractionally crystallize the stearic and palmitic acids, which are then separated by filtration (oleic acid in the liquid), and fractional distillation under diminished pressure. With sodium hydroxide, stearic acid forms sodium stearate, a soap. Most soaps are mixtures of sodium stearate, palmitate and oleate.

The following are representative esters of stearic acid: Methyl stearate $C_{17}H_{35}COOCH_3$, melting point 38°C, boiling point 215°C at 15 millimeters pressure; ethyl stearate $C_{17}H_{35}COOC_2H_5$, melting point 35°C, boiling point 200°C at 10 millimeters pressure; glyceryl tristearate [tristearin $C_3H_5(COOC_{17}H_{35})_3$], melting point 70°C approximately.

Stearic acid is used (1) in the preparation of metallic stearates, such as aluminum stearate for thickening lubricating oils, for waterproofing materials, and for varnish driers, (2) in the manufacture of "stearin" candles, and is added in small amounts to paraffin wax candles. As the glyceryl ester, stearic acid is one of the constituents of many vegetable and animal oils and fats.

STEARONE. An aliphatic ketone, insoluble in water, stable to high temperatures, acids, and alkalies; compatible with high-melting vegetable waxes, paraffins, and fatty acids; incompatible with resins, polymers and organic solvents at room temperature but compatible with them at high temperature.

STEELS AND STEELMAKING. See **Iron Metals, Alloys, and Steels**.

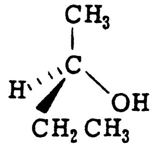
STENGEL PROCESS. A method of making ammonium nitrate fertilizer from anhydrous ammonia and nitric acid. The fertilizer particles can be made in different sizes according to use.

STEPHANITE. The mineral stephanite, silver antimony sulfide, Ag_5SbS_4, is found in short prismatic or tabular orthorhombic crystals. It is a brittle mineral; hardness, 2–2.5; specific gravity, 6.25; metallic luster; color, black; streak, black; opaque.

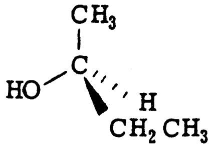
Stephanite occurs associated with other silver minerals and is believed to be primary in character. Localities are in the Czech Republic and Slovakia, Saxony, the Harz Mountains, Sardinia; Cornwall, England; Chile and Mexico. In the United States it is found in Nevada, where it is an important silver ore. It was named for the Archduke Stephan of Austria, mining director of that country at the time this mineral was first described.

STEPHEN ALDEHYDE SYNTHESIS. Preparation of aldehydes from nitriles by reduction with stannous chloride in ether saturated with hydrochloric acid. The intermediate aldimine salts have to be hydrolyzed. The best results are obtained in the aromatic series.

STEREOCHEMISTRY. Two molecules are said to be sterioisomers if they possess identical chemical formulas with the same atoms bonded one to another, but differ in the manner these atoms are arranged in space. Thus *sec*-butanol can exist in two forms, I and II, which cannot be superimposed on each other.



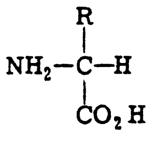
I



II

This particular example represents one class of stereoisomers known as *enantiomers*, which may be defined as two molecules that are mirror images but are nonetheless nonsuperimposable. Such molecules are said to possess opposite configuration. If these isomers are separated (*resolved*), the separate enantiomers have been found to rotate the plane of plane-polarized light. This phenomenon of *optical activity* has been known for well over a century. A 50–50 mixture of two enantiomers is optically inactive or *racemic*, since the rotation of light by one enantiomer is precisely compensated by the rotation of light in the opposite direction by the other enantiomer.

Physiological activity is closely related to configuration. Thus the left-rotating, or *levo*, form of adrenalin is over ten times more active in raising the blood pressure than is the right-rotating, or *dextro* form. Many organic chemicals essential to plants and animals are optically active. Enzymes, which catalyze chemical reactions in the body, are frequently programmed to accept only one enantiomer. All the essential amino acids, generally of the formula III, are of the *levo* type, although important

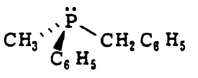


III

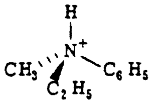
exceptions exist. Recently, several amino acids were found by NASA in a meteorite that presumably originated from the asteroid belt between Mars and Jupiter. The proof that the amino acids were extraterrestrial came

from the fact that they were racemic. Any terrestrial contaminants from laboratory handling would have been optically active and *levo*.

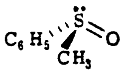
Many examples of optically active molecules contain an asymmetric carbon atom, that is, one with four different groups attached, as in I-III. A wide variety of other atoms may also be asymmetric (IV-VI). An asymmetric center is by no means



IV

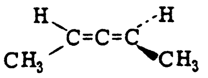


V

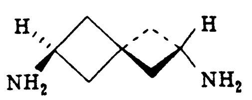


VI

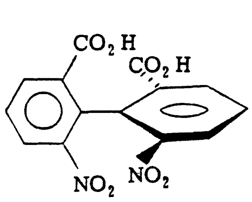
a necessary condition for enantiomerism. Well-known examples of nonsuperimposable mirror images without asymmetric atoms are allenes (VII), spiranes (VIII), biphenyls (IX), and various



VII



VIII

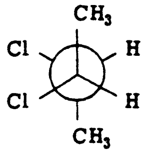


IX

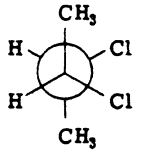
inorganic complexes. Molecules that can support optical activity are said to be *chiral*, and to possess *chirality* (meaning *handedness*, since the human hand is chiral).

The process of converting optically active materials into equal amounts of the enantiomers is called *racemization*. Ordinarily this process requires breaking of bonds to form a symmetrical (*achiral*) intermediate, and reforming the bonds to generate the racemic material. For special cases such as phosphines (IV) and sulfoxides (VI), in which one "substituent," is a nonbonding electron pair, configurational inversion may occur without breaking any bonds. For such molecules the tetrahedral enantiomers may interconvert through a metastable planar intermediate.

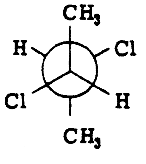
Stereoisomers that are not enantiomers are called *diastereoisomers*. Three classes may be distinguished: configurational, geometrical, and conformational isomers. Configurational diastereomers include molecules with more than one chiral center. Thus 2,3-dichlorobutane can exist in three configurationally



X



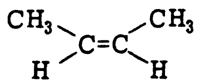
XI



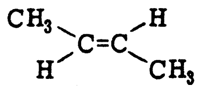
XII

different forms, X-XII. Although forms X and XI are enantiomers, XII is a stereoisomer that is not a mirror image of X or XI. It is therefore termed a diastereomer of X and XI. Even though there are two asymmetric centers in XII, it is superimposable on its mirror image. The molecule is therefore achiral. The term *meso* is applied to molecules that contain chiral centers but are achiral as a whole. The molecules of nature frequently have many asymmetric centers. If a molecule has n centers, there can be 2^n stereoisomers, although this number may be reduced if some of the diastereoisomers are *meso* or if certain ring constraints are present. Glucose is one of the aldohexose sugars, which contain four chiral centers (disregarding the phenomenon known as anomerism). The naturally occurring *dextro*-glucose is enantiomeric to *levo*-glucose, and diastereomeric to the other fourteen isomers.

Geometrical isomers differ in the arrangement of groups about certain bonds, rather than about a chiral center. 2-Butene may exist in *cis* (XIII) or *trans* (XIV) forms. In the former case the methyl groups lie on the same side of the double bond, and in the latter on opposite sides. Chirality is not important in geometrical isomerism. The isomers may be interconverted



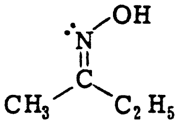
XIII



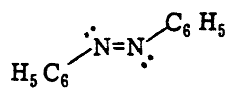
XIV

if the double bond is broken to leave a residual single bond about which rotation may occur, followed by reformation of the double bond.

Geometrical isomerism may occur not only in alkenes (XIII, XIV), but also in oximes (XV), azo compounds (XVI), and many other doubly bonded systems. More importantly, cyclic

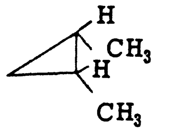


XV

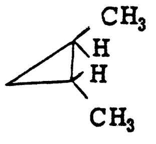


XVI

molecules exhibit this type of isomerism; the average plane of the ring serves as the reference. Molecule XVII is therefore named *cis*-1,2-dimethylcyclopropane, and XVIII is the *trans* isomer. Interconversion of XVII and XVIII would require breaking and reforming a ring bond.

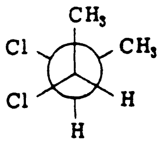


XVII

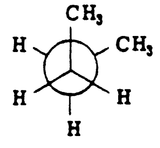


XVIII

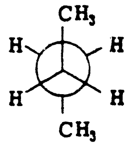
Conformational isomers differ only in the arrangements of atoms obtainable by rotations about one or more single bonds. *meso*-2,3-Dichlorobutane can exist not only in the form XII, but also as the representation XIX. To take a simpler case,



XIX

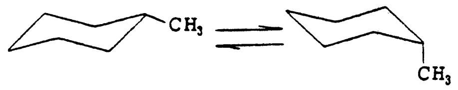


XX



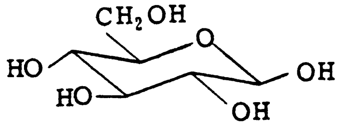
XXI

n-butane may exist in two conformational forms, known as the *gauche* (XX) and the *anti* (XXI). These isomers may inter-convert by rotation about the C−C single bond, a process that requires an energy of only 3–5 kilocalories/mole. No bonds are broken, in contrast to the manner by which geometrical isomers are interconverted. In a more complicated but very common case, substituents on the six-membered cyclohexane ring may assume either the equatorial (XXII) or axial (XXIII) positions. These isomers may interconvert by *ring reversal*, Eq. (1),



XXII XXIII

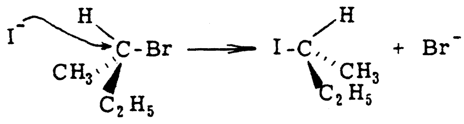
which consists of a sequence of single-bond rotations. β-D-(+)-Glucose has the specific conformation of XXIV, in which all the substituents are equatorial.



XXIV

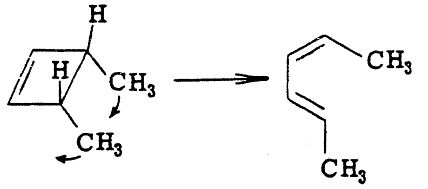
Stereochemistry is one of the most important characteristics of a reaction mechanism. In the nucleophilic displacement of iodide ion on *sec*-butyl bromide, Eq. (2), the reaction is known to occur with inversion. If one

disregards the identity of the

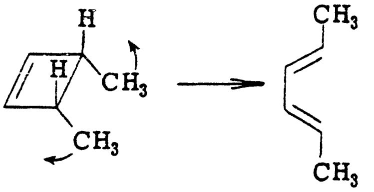


halogen, then the starting material and product have opposite configurations. Thus the iodide ion must attack the C—Br bond from the backside, thereby effecting an inversion of the chiral center.

Important mechanistic consequences may also derive from geometrical isomerism. *cis*-3,4-Dimethylcyclobutene may ring-open to form either *cis, trans-* or *trans,trans*-2,4-hexadiene. The methyl groups may rotate away from each other (disrotation, Eq. (3)) to form the *trans, trans* isomer. Alternatively, they



may rotate in the same direction (conrotation, Eq. (4)) to form the *cis,trans* isomer. An alternative disrotatory mode to form



a *cis,cis* isomer by rotation of the methyl groups toward each other need not be considered because the methyl groups cannot pass by each other. Recent experimental and theoretical consideration of this problem has demonstrated that only the conrotatory mode is permitted for this ring opening. Thus *cis*-dimethylcyclobutene always forms only *cis,trans*-hexene.

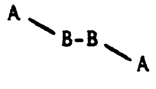
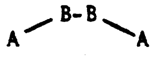
STEREOISOMERISM. If one considers a molecular unit consisting of three unlike atoms A, B, and C which are connected (*bonded*) to each other to form a linear system, three arrangements are possible: A—B—C, A—C—B, and B—A—C. By employing the simple test of superimposability it is seen that these arrangements are nonidentical and are termed *structural isomers* (Gr. *isos*, equal). Structural isomers are thus chemical species that have the same molecular formula (the same number and types of atoms) but differ in the sequence in which the atoms are bonded. Of great significance is the fact that these isomers are separated by an energy barrier: in order to convert, for example, A—B—C into A—C—B an input of energy would be necessary to break the existing A—B and B—C bonds, followed by a rearrangement of the sequence of the atoms to yield A—C—B. The rearrangement process is termed an *isomerization* and the magnitude of the energy required (the barrier) for the conversion has important consequences regarding the number of arrangements that may exist for structural isomers. This will be discussed shortly.

Turning to a four-atom arrangement consisting of A_2B_2, four structural isomers are possible if linearity of the system is again assumed: A—A—B—B; A—B—A—B; A—B—B—A; B—A—A—B. Each arrangement can be characterized in terms of interatomic distances (A to B, B to B, and A to A) and such distances would be distinctive for each isomer. It is not mandatory, however, that any one of these A_2B_2 combinations exists in a linear form and the consequences of nonlinearity will be viewed. If (for the ABBA case) planarity of the unit still exists but the internuclear angles A—B—B are set at, say, 120°, two arrangements are apparent:



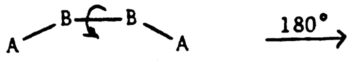
(1)



(2)

Arrangements **1** and **2** are clearly different forms of the same structural isomer and are called *stereoisomers* (Gr. *stereo*, solid or space). The relationship between **1** and **2** may be expressed in terms of the geometry of the molecule and hence these forms have also been called *geometrical isomers*. (Recalling the provisos set down for this system—planarity and angles—the difference between **1** and **2** is merely the location of one A with respect to the other in the unit.)

The statement made earlier about the energy requirement for the conversion of one structural isomer into another will now be examined. Conversion of **2** into **1** may be viewed in the simplest manner is involving a rotation of 180° about the B—B internuclear axis:

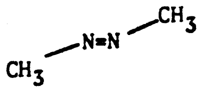


(1)

(2)

This operation involves no reshuffling of the atomic arrangement (or constitution) within the unit but does represent an isomerization. How readily such a conversion occurs then depends upon the size of the energy barrier to rotation. Looking at specific examples, the compound CH_3—N=N—CH_3, exists in two different and stable stereochemical arrangements (**3**, *cis* and **4**, *trans*) corresponding to **1** and **2** above:

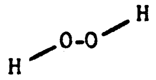
(3)



(4)

The C—N—N—C atoms are coplanar in each form and the interconversion of **3** and **4** requires a relatively high amount of energy. On the other hand, hydrogen peroxide (H_2O_2), which may be thought of as existing in similar *cis* and *trans* stereochemical arrangements (**5** and **6**), does *not* exhibit stereoisomerism

(5)



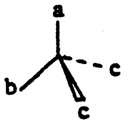
(6)

and only one isolable H_2O_2 is known. The difference in the two systems lies in the fact that rotation about the O—O single bond in H_2O_2 is relatively "free" (i.e., requires little energy) whereas the interconversion of **3** and **4** is a higher energy process that necessitates breaking a π bond before rotation may occur.

We now consider the case of four atoms (called *ligands*) that are attached to a center atom. If the general case consists of grouping A_{abcc}, square planar and tetrahedral structures, among others, may result:

(7)

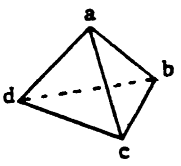
(8)



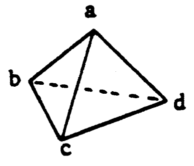
(9)

The square planar forms **7** and **8** are stereoisomers which are nonequivalent to the single nonplanar tetrahedral arrangement **9**. Now of grouping A_{abcd} is

examined one predicts three square planar stereoisomers and the following *two* tetrahedral stereoisomers (**10** and **11**):



(10)



(11)

The relationship of **10** to **11** is that of the right hand to the left hand and these nonsuperimposable stereoisomers are mirror images or *enantiomers* (Gr. *enantio-*, opposite). Thus, *chiral* (Gr. *cheir*, hand) molecules are those which possess mirror images and arise when appropriate conditions of geometry and number and types of ligands are present in a system.

A molecule that has a mirror image is also said to be dissymmetric while one that does not (an achiral molecule) have an enantiomer is nondissymmetric. The classification of a given structure as dissymmetric or nondissymmetric is based upon the presence (or lack) of symmetry elements (axes, planes) in the structure.

It is important to note that in either **10** or **11** the magnitude of any internuclear angle (e.g., a—A—c), or any bond length (e.g., A—b), or the distance between any two ligands is exactly the same. This is not true in the case of the achiral square planar isomers that may be written for the A_{abcd} system.

The single most important physical property that differentiates enantiomers is their ability to rotate the plane of plane polarized light. This property is called *optical activity* and is displayed only by chiral molecules. Thus, stereoisomers which are also chiral are known as *optical isomers*. Chiral molecules that rotate polarized light in a clockwise fashion are termed *dextrorotatory* (*d*) while those that rotate the beam counterclockwise are *levorotatory* (*l*). Enantiomers have optical rotations of the same magnitude but of different signs (*d* or *l*).

The structures **10** and **11** denoted above contain a single chiral center **A**, the atom to which the ligands are attached. If two different such centers, A and B, are in a molecule the number of optical isomers is increased to four:

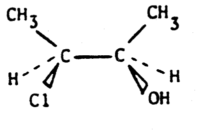
one chiral center	two different chiral centers
A±	A±
	B±

where + and − refer to the handedness or *configuration* at the chiral center. In the AB system, each optical isomer will have a mirror image whose configurations are opposite at the

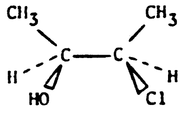
A+ A−	A+ A−
B+ B−	B− B+
mirror images	mirror images

chiral centers. The relationship of A+B+ or A−B− to A+B− (or A−B+) cannot be an enantiomeric one for the obvious reason that a given optical isomer may have only one mirror image. Instead, the relationship is said to be *diastereomeric* (Gr. *dia*, apart). Any given AB optical isomer will therefore have one enantiomer and two diastereomers.

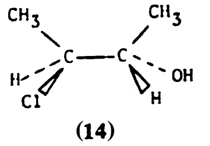
We again examine a specific case. In 3-chloro-2-butanol, $\underset{Cl}{CH_3CH}-\underset{OH}{CHCH_3}$, and A±B± situation—exists whose four isomers (**12–15**) are shown in three dimensions so that the mirror image relationship of **12** to **13** and **14** to **15** is readily apparent.



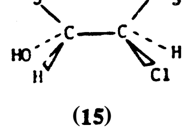
(12)



(13)

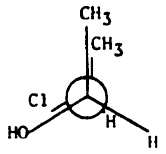


(14)



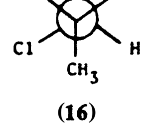
(15)

(The carbon atoms in the middle of the carbon chain are the chiral centers A and B.) Taking **12** (which is assumed to be the A+B+ combination) if one views down the bond axis of the chiral centers from the right a projection of the molecule results which shows the orientation of ligands to one another.



(12)

As noted earlier rotation may occur about single bonds in molecules and if a clockwise rotation of 180° is made about the bond axis of the chiral centers, a different form (*conformation*), **16**, results.

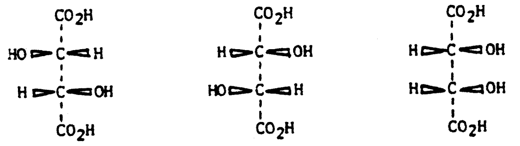


(16)

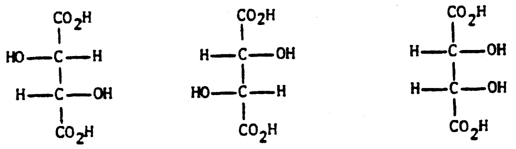
Conformations **16** and the *infinite number* of others that are obtained by rotation about the single bond in **12** are all nonidentical but the energy barrier separating them is small hence only one chiral compound having configurations ++ at the chiral centers may be isolated under normal conditions for **12**.

If two *identical* chiral centers are present in a molecular unit the number of stereoisomers is reduced to three: A+A+ and A−A− represent a pair of enantiomers but A+A− and A−A+ are identical arrangements. The +− form is said to be a *meso* or optically inactive diastereomer of the active forms A+A+ and A−A−.

The three tartaric acids may be used to illustrate the method employed in depicting three-dimensional molecules in two-dimension projections.



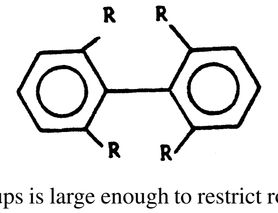
enantiomers **meso**



D enantiomers L **meso**

The top formulas show the three-dimensional relation of the groups along the main carbon chain (dashed groups lie below the plane of the paper, bold above) while the bottom formulas correspond to projections in two dimensions obtained by lifting the dashed substituents into the plane of reference and pushing the bold groups down into the plane. In this process a unique projection is obtained for each three-dimensional molecule. The symbols D and L under the formulas for the enantiomeric tartaric acids are notations used to relate the configuration at the bottom chiral center to that of a standard compound, glyceraldehyde.

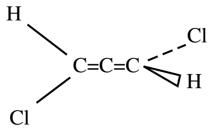
The presence of a chiral center is a sufficient, but not a necessary condition, for the existence of chirality in a molecule. For example, numerous biphenyl derivatives may exist in chiral pairs



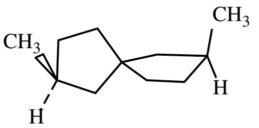
if the size of the R groups is large enough to restrict rotation about the single bond connecting the two rings. The restriction causes the rings to adopt

a nonplanar orientation and raises the energy barrier to rotation about the connecting bond. No chiral center is present and the resulting enantiomers in the example following

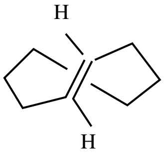
are said to possess a *chiral axis* (coinciding with the connecting bond). Axial chirality is also found in the compounds known as allenes



and in spiranes



while chiral structures such as *trans*-cyclooctene

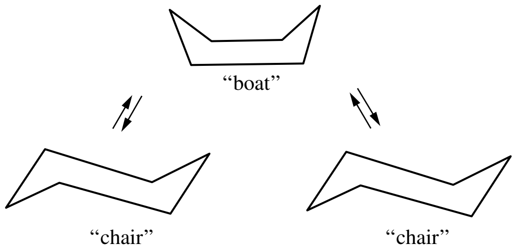


are said to possess a *chiral plane*. Each of the last three structures has a mirror image.

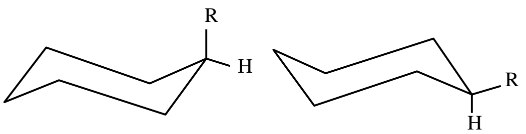
It is clear, then, that the number of chiral isomers that may exist for a given structural isomer is 2^n, where $n =$ the number of different chiral elements (centers, axes, or planes). When identical chiral elements are present, the 2^n formula does not hold.

The examples used above to illustrate centers of chirality included carbon atoms which were attached to four unlike ligands, resulting in localized tetrahedral geometry. Numerous other atoms may serve as chiral centers, however, and these include the Group IVA elements silicon, germanium, and tin; the Group VA elements nitrogen, phosphorus, antimony, and arsenic; and the Group VIA elements sulfur, selenium, and tellurium. Under conditions of bonding to three or four dissimilar ligands, chiral molecules containing these atoms as chiral centers may be isolated. Also, the geometric form about the chiral center need not be tetrahedral, for octahedral complexes of the transition metals or their ions (Co^{3+}, Cr^{3+}, etc.) may be chiral when substituted by the proper number and type of ligands.

Conformations in Six-Membered Rings. The nonplanar ring compound, cyclohexane, which contains six contiguous $-CH_2-$ units, may exist in chair or boat forms (hydrogens are not shown):

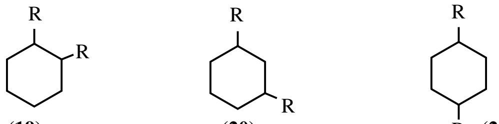


These forms are conformations of the C_6H_{12} structure and are separated by energy barriers which restrict, but do not prohibit, interconversion of the conformations. Substitution of a group on the ring yields a single nonchrial structure that exists in two main conformations, one with the substituent R *axial* and the other *equatorial* to the main plane of the ring.



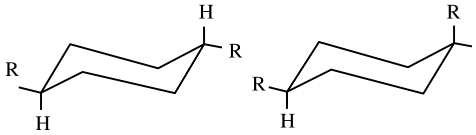
R *axial* **(17)** R *equatorial* **(18)**

Conformation **18** is in a lower energy state and predominates in the equilibrium mixture. The introduction of a second substituent into the ring gives rise to three structural isomers (shown here in projection):



(19) **(20)** **(21)**

In **19** and **20**, both carbon atoms in the ring to which the R groups are bonded are identical chiral centers and hence one pair of enantiomers and one meso diastereomer exist for each structure. In **21** no chiral center is present but the isomers that are possible in this case (shown below in the preferred conformations)

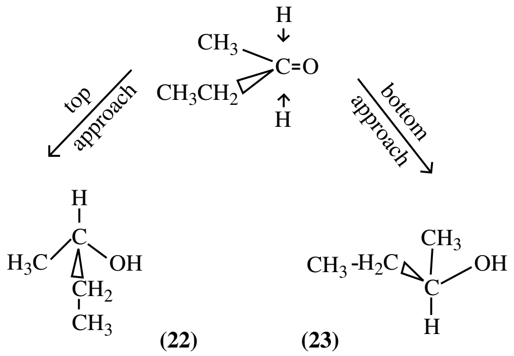


trans *cis*

may be viewed as having a diastereomeric relationship.

Consequences of Molecular Chirality. A mixture containing an equal number of molecules of enantiomers is known as a *racemic modification*. The preparation and reactions of these modifications (as well as the individual enantiomers themselves) represent important aspects of the study of stereochemistry.

If a molecule $CH_3—C(=O)—CH_2CH_3$ is converted into $CH_3—CH(OH)—CH_2CH_3$ by some achiral reagent (e.g., hydrogen gas and a catalyst) the chiral center in the product molecule may be considered as being generated by approach of a hydrogen from the top *or* bottom "face" of the planar $C—C(—C)—O$ grouping in reactant molecule

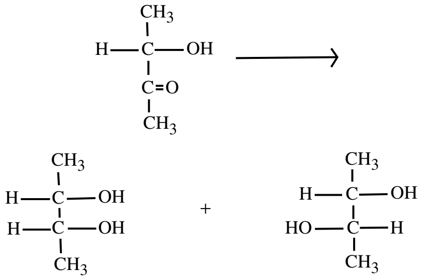


(22) **(23)**

The molecule (**22**) produced by "top" approach is the enantiomer of that (**23**) resulting from "bottom" approach. In fact, the pathways leading to each are enantiomeric, hence are of equal energy. The overall result is thus the production of a racemic modification, since one approach is as probable as another.

Now if a similar reaction were conducted with a chiral substrate that has a preexisting chiral center (A+), the combinations of configurations at the centers in the product molecules would be A + B+ and A + B−. These are

diastereomers, the pathways involving their information are diastereomeric (unequal energy!), and hence they are produced in unequal amounts. Such a case is illustrated as follows:



diastereomers

Diastereomeric reaction pathways may be obtained in numerous other ways. An interesting case is represented by the biological reduction of acetaldehyde-1-D,  The product is the chiral structure  and a racemic modification might be expected from the reduction. In fact, the transfer of a hydrogen during the enzymatic reduction (an enzyme is a large chiral molecule) to one face of the acetaldehyde is diastereomeric with the transfer to the opposite face, hence (very) unequal amounts of the enantiomers are formed. These interactions may be described as E + ... A+ and E + ... A−, where E+ represents the chirality of the enzyme and A+ or A− represent the incipient chirality in the reduced acetaldehyde molecules.

The last example reflects in a modest way the importance of the study of stereoisomerism. Biological conversions represent a glorious array of diastereomeric reactions and interactions: a given chiral amino acid is metabolized but its enantiomer is not; a certain complex drug (often a chiral molecule) alleviates pain but its enantiomer is inactive; and subtle changes in structure alter a given chiral compound's action completely in the human body.

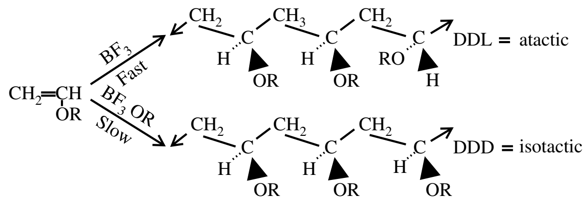
STEREOREGULAR POLYMERS. The properties of natural and synthetic high polymers and their applications in plastics, fibers, elastomers, adhesives and coatings are determined in large part by (a) their average molecular weights, (b) the forces between the long chain molecules and (c) geometrical considerations, especially the degree of regularity of repeating units. Molecular weight characteristics and forces have received attention for many years. In contrast, the importance of stereoregularity vs. irregularity of chemical substituents became fully appreciated only around 1950. In general, strong interchain forces and regularity promote normal crystallinity, along with high strength, high softening temperatures, hardness and insolubility in common solvents.

Some polymers have regular structure free of diastereoisomerism because of the symmetry of the monomers, such as vinylidene chloride, $CH_2{=}CCl_2$ and isobutene $CH_2{=}C(CH_3)_2$. However, the term stereoregular polymer is generally reserved for stereoregular polymer structures derived from unsymmetrical monomers which can be obtained by special ionic methods of polymerization (usually from heterogeneous systems). These polymerization processes often using complex catalysts such as Ziegler-Natta activated transition metal catalysts, e.g., from AlR_3 and polymeric $TiCl_3$, have been called stereoregulated, stereospecific or oriented polymerizations. In 1964 the writer suggested the word *stereopolymerization* to describe those special ionic polymerization systems for treating unsymmetrical ethylenic monomers to obtain either normally crystalline polymers with DDDDD regularity, permanently amorphous polymers with irregular DLDDL sequences or intermediate structures according to conditions chosen. Such control of polymer stereoisomerism was achieved first with vinyl alkyl ethers, but the first stereoregular polymers to become the basis of a major industry were the stereoregular or isotactic propylene polymers (heat-resistant molding plastics and fibers).

Crystallinity has been one of the principal effects by which stereoregularity or tacticity has been studied in polymers. However, as expected, not all stereoregular polymers are equally crystallizable. Differences in chemical reactivity, nuclear magnetic resonance and infrared have given useful information about stereoregularity. However, for comparing polymers from a given monomer x-ray diffraction and solubility data are most reliable for estimating tacticity.

Interest in controlling steric configurations and stereoisomerism in polymers by polymerization conditions developed only slowly. Staudinger and Schwalbach in 1931 suggested that invariable low crystallinity in polyvinyl acetate might be caused by diastereoisomerism, that is randomness in D and L positions of the acetate groups along the chain molecules[1]. Branching and deviations from head to tail addition were studied mean-while as types of isomerism. However not until 1948 were examples of stereoregulated polymerizations of a vinyl-type monomer disclosed by Schildknecht and coworkers. In both early types of stereopolymerizations vinyl isobutyl ether diluted by liquid propane could be treated at low temperatures. Addition of gaseous boron fluoride gave very rapid polymerizations to rubber-like substantially amorphous high polymers. Careful addition of cold boron fluoride etherate, immiscible with liquid propane at −78°C or above produced a slow growth or proliferous polymerization to form normally crystalline polymers.



This suggested that it might be possible to prepare normally crystalline polymers from other unsymmetrical monomers of the type $CH_2{=}CHY$ in ionic heterogeneous systems.

The discovery of stereopolymerizations of 1-alkenes by use of Ziegler-Natta catalysts in heterogeneous systems in 1954, and subsequent studies of polymer structure, attracted world-wide attention to this field. Propylene and 1-butene, which are monoallylic compounds, had not been homopolymerized by conventional ionic or free radical conditions to give linear high polymers suitable as plastics or other synthetic materials. Short branches in polyethylenes had been shown to reduce crystallinity and hardness. Natta and coworkers demonstrated the ability of catalysts such as those from reaction of aluminum alkyls with titanium halides to form normally crystalline, surprisingly high softening polymers from propylene. A helix of three monomer units explained the regularity required for crystallization and the identity period observed from x-ray diffraction. Stereoregular isotactic polymers of crystal melting ranges shown in Table 1 were prepared by slow heterogeneous ionic polymerizations using special catalysts at moderate pressures and temperatures.

Stereoregular propylene polymer plastics have outstanding utility, for example, heat resistance superior to that of polyethylenes in sterilizable hospital devices. By copolymerization and control of the degree of stereoregularity brittleness at low temperatures can be avoided. Stereoregular 1-butene and isobutylethylene polymers are also manufactured, but the isotactic polymers from styrene and from methyl methacrylate are too brittle for much use. Crystallizable polystyrenes also have been prepared by heterogeneous anionic polymerizations (Lewis basic catalysts) and crystalline methyl methacrylate polymers can be prepared using Grignard catalysts.

Soluble catalysts derived from organoaluminum compounds and vanadium halides promote formation of atactic elastomeric propylene polymers and copolymers such as ethylene-propylenediene terpolymer rubbers (EPDM). Amorphous adhesive propylene homopolymers have some commercial use. Syndiotactic or DLDL propylene polymers have been reported but their structures and properties have not been completely established.

Isomeric isoprene polymers are formed biologically as natural rubber (*cis*-1,4) and balata or gutta-percha (largely *trans*-1,4). Modified Ziegler-Natta type catalysts, colloidal lithium or lithium alkyls (in absence of ethers) were found to give predominantly *cis*-1,4 polymer rubbers from isoprene. *Cis*-1,4-polybutadiene, so-called synthetic natural rubbers, have become important in tires and in graft copolymerization with styrene for high-impact plastics. Different conditions of polymerization give rigid *trans*-1,4-diene polymers resembling balata.

TABLE 1. CRYSTAL MELTING RANGES OF SOME STEREOREGULAR POLYMERS

Isotactic stereopolymers	Melting range	Stereopolymers	Approximate maximum melting point
Propylene	165–176°C	Isotactic 1,2-butadiene	120°C
1-Butylene	120–136	Syndiotactic 1,2-butadiene	154
1-Amylene	60–70	*Cis*-1,4-butadiene	+1
Isopropylethylene	300–310	*Trans*-1,4-butadiene	148
Isobutylethylene	235–250	*Cis*-1,4-isoprene	22
Isoamylethylene	about 110	*Trans*-1,4-isoprene	65
4,4-Dimethyl-1-pentene	>380	*Cis*-1,4-(2,3-dimethyl butadiene)	190
Styrene	230–250	*Trans*-1,4-(2,3-dimethyl butadiene)	260
Isobutyl vinyl ether	100–130		
Methyl methacrylate	160		

Although precise mechanisms of the stereopolymerizations are yet uncertain, several characteristics become evident. The reactions are predominantly heterogeneous, ionic reactions at low or moderate temperatures. The more stereoregular polymers grow as a separate phase upon the solid or immiscible liquid catalyst. However, some monomers such as vinyl isobutyl ether can form somewhat isotactic polymer fractions even from homogeneous solutions of Lewis acid and monomer. In contrast, the polymers from vinyl isopropyl ether, which apparently are stereoregular when obtained by slow growth polymerization using boron fluoride etherate catalysts, nevertheless do not crystallize readily. BF_3 can be used to form isotactic vinyl isobutyl ether polymers if it is applied in a separate phase of methylene chloride immiscible with liquid propane. Relatively polar solvents which favor separation of gegen ions from their growing macroions generally impair stereospecificity.

Although the Ziegler-Natta catalyst systems for stereopolymerization of 1-olefins were regarded by Natta, Mark, and others as examples of anionic polymerizations, the writer considers them as a special type of cationic polymerization. A consistent system relating monomer structure to response to catalyst types is only possible if propylene containing an electron repelling methyl group attached to the ethylene nucleus polymerizes with Lewis acid catalysts (cationic polymerization). Propylene as an allyl compound lacks sufficient electron withdrawal from the ethylene group to homopolymerize by free radical initiation (peroxide, azo catalysts or ultraviolet light) and it also lacks sufficient electron donation (as in isobutene) for homopolymerization by conventional cationic system. Ziegler-Natta catalysts have been observed to homopolymerize some other monoallyl compounds. An intensive study of the literature by the writer and Mabel D. Reiner showed no well-characterized homopolymers of high molecular weight obtained from monoallyl compounds by free radical or conventional ionic catalyst systems.

Transition metal catalysts for polymerization of 1-alkenes similar to those of Ziegler were developed in DuPont laboratories and have been called coordination catalysts.

Outside of vinyl addition polymerizations some crystallizable stereoregular polymers also have been prepared. An example is isotactic polymer from propylene oxide

$$\text{—}\underset{\displaystyle \text{CH}}{\overset{\displaystyle CH_3}{|}}\text{CH}_2\text{O—}$$

made by using ferric chloride complex catalysts for proliferous type reactions.

After the demonstrations of preparation of stereoregular polymers having novel properties by means of special ionic methods, the possibilities of free radical methods were examined extensively. It must be concluded that in free radical systems the structures of homopolymers and copolymers can be little influenced by specific catalysts and other reaction conditions, but are determined largely by monomer structure. This is consistent with the relative uniformity of comonomer reactivity ratios in radical copolymerizations. However, it has been found possible to obtain somewhat more syndiotactic structure, DLDL, than normally obtained by radical reactions, at low temperatures and by selecting solvents. Examples are polyvinyl chlorides of higher than usual crystallinity from polymerizations at low temperature e.g., −50°C under ultraviolet light.

Although they do not crystallize, polyvinyl acetates prepared at low temperatures apparently are more syndiotactic since they yield more than usually crystalline polyvinyl alcohols by saponification. Monomers of high polarity such as vinyl trifluoracetate by radical polymerization can form relatively syndiotactic polymers from which more crystalline polyvinyl alcohols can be prepared by saponification.

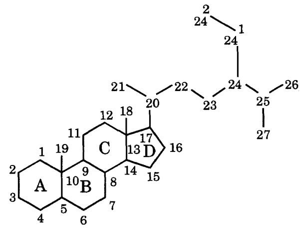
STERLING SILVER. Silver alloy, usually with copper, containing at least 92.5% silver.

STEROIDS. Steroids are members of a large class of lipid compounds called terpenes that are biogenically derived from the same parent compound, isoprene, C_5H_8. Steroids contain or are derived from the perhydro-1,2-cyclopentenophenanthrene ring system (**1**) and are found in a variety of different marine, terrestrial, and synthetic sources. The vast diversity of the natural and synthetic members of this class depends on variations in side-chain substitution (primarily at C17), degree of unsaturation, degree and nature of oxidation, and the stereochemical relationships at the ring junctions.



(**1**)

There are many classes of natural and synthetic steroids best known for their wide array of biological activity. The naturally occurring steroids can be subdivided into several categories that include (*1*) nonhormonal, mammalian steroids; (*2*) vitamin D; (*3*) hormonal steroids; and (*4*) other naturally occurring steroids. See also **Hormones**; **Vitamin**; and **Vitamin D**.

Structure and Nomenclature

The position-numbering and ring-lettering conventions for steroids are shown in (**1**). Positions 18 and 19 are often angular methyl groups; in addition, position 19 can be a hydrogen and is not substituted when the A-ring is aromatic. Position 17 can be substituted, unsubstituted, and/or oxygenated. Compounds are systematically named as derivatives of the parent hydrocarbons shown in Figure 1. Substituents that extend below the plane of the steroid are referred to as α and are designated by a broken line; those attached to the plane of the steroid from above are called β and are shown by a bold or solid line. Substituents of unknown configuration are indicated by a wavy line. Generally, the ring junctions have an all-trans relationship with the hydrogen attached to C9 on the α-face, unless otherwise indicated. Changes in steroid nomenclature that have been introduced since 1972 include a wider use of the (R), (S)-system for designating the stereochemistry in the side chain. Although the systematic nomenclature for steroids has been firmly established, the most common and most important steroids are often designated by trivial names.

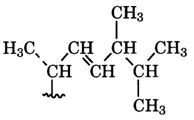

Fig. 2. Vitamin D: prohormones (10), and active hormone (11)

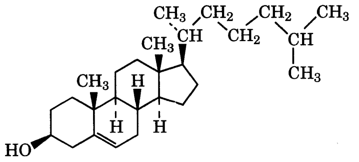
Classification of Biologically Active, Natural Steroids

Nonhormonal Mammalian Steroids

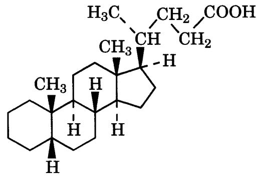
Sterols and Cholesterol. Natural sterols are crystalline $C_{26}-C_{30}$ steroid alcohols containing an aliphatic side chain at C17. Sterols were first isolated as nonsaponifiable fractions of lipids from various plant and animal sources and have been identified in almost all types of living organisms. By far, the most common sterol in vertebrates is cholesterol (**8**). Cholesterol serves two principal functions in mammals. First, cholesterol plays a role in the structure and function of biological membranes. Secondly, cholesterol serves as a central intermediate in the biosynthesis of many biologically active steroids, including bile acids, corticosteroids, and sex hormones.

Bile Acids and Alcohols. Bile acids have been detected in all vertebrates that have been examined and are a result of cholesterol metabolism. The C_{24} acid, 5β-cholanic acid (**9**) is the structural derivative of the majority of bile acids in vertebrates. Most mammalian bile acids have a cis-fused A–B ring junction resulting in a nonplanar steroid nucleus. Bile acids, like sterols, typically contain a C3α-hydroxyl group (lithocholic acid: 3α-hyroxycholanic acid.



(8)

Along with the C3α-hydroxyl group, bile acids may contain a hydroxyl at C7α, at C12α, and at other positions. Bile salts, cholesterol, phospholipids, and other minor components are secreted by the liver.



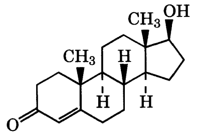
(9)

Vitamin D. The term vitamin D refers to a group of seco-steroids that possess a common conjugated triene system of double bonds. Vitamin D_3 (**10a**) and vitamin D_2 (**10b**) are the best-known examples (Fig. 2). Vitamin D_3 (**10a**) is found primarily in vertebrates, whereas vitamin D_2 (**10b**) is found primarily in plants. The term *vitamin* is a misnomer. Vitamin D_3 is a prohormone that is converted into physiologically active form, primarily 1,25-dihydroxyvitamin D_3 (**11**), by successive hydroxylations in the liver and kidney. This active form is part of a hormonal system that regulates calcium and phosphate metabolism in the target tissues.

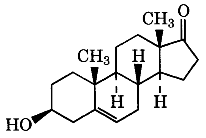
Steroid Hormones. Generally, steroid hormones are metabolically short-lived steroids produced in small amounts by various endocrine glands. They serve as chemical messengers that regulate a variety of physiological and metabolic activities in vertebrates. Steroid hormones bind to soluble, intracellular receptor molecules. In the nucleus of the cell, dimeric steroid receptors bind to DNA and together with a heteromeric complex of proteins, regulate gene transcription. Molecules that interfere with steroid hormone gene regulation are called antagonists or antihormones. Steroid hormones can be subdivided into sex hormones (androgens, estrogens, and progestins) and corticosteroids (glucocorticoids and mineralocorticoids).

Sex Hormones. Androgens, estrogens, and progestins are steroids that are secreted primarily by the genital glands. From a chemical point of view, the division of the sex hormones into these three groups is convenient; however, they may possess common physiological properties. Therefore, the sex hormones are organ-specific rather than sex-specific.

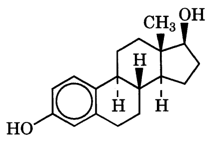
Androgens are C_{19} steroids that contain the basic perhydro-1,2-cyclopentenophenanthrene ring system with the C18 and C19 angular methyl group. A primary function of androgens is to maintain the male sex organs and secondary sex characteristics. Examples of androgens are testosterone (**12**) and dehydroepiandrosterone (DHEA) (**13**). DHEA is one of the most abundant steroids in human males; however, it is not a potent androgen.



(12)



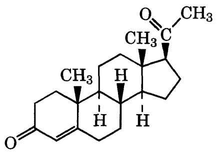
(13)



(14)

Estrogens. Estrogens are characterized by having an aromatic A-ring and thus having a phenolic character. Estrogens stimulate the growth and development of the female reproductive organs and the secondary sex characteristics. Another primary function of estrogens along with progesterone, is to regulate the ovulatory cycle. Estrogens, as with all the steroid hormones, are important for healthy growth and development in women and men. The main production site of estradiol (**14**) is the female ovary; however, small amounts of estrogens are produced in testes and the adrenal cortex. Synthetic and natural estrogens play an important role

in the treatment of osteoporosis in post-menopausal women. Antiestrogens are important for the treatment of breast cancer.

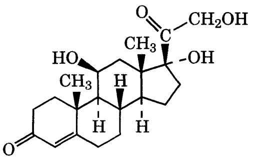


(15)

Progesterone (**15**), the principal progestin in mammals, is secreted primarily by the corpus luteum of the ovary. A main responsibility of progesterone, together with estrogen, is to prepare the endometrium for pregnancy.

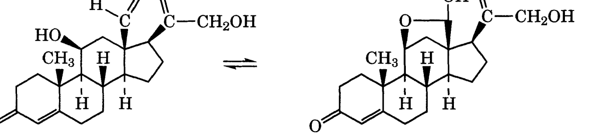
Corticosteroids. Although the adrenal cortex secretes small amounts of androgens and estrogens, the major secretory steroids from this gland are called corticosteroids. Corticosteroids have several biological activities, including the regulation of electrolyte balance by mineralocorticoids and carbohydrate and protein metabolism by glucocorticoids.

Natural, potent glucocorticoids possess a Δ^4-3-one group, an oxygen substituent at C11β (necessary for agonism), and a C17β-2-hydroxyethan-1-one sidechain. Atypical example is cortisol (**16**). The principal effects of glucocorticoids are to mobilize fat and protein from tissues, utilize these nutrients to supply energy for the body, and decrease the rate of carbohydrate utilization. Thus, they are diabetogenic and act as functional insulin antagonists. Glucocorticoids are also potent inhibitors of inflammation, and they are used as therapeutics.



(16)

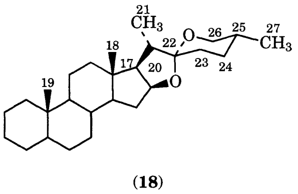
Aldosterone (**17**), the most potent natural mineralocorticoid, also possesses a Δ^4-3-one group, an oxygen substituent at C11β, and a C17β-2-hydroxyethan-1-one side chain. In addition, the C18 of aldosterone is oxidized to an aldehyde. Mineralocorticoids act to retain sodium and to prevent the retention of excess potassium.



(17)

Other Natural Steroids. Steroids are nearly ubiquitous to all living organisms and have a variety of structural variations.

Sapogenins and Saponins. Steroids isolated from a variety of plant sources that contain a spiroketal between hydroxyl moieties at C16 and C26 and a carbonyl at C22 are called sapogenins (**18**). Sapogenin aglycones have been an important source of starting materials for the commercial steroid industry. Saponins are widely distributed in plants and marine organisms and consist of a steroid or terpene skeleton attached to a saccharide. Because of diversity in structure, pharmacology, and biological activities, saponins have been studied for a number of different commercial applications. Saponins have been used as detergents, foaming agents, and fish toxins. Although toxic to fish, saponins are nontoxic when ingested by humans. Another commercial application of saponins is in food flavoring.

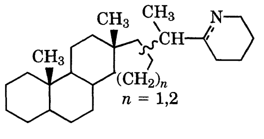


(18)

Plant Sterols. Sterols have been identified in almost all types of living organisms and can be isolated, in varying quantities, from many different plants. Similar to cholesterol, plant sterols have a structural and functional role in biological systems and serve as intermediates in the biosynthesis of an assortment of biologically active steroids.

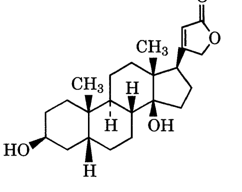
Steroid Alkaloids. Steroid alkaloids are compounds isolated from plants and some higher animals that possess the basic steroidal skeleton with nitrogen(s) incorporated as an integral part of the molecule. The nitrogen can be located within the perhydro-1,2-cyclopentenophenanthrene ring system or in a side chain.

Steroid alkaloids have been isolated from four families of terrestrial plant sources (*Solanaceae, Liliaceae, Apocynaceae*, and *Buxaceae*), two animal sources (*Salamandra* and *Phyllobates*), and several marine sources. Steroid alkaloids can be classified based on structure and fall into a variety of categories. The spirosolanes contain a C_{27} cholestane skeleton with a C20 spiroaminoketal moiety. Solanidine-type steroidal alkaloids are a small subclass. The largest subclass of steroidal alkaloids is the secosoline bases; (**19**) is a general secosolanidine. The pregnane-type alkaloids have one or more nitrogens attached to a pregnane skeleton. The buxus alkaloids, isolated from evergreen shrubs, contain carbon substitution at C4 and C14 and either a cyclopropane moiety between C9, C10, and C19 or the B-ring expanded diene. Buxus alkaloids have been used as folk remedies for a variety of disorders, including venereal disease, tuberculosis, cancer, and malaria. The samanine, jerveratrum, and ceveratrum-type compounds all have a structurally altered C_{27} steroid skeleton. The samanine alkaloids have an expanded A-ring with the formation of an isoxazoline ring system and a cis-A–B ring junction. Ritterazines and cephalostatins are among steroid alkaloids recently isolated from marine sources. When assayed *in vitro*, cephalostatins are among the most potent cytotoxins ever screened by the National Cancer Institute.



(19)

Cardiac Steroids. Cardiac steroids (steroid lactones) and corresponding glycosides are characterized by their ability to exert a powerful inotropic (increasing the force of cardiac contraction) effect, and are used both for their inotropic and antiarrhythmic properties. The two most prevalent cardiac aglycones are the cardenolides and bufadienolides. The cardenolides are C_{23} steroids that have a C17β-substituted five-membered lactone that is generally α,β-unsaturated, an unusual β-faced oxygen on C14, and a bile acid-like cis-A–B ring junction. Cardenolides are exemplified by digitoxigenin (**20**) which is an active ingredient in digitalis. The bufadienolides differ in that they are C_{24}-steroids that possess a C17β-substituted six-membered lactone ring that generally has two degrees of unsaturation. Other structural variations in both series are the stereochemistry at C3 and the degree of oxidation on the nucleus and side chains.



(20)

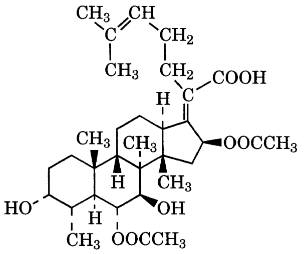
Withanolides. Withanolides are C_{28}-steroidal lactones that are isolated from the Solanaceae plant family. Withanolides are characterized by an ergostane-type skeleton, the C17-side chain of which is transformed into a six-member lactone ring. The withanolides and the related ergostanes are the only known natural steroids obtained from the same family that have representatives with both α- and β-orientations of the C17 side chain.

Ecdysteroids. Ecdysteroids can be isolated from many species of the animal kingdom that belong to the phyla Protomia, e.g., insects, worms, and arthropods, as well as a variety of different plant species. Ecdysteroids include the molting hormones; however, not all the over 60 ecdysteroids that have been isolated are active hormones. Ecdysteroids from animals

are referred to as zooecdysteroids and from plants are referred to as phytoecdysteroids.

Marine Sterols. Several hundred unique sterol structures have been elucidated from a variety of marine invertebrates. A single nucleus can be used to describe most terrestrial sterols, but no single template suffices for marine sterols. Similar to cholesterol, marine sterols play a critical role in both the physiology and biochemistry of biological systems.

Steroid Antibiotics. The steroid antibiotics are a structurally diverse class of steroids that have a common biological function, i.e., antibacterial, antifungal, antiviral, or antitumor activities. This group of compounds can overlap with other steroid classes listed above. Fusidic acid, helvolic acid, and cephalosporin P_1 (**21**) exemplify a set of antibacterial steroids that contain a prolanostane skeleton with an unique trans–syn–trans–antitrans stereochemistry. These compounds inhibit the growth of gram-positive bacteria by inhibiting protein synthesis, but have little activity against gram-negative bacteria. An antibiotic isolated from the tissues of the dogfish shark is the steroid alkaloid squalamine, a broad-spectrum antibiotic that exhibits potent antimicrobial activity against fungi, protozoa, viruses, and both gram-negative and gram-positive bacteria.



(**21**)

Biosynthesis

Steroids are members of a large class of lipid compounds called terpenes. Using acetate as a starting material, a variety of organisms produce terpenes by essentially the same biosynthetic scheme (Fig. 3). The self-condensation of two molecules of acetyl coenzyme A (CoA) forms acetoacetyl CoA. Condensation of acetoacetyl CoA with a third molecule of acetyl CoA, then followed by an NADPH-mediated reduction of the thioester moiety produces mevalonic acid (**22**). Phosphorylation of (**22**) followed by concomitant decarboxylation and dehydration processes produce isopentenyl pyrophosphate. Isopentenyl pyrophosphate isomerase establishes an equilibrium between isopentenyl pyrophosphate and 3,3-dimethylallyl pyrophosphate (**23**). The head-to-tail addition of these isoprene units forms geranyl pyrophosphate. The addition of another isopentenyl pyrophosphate unit results in the sesquiterpene (C_{15}) farnesyl pyrophosphate (**24**). Both of these head-to-tail additions are catalyzed by prenyl transferase. Squalene synthetase catalyzes the head-to-head addition of two achiral molecules of farnesyl pyrophosphate, through a chiral cyclopropane intermediate, to form the achiral triterpene, squalene (**25**).

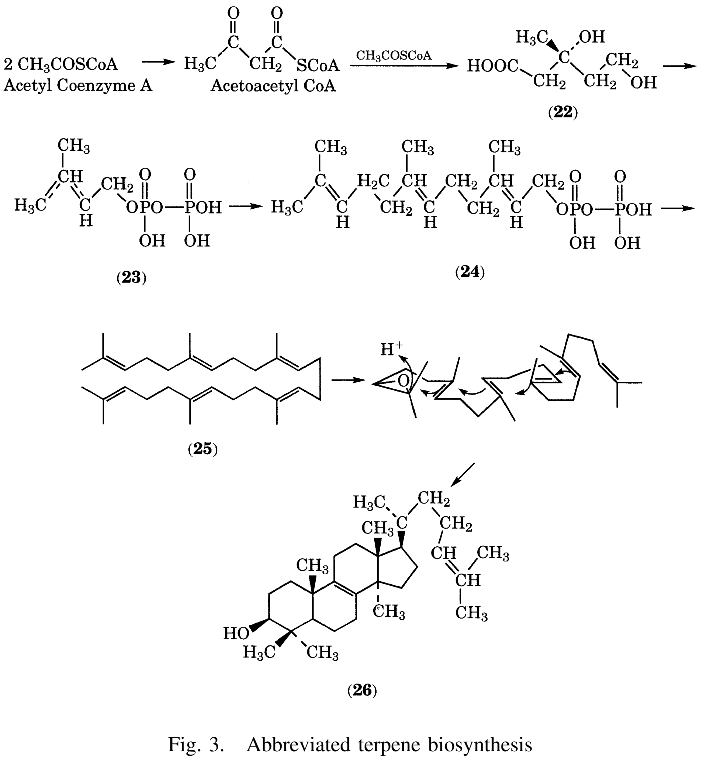


Fig. 3. Abbreviated terpene biosynthesis

Stereospecific 2,3-epoxidation of squalene, followed by a non-concerted carbocationic cyclization and a series of carbocationic rearrangements, forms lanosterol (**26**) in the first steps dedicated solely toward steroid synthesis. Cholesterol is the principal starting material for steroid hormone biosynthesis in animals. The cholesterol biosynthetic pathway is composed of at least 30 enzymatic reactions. Lanosterol and squalene appear to be normal constituents, in trace amounts, in tissues that are actively synthesizing cholesterol.

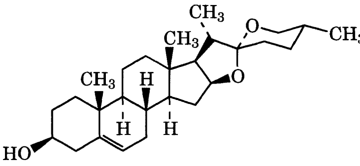
Manufacture and Synthesis

There are three general processes for steroid production: (*1*) direct isolation from natural sources, (*2*) partial synthesis from steroid raw materials that have been isolated from plants and animals, and (*3*) total synthesis from nonsteroidal starting materials.

Direct Isolation. The two most important classes of steroid pharmaceuticals that are isolated directly from natural products are some estrogens and most cardiac steroids. Compounds with estrogenic activity have been isolated from different sources, including urine from pregnant women and from pregnant mares. Cardiac steroids occur in small amounts in various plants with a wide geographical distribution.

Partial Syntheses.

Raw Materials and Extraction. The variety of natural sources of steroid raw materials is vast, and the exact details of manufacturing processes are ambiguous closely held industrial secrets. However, the most widely utilized raw materials for the partial synthesis of steroids appear to be the following: (*1*) the sapogenins, for example, diosgenin (**27**), (*2*) the structurally related steroid alkaloids, (*3*) sterols, such as cholesterol (**8**), and (*4*) bile acids.



(**27**)

Plants of the genus *Dioscorea* are the most common source of diosgenin. This genus occurs abundantly in tropical and subtropical regions throughout the world.

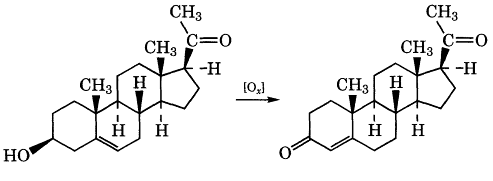
Owing to periodic fluctuations in the price of diosgenin, alternative raw materials such as solasodine have been used for the synthesis of steroid drugs. In the U.S., the plant sterols stigmasterol and β-sitosterol are a significant raw material for the synthesis of antiinflammatory glucocorticoids and other steroid hormones.

Methods of Partial Synthesis. Partial syntheses are done typically by chemical degradation or fermentation/biotransformation.

An important commercial method for the commercial synthesis of steroids is the chemical degradation of diosgenin. The Marker degradation became the principal method for commercial steroid synthesis in the 1940s and 1950s, and modifications of this process are still in use. When diosgenin is heated to approximately 200°C in acetic anhydride, elimination and acetylation of the oxygen in the F-ring produce the bis-acetylated enol ether. Oxidative cleavage of the enol ether with chromium trioxide followed by elimination of the C16-acyl-oxygen results in steroid. Selective hydrogenation of the α, β-unsaturated ketone in the D-ring from the sterically less hindered α-face forms pregnenolone (**28**). Pregnenolone is readily converted into progesterone (**15**) under oxidative conditions.

This process was improved and expanded to provide starting materials for the C19-sex hormones that include estrogens and androgens. Another commercial method that has been used for the production of progesterone

is the chemical degradation of the side chain of stigmasterol.



(**28**) (**15**)

Fermentation/Biotransformation. Commercial biotechnology operations have focused on microbial agents for specific transformations of individual steroid substrates. The regio- and stereoselective hydroxylation of every site on virtually every steroid nucleus is possible. Many of these hydroxylation steps are of commercial importance. For example, the 9α-, 11α-, 11β-, and 16α-hydroxylations are key steps in the industrial synthesis of synthetic corticosteroid antiinflammatory drugs. These steps are accomplished almost exclusively by microbial transformations. In addition to hydroxylations, other useful microbial oxidations of steroids include alcohol oxidations, epoxidations, oxidative cleavage of carbon–carbon bonds, introduction of double bonds, peroxidations, and heteroatom oxidations. Other invaluable microbial steroid transformations include reductions, degradations, A-ring aromatization, resolutions, isomerizations, conjugations, hydrolyses, heteroatom introduction, and sequential reactions.

There are two principal biotechnological applications dealing with steroids. Microbial agents are used for processing raw materials into useful intermediates for general steroid production and for specific transformations of steroids to advanced intermediates or finished products (Table 1).

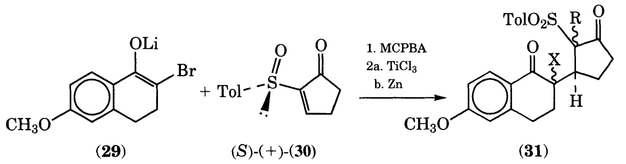
Processing Raw Materials. Along with the aforementioned chemical methods of processing steroid raw materials, microbial transformations have been and are used in a number of commercial degradation processes. The microbial degradation of the C17 side chain of the two most common sterols, cholesterol (**8**) and β-sitosterol, is a principal commercial method for the preparation of starting materials in Japan and the U.S.

Representative Partial Syntheses. The synthesis of 19-nor-steroids was stimulated by the development of orally active progestins as birth control agents.

Total Synthesis.

Estranes. Investigations into the total synthesis of steroids began in the 1930s shortly after the precise formula for cholesterol was established. The earliest studies focused on equilenin. Initially, equilenin was synthesized in 20 chemical steps with an overall yield of 2.7%. This synthesis helped to confirm the perhydro-1,2-cyclopentenophenanthrene ring system of the steroid nucleus. Estrone was the second natural steroid to be synthesized from nonsteroidal starting materials in 0.1% overall yield in 18 steps. Since these original processes, a vast number of total syntheses of aromatic A-ring steroids have appeared.

An asymmetric synthesis of estrone begins with an asymmetric Michael addition of lithium enolate (**29**) to the scalemic sulfoxide (**30**). Direct treatment of the crude Michael adduct with *meta*-chloroperbenzoic acid to oxidize the sulfoxide to a sulfone, followed by reductive removal of the bromine affords (**31**) X = α and βH; R = H in over 90% yield.



(**29**) (*S*)-(+)-(**30**) (**31**)

The most recent, and probably most elegant, process for the asymmetric synthesis of (+)-estrone applies a tandem Claisen rearrangement and intramolecular ene-reaction. Most 19-norsteroid contraceptive agents are produced by total synthesis from nonsteroidal starting materials.

Androstanes and Pregnanes. The first total syntheses of nonaromatic steroids that contain the C19-angular methyl substituent were accomplished in the early 1950s. These syntheses all began with starting materials containing a two-ring system. A more recent ring annulation strategy for the total synthesis of steroids begins with the formation of the C–D-ring system as a suitably functionalized indane. Condensation of the pyrrolidine enamine of cyclopentanone with ene-one results in the bicyclic keto-ester in 60–70% yield. Treatment of the latter with isopropenyl acetate and sulfuric

TABLE 1. COMMERCIAL MICROBIAL TRANSFORMATIONS USED TO PRODUCE ADVANCED INTERMEDIATES OR FINISHED PRODUCTS

Substrate[a]	Transformation	Product	Organism
progesterone	11α-hydroxylation oxidation/lactonization		*Rhizopus nigricans* *Cylindrocarpon radicicola*
11-deoxycortisol (17α-derivatives)	11β-hydroxylation	cortisol/derivatives	*Curvularia lunata*
6α-fluoro-16α-methyl-21-hydroxypregn-4-ene-3,20-dione	11β-hydroxylation	Paramethasone	*Curvularia lunata*

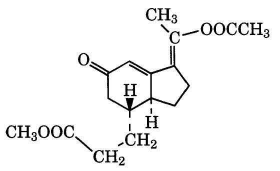
[a] Class is corticosteroid unless otherwise noted.
[b] Class is estrogen–progestin.
[c] Class is androgen.

acid produces a dienol acetate. Treatment of this dienol acetate with acetic anhydride and boron trifluoride etherate forms (**32**) as the major product.



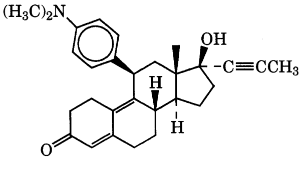
(**32**)

Several additional Diels-Alder cycloaddition strategies have been applied to the total synthesis of the steroid skeleton. For example, the first enantio-selective synthesis of (+)-cortisone was accomplished by the intramolecular [4 + 2] cycloaddition of an olefinic *o*-quinodimethane that contained an optically active stereodirecting group as the key chemical step.

Other approaches to the stereoselective total synthesis of nonaromatic steroids include the carbocationic, biomimetic cyclization reactions. Generally, these cyclizations begin with the synthesis of an appropriately functionalized cyclopentenol. Acid-catalyzed cyclization forms the B–C–D rings of the steroid nucleus with the natural relative stereochemistry in a single step.

Removable cation-stabilizing auxiliaries have been investigated for polyene cyclizations. For example, a silyl-assisted carbocation cyclization has been used in an efficient total synthesis of lanosterol. Other conditions for the cyclization of polyenes and of ene-ynes to steroids have been investigated. Oxidative free-radical cyclizations of polyenes produce steroid nuclei with exquisite stereocontrol. Besides the aforementioned A-ring aromatic steroids and contraceptive agents, partial synthesis from steroid raw materials has also accounted for the vast majority of industrial-scale steroid synthesis.

An interesting breakthrough in steroid endocrinology occurred with the discovery of a novel class of steroid antihormones. Several 11β-substituted 19-norsteroids display potent antiprogestinal activity. For example, RU-486 (**33**) is marketed in Europe as a contragestive agent. The synthesis of RU-486 demonstrates a unique method for functionalization of the 11β-position of a steroid nucleus.



(**33**)

Uses: Therapeutics and Toxicology

Steroid Hormones

Sex Hormones. The largest economic impact of synthetic estrogen and progestin production has been for use as contraceptive agents and for treatment and prevention of osteoporosis. Mixtures of estrogens and progestins have been used as contraceptive agents since the early 1960s. The principal mode of steroid contraceptive action is exerted at the hypothalamic–pituitary–ovarian and uterine sites. Thus, contraceptive steroid mixtures have been used to treat a variety of related abnormal states including endometriosis, dysmenorrhea, hirsutism, polycystic ovarian disease, dysfunctional uterine bleeding, benign breast disease, and ovarian cyst suppression.

Estrogens are routinely prescribed to post-menopausal women to prevent the development and exacerbation of osteoporosis, because it can increase bone density and reduce fractures. Estradiol (**14**) or conjugated estrogens are typical agents used for the prevention and treatment of osteoporosis.

Antiprogestins, such as RU-486 (17β-hydroxy-11β-(4-dimethylamino-phenyl-1)-17α-(prop-1-ynyl)-estra-4,9-diene-3-one) (**33**) and ZK98299 11β-(4-dimethylaminophenyl)-17α-hydroxy-17β-(3-hydroxypropyl-13α-methyl-4,9-gonadien-3-one) represent a new class of drugs for fertility regulation. Also, these drugs have potential applications in the treatment of uterine cancer.

During the 1960s and 1970s a wide range of estrogens and antiestrogens were synthesized primarily to study reproductive endocrinology. The focus of clinical applications of many of these antiestrogens has shifted to breast cancer therapy. Although structurally different, these antiestrogens bind to the estrogen receptor in the breast cancer cell and exert a profound influence on cell replication.

Testosterone, alkylated testosterone, or testosterone esters are the primary anabolic–androgenic steroid drugs. The medicinal uses for these drugs include treatment of certain types of anemias, hereditary angioedema, certain gynecological conditions, protein anabolism, certain allergic reactions, and use in replacement therapy in gonadal failure states. However, anabolic–androgenic steroids are best known for their nonmedical, and illegal, use to aid in body-building or to increase skeletal muscle size, strength, and endurance.

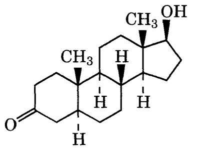
Corticosteroids. The greatest portion of steroid drug production is aimed at the synthesis of glucocorticoids, which are highly effective agents for the treatment of chronic inflammation. Glucocorticoids exert their effects by binding to the cytoplasmic glucocorticoid receptor within the target cell and thus either increase or decrease transcription of a number of genes involved in the inflammatory process. Glucocorticoids are used to treat a variety of different diseases that are exacerbated by inflammation, such as arthritis, asthma, rhinitis, and skin irritations.

Corticosteroids are the most efficacious treatment available for the long-term treatment of asthma, and inhaled corticosteroids are considered to be a first-line therapy for asthma. Rhinitis is characterized by nasal stuffiness with partial or full obstruction, and itching of the nose, eyes, palate, or pharynx, sneezing, and rhinorrhoea. If left untreated it can lead to more serious respiratory diseases such as sinusitis or asthma. Nasal spray topical corticosteroids are widely regarded as the reference standard in rhinitis therapy.

Other Therapeutics Steroids.

Saponins. Synthetic steroids that are structurally related to saponins have been shown to lower plasma cholesterol in a variety of different species.

Heterocyclic Steroids. Steroid 5α-reductase (types 1 and 2) converts testosterone (**12**) to the physiologically more potent androgen dihydrotestosterone (DHT) (**34**). The type 1 isoform occurs in nongenital skin, whereas the type 2 isoform is the predominant form in the prostate (the type 1 isoform is present in a lesser extent) and genital skin fibroblasts. There has been much interest in developing inhibitors of steroid 5α-reductase as a therapy for a variety of disorders associated with elevated levels of DHT, including benign prostatic hyperplasia (BPH), some prostatic cancers, certain skin disorders, and male pattern baldness.



(**34**)

Analytical Methods

The field of steroid analysis includes identification of steroids in biological samples, analysis of pharmaceutical formulations, and elucidation of steroid structures. Many different analytical methods, such as ultraviolet (uv) spectroscopy, infrared (ir) spectroscopy, nuclear magnetic resonance (nmr) spectroscopy, x-ray crystallography, and mass spectroscopy, are used for steroid analysis.

Generally, the most powerful method for structural elucidation of steroids is nuclear magnetic resonance (nmr) spectroscopy. A definitive method for structural determination is x-ray crystallography. Extensive x-ray crystal structure determinations have been done on a wide variety of steroids. In addition, other analytical methods for steroid quantification or structure determination include, mass spectrometry, polarography, fluorimetry, radioimmunoassay, and various chromatographic techniques.

STEVENS REARRANGEMENT. Migration of an alkyl group from a quaternary ammonium salt to an adjacent carbanionic center on treatment with strong base. The product is a rearranged tertiary amine, sulfonium, or sulfide.

STIBNITE. The mineral stibnite, antimony sulfide, Sb_2S_3, is found in radiated groups of acicular orthorhombic crystals or in other sorts of aggregates, as well as blades, also as columnar or granular masses. It shows a highly perfect pinacoidal cleavage; conchoidal fracture; hardness, 2; specific gravity, 4.63–4.66; luster, metallic and very brilliant on cleavage faces or freshly fractured surfaces. Its color is a steely gray; the streak very similar in color, may be covered with a black, sometimes iridescent tarnish.

Stibnite is the most common antimony mineral known and is the chief ore of that metal. It is a primary ore mineral and occurs with other antimony minerals and galena, sphalerite, and silver ores. It is found in Germany, Rumania, the Balkans, Italy, Borneo, Peru, Japan, China, Mexico; and in the United States in California and Nevada.

The name stibnite is derived from the Latin word for antimony, *stibium*.

STILBITE. The mineral stilbite, $NaCa_2(Al_5Si_{13})O_{36} \cdot 14H_2O$, is a zeolite, the compound monoclinic crystals of which are usually grouped in approximately parallel positions, forming sheaf-like aggregates, which have a soft pearly luster, whence the name stilbite from the Greek, meaning luster. The less commonly used term desmine is likewise from the Greek, meaning a bundle. Stilbite has one perfect cleavage; uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 2–2.2; luster, vitreous to pearly; color, usually white but may be brownish, yellowish, red or pink. Its streak is white, and it is transparent to translucent. Like the other zeolites stilbite occurs in cavities in basalts and traps, rarely in granites and gneisses. Of the many localities may be mentioned Trentino, Italy; the Harz Mountains; Valais, Switzerland; Arendal, Norway; the Ghats Mountains of India; and Mexico. The Triassic traps of New Jersey and Pennsylvania furnish specimens as do also rocks of the same age in Nova Scotia. This mineral sometimes is called *desmine*.

STOICHIOMETRY. The mathematics of chemical reactions and processes. It relates to all the quantitative aspects of chemical changes, both mass and energy. Stoichiometry is based on the absolute laws of conversion of mass and of energy and on the chemical law of combining weights. This basis makes stoichiometry as exact as any other branch of mathematics.

The law of conservation of mass dictates that, regardless of the nature of the changes undergone in a physical or chemical process, the total mass of all the materials in the system remains the same, even though the physical states and chemical compositions of the materials may change. Likewise, the law of conservation of energy is based upon the fact that the total energy in a reacting system remains constant even though the level or form of the energy may change. In radioactive transformations, however, a slight correction must be applied to the law of the conservation of mass. Mass and energy have been found to be interconvertible, so that in general the total energy of the system remains constant even though there may be small mass changes.

The above concepts form the basis for weight and heat balance calculations. Such calculations are of great significance in engineering practice for the purpose of evaluating performance of existing operations or designing new manufacturing facilities and equipment.

The basic laws of conservation specifically state that matter or energy in a given system cannot be created or destroyed, and accordingly this requires that the following equality holds true:

$$\text{Input} = \text{output} + \text{accumulation}$$

For continuous, steady flow systems the change in in-process inventory is zero during any interval of time. In this case, therefore, the above expression reduces to the simplified form of input = output.

In making material weight balances the above relation may be applied to a single unit of the operation, or to the over-all operation with reference to the separate elements and/or the total mass entering and leaving the system. This method of analysis can best be exemplified by means of a synthetic problem: Let it be assumed that consideration is being given to a continuous, steady flow system, to which X pounds of material is fed per minute and from which Y pounds of useful product are analyzed to contain $a\%$ and $b\%$ by weight of a certain constituent, respectively. It is desired to determine the extent of unmeasured loss, Z pounds per minute, incurred from the system and the average concentration, c, of the said constituent in the waste stream.

First, it may be written that input = output. By dividing each side of this equality by an element of time, this relationship can then be transformed into the following expression:

$$\text{Rate of input} = \text{rate of output}$$

Then, a total weight balance can be written to express this statement of equality in terms of the quantities specified in the problem:

$$X = Y + Z \tag{1}$$

A similar balance may also be written in terms of the constituent in question:

$$\frac{a}{100}X = \frac{b}{100}Y + \frac{c}{100}Z \tag{2}$$

Finally, by algebraic solution of the two simultaneous equations it follows that

$$Z = X - Y \tag{3}$$

and

$$c = \frac{aX - bY}{X - Y} \tag{4}$$

The above example is only a simple illustration of a weight balance. Similarly, the reaction between elements and compounds may be symbolically expressed to portray the principle of conservation of matter. For example, if hydrogen is completely burned to water, the reaction between it and oxygen can be represented as follows:

$$\text{(Hydrogen)} + \text{(Oxygen)} \longrightarrow \text{(Water)}$$

$$H_2 + \tfrac{1}{2}O_2 \longrightarrow H_2O$$

$$\text{(2.02 Wgt. units)} + \text{(16.00 Wgt. units)} \longrightarrow \text{(18.02 Wgt. units)}$$

It would be found that these materials would always react in the same relative proportions to form water in an amount equal to the total weight of reactants. The relative weights indicated are equal to the molecular weights of the materials in question. Even if a reaction does not go to completion, the quantities which did react would be proportional to the combining weights expressed in the balanced chemical equation.

Since the element of time is usually involved as the basis of a stoichiometric calculation, proper quantitative deductions often depend on adequate knowledge of other laws or principles, such as those governing rates of reaction and those pertaining to chemical equilibria. When materials in the gaseous state are involved, the general gas laws are of great utility.

Another independent relation for a system is obtainable by applying the law of conservation of energy, which requires that energy input equals energy output. A valid equality of this type must include all forms of energy such as potential energy, kinetic energy, internal energy, flow work, electrical energy, etc. This type of equality results in the so-called "total energy balance." Another very useful but similar expression is the Bernoulli mechanical energy balance for steady mass flow of fluids. However, heat energy is very frequently the only primary effect in a process so that, in such cases, the total energy balance can be simplified to the very advantageous expression of heat input equals heat output. This constitutes the basis for heat balances which, together with weight balances, are the most useful tools in any stoichiometric calculations.

Since chemical reactions involve combination of atoms or molecules to form new compounds or decomposition of compounds to form simpler ones, it is most convenient in stoichiometric calculations to employ molecular units rather than weight units. This particular kind of unit is called a "mole" and represents the quantity of substance numerically equal to its molecular weight. This weight quantity may be based on any system of weight units desired, and it is thus necessary to designate this basis by referring to pound moles, gram moles, etc.

A particular chemical reaction may be written to embody both laws of conservation of mass and energy as demonstrated below:

$$FeS + \tfrac{7}{4}O_2 \longrightarrow \tfrac{1}{2}Fe_2O_3 + SO_2 + 268{,}000 \text{ Btu}$$

This equation states that 1 pound mole of ferrous sulfide reacts with 7/4 moles of oxygen to form $\frac{1}{2}$ mole of ferric oxide and 1 mole of sulfur dioxide, accompanied by a release of heat amounting to 268,000 Btu.

However, to assign a specific meaning to the numerical value for this heat release, it is customary to specify a reference temperature and pressure for the reaction, these being 25°C and 1 atmosphere in the example cited. In making heat balance calculations, it is then convenient to choose these conditions as the datum level and then calculate the heat input and heat output quantities above or below the reference state.

Walter C. Lapple
Alliance, Ohio

STOKE'S LAW. (1) The rate at which a spherical particle will rise or fall when suspended in a liquid medium varies as the square of its radius; the density of the particle and the density and viscosity of the liquid are essential factors. Stoke's law is used in determining sedimentation of solids, creaming rate of fat particles in milk, etc. (2) In atomic processes, the wavelength of fluorescent radiation is always longer than that of the exciting radiation.

STORAGE BATTERY. A secondary battery so called because the conversion of chemical to electrical energy is reversible and the battery is thus rechargeable. An automobile battery usually consists of 12–17 cells with plates (electrodes) made of sponge lead (negative plate or anode) and lead dioxide (positive plate or cathode) that is in the form of a paste. The electrolyte is sulfuric acid. The chemical reaction that yields electric current is $Pb + PbO_2 + 2H_2SO_4 \leftrightarrow 2PbSO_4 + 2H_2O + 2e$. More complicated and expensive types have nickel-iron, nickel-cadmium, silver-zinc, and silver-cadmium as electrode materials. A sodium-liquid sulfur battery for high-temperature operation as well as a chlorine-zinc type using titanium electrodes have also been developed.

As part of the U.S. effort to replace gasoline with another form of energy, DOE is supporting short-and long-term research on batteries for electric vehicles at Argonne National Laboratories. These types intended to deliver 20–30 kwh are in the short-term program: improved lead-acid, nickel-zinc and nickel-iron. The long-term program includes lithium-metal sulfide, sodium-sulfur (β-battery), zinc-chlorine, and metal-air. Independent research indicates that a zinc-nickel oxide system has encouraging possibilities. A lead-acid battery for storing energy from solar cells has been reported to have a life of 5–7 years.

STRAIN THEORY. A theory first proposed by von Baeyer to explain the relative stability of various carbon compounds. It may be stated in the form: The regular tetrahedral-symmetric position is the most stable of all possible positions of neighboring carbon compounds; variations from this position produces increased energy content, and hence strain. Since the angle at the vertex of a regular tetrahedron is 109° 28; this theory ascribes minimum strain to cyclopentane, of the polymethylenes. The theory is borne out by the lesser stability of cyclobutane and cyclopropane, but not to the degree that might be expected by the stability of some of the higher-membered rings. In that case, the lesser strain is often due to a spatial or three-dimensional structure.

Extensions of the strain theory have been made, with varying success, to other hydrocarbon ring structures, saturated and unsaturated, to ring compounds in which the hydrogen atoms have been variously substituted, and to rings containing atoms other than carbon, as well as to bicyclic and polycyclic systems.

STREAMING (Molecular). Application of kinetic theory to the flow of gas through a tube at low pressures, such that the mean free path is large compared with the diameter of the tube. In this case, the streaming of the gas is due to the random motion of the molecules, and to the density gradient down the tube, so that the numbers of molecules traversing a given cross section in opposite directions is different. For a tube of circular cross section, the mass flowing per second is proportional to the pressure difference and the cube of the radius.

STRIPPING COLUMN. See **Distillation**.

STROMATOLITE. A term that has been generally applied to variously shaped (often domal), laminated, calcareous sedimentary structures formed in a shallow-water environment under the influence of a mat or assemblage of sediment-binding blue-green algae that trap fine (silty) detritus and precipitate calcium carbonate and that commonly develop colonies or irregular accumulations of a constant shape, but with little or no microstructure. It has a variety of gross forms, from near-horizontal to markedly convex, columnar, and subspherical. Stromatolites were originally considered animal fossils, and although they are still regarded as fossils because they are the products of organic growth, they are not fossils of any specific organism, but rather consist of associations of different genera and species of organisms that can no longer be recognized and named or that are without organic structures. An excellent treatise on stromatolites is *Stromatolites* (M.R. Walter, editor), Elsevier, New York, 1976.

STRONG INTERACTION. See **Particles (Subatomic)**.

STRONTIANITE. The mineral strontianite is strontium carbonate, $SrCO_3$, usually occurring in whitish-yellow or whitish-green masses of radiated acicular crystals, or in fibrous or granular form. When distinctly crystallized it is obviously orthorhombic, but such crystals are rare. It has a nearly perfect prismatic cleavage; uneven fracture; brittle; hardness, 3.5; specific gravity, 3.785; luster, vitreous; color, as above, also green, gray and colorless; streak, white; transparent to translucent. Strontianite occurs in veins, chiefly in limestones, occasionally in the crystalline rocks, and it is usually associated with calcite and celestite. It is found in the metalliferous veins in the Harz Mountains and Saxony. It is commercially important in Westphalia where it is mined for use in the beet sugar industry. In the United States, crystalline masses and gorges of strontianite are found in Schoharie County, New York, long a famous locality for this mineral.

STRONTIUM. [CAS: 7440-24-6], Chemical element, symbol Sr, at. no. 38, at. wt. 87.62, periodic table group 2, mp 769°C, bp 1384°C, density 2.54 g/cm^3 (20°C). Below 215°C, elemental strontium has a face-centered cubic crystal structure; between 215–605°C, a hexagonal close-packed crystal structure; and above 605°C, a body-centered cubic crystal structure.

Strontium is a silver-white metal, soft as lead, malleable, ductile, oxidizes rapidly on exposure to air, burns when heated in air emitting a brilliant light and forming oxide and nitride, reacts with H_2O yielding strontium hydroxide and hydrogen gas. Discovered by Hope and by Klaproth in 1793, and isolated by Davy in 1808.

There are four stable isotopes, ^{84}Sr and ^{86}Sr through ^{88}Sr, and seven known radioactive isotopes, ^{82}Sr, ^{83}Sr, ^{85}Sr, and ^{89}Sr through ^{92}Sr, all with relatively short half-lives measurable in hours or days except 90Sr which has a half-life of about 26 years. The latter isotope represents a hazard from nuclear blasting activities because of its long half-life, tendency to contaminate food products, such as milk, and retention in the body. See also **Radioactivity**. In terms of abundance, strontium is 21st among the elements occurring in the rocks of the earth's crust. In terms of the content of sea water, the element ranks 11th, with an estimated 38,000 tons of strontium per cubic mile (9120 tons/cubic kilometer) of seawater. First ionization potential 5.692 eV; second, 10.98 eV. Oxidation potentials $Sr \longrightarrow Sr^{2+} + 2e^-$, 2.89 V; $Sr + 2OH^- + 8H_2O \longrightarrow Sr(OH)_2 \cdot 8H_2O + 2e^-$, 2.99 V. Other important physical properties of strontium are given under **Chemical Elements**.

Occurrence and Characteristics

Strontium occurs chiefly as sulfate (celestite, $SrSO_4$) and carbonate (strontianite, $SrCO_3$) although widely distributed in small concentration. The commercially exploited deposits are mainly in England. The sulfate or carbonate is transformed into chloride, and the electrolysis of the fused chloride yields strontium metal.

As is to be expected from its high oxidation potential (2.89 V) strontium, like calcium and barium, reacts readily with all halogens, oxygen and sulfur to form halides, oxide and sulfide. See also **Celestite**; and **Strontianite**. In all its compounds it is divalent. It reacts vigorously with H_2O to form the hydroxide, displacing hydrogen and it forms a hydride with hydrogen. Strontium hydroxide forms a peroxide on treatment with H_2O_2 in the cold. Strontium exhibits little tendency to form complexes; the amines formed with NH_3 are unstable, the β-diketones and alcoholates are not well characterized, and the chelates formed with ethylenediamine and related compounds are the only representatives of the type.

Strontium Compounds

Strontium acetate, [CAS: 543-94-2], $Sr(C_2H_3O_2)_2$, white crystals, soluble, formed by reaction of strontium carbonate or hydroxide and acetic acid.

Strontium carbide (acetylide), SrC_2, black solid, formed by reaction of strontium oxide and carbon at electric furnace temperature; the carbide reacts with water yielding acetylene gas and strontium hydroxide.

Strontium carbonate, [CAS: 1633-05-2], $SrCO_3$, white solid, insoluble ($K_{sp} = 9.4 \times 10^{-10}$), formed (1) by reaction of strontium salt solution and sodium carbonate or bicarbonate solution, (2) by reaction of strontium hydroxide solution and CO_2. Strontium carbonate decomposes at 1,200°C to form strontium oxide and CO_2, and is dissolved by excess CO_2, forming strontium bicarbonate, $Sr(HCO_3)_2$, solution.

Strontium chloride, [CAS: 10476-85-4], $SrCl_2 \cdot 6H_2O$, white crystals, soluble, formed by reaction of strontium carbonate or hydroxide and HCl. Anhydrous strontium chloride, $SrCl_2$, absorbs dry NH_3 gas.

Strontium chromate, [CAS: 7789-06-2], $SrCrO_4$, yellow precipitate ($K_{sp} = 3.75 \times 10^{-5}$) formed by reaction of strontium salt solution and potassium chromate solution.

Strontium cyanamide, $SrCN_2$, formed with the cyanide, $Sr(CN)_2$, by heating strontium carbide at 1,200°C with nitrogen.

Strontium hydride, SrH_2, white solid, formed by heating strontium metal or amalgam in hydrogen gas at 250°C. Is reactive with H_2O, yielding strontium hydroxide and hydrogen gas.

Strontium nitrate, [CAS: 10042-76-9], $Sr(NO_3)_2$, white crystals, soluble, formed by reaction of strontium carbonate or hydroxide and HNO_3.

Strontium oxide, [CAS: 1314-11-0], SrO, white solid, mp about 2,400°C, reactive with H_2O to form strontium hydroxide ($K_{sp} = 3.2 \times 10^{-4}$); strontium peroxide, $SrO_2 \cdot 8H_2O$, white precipitate, by reaction of strontium salt solution and hydrogen or sodium peroxide, yields anhydrous strontium peroxide SrO_2, upon heating at 130°C in a current of dry air.

Strontium oxalate, [CAS: 814-95-9], SrC_2O_4, white precipitate ($K_{sp} = 5.6 \times 10^{-8}$) formed by reaction of strontium salt solution and ammonium oxalate solution.

Strontium sulfate, [CAS: 7759-02-6], $SrSO_4$, white precipitate ($K_{sp} = 3.2 \times 10^{-7}$), formed by reaction of strontium salt solution and H_2SO_4 or sodium sulfate solution, insoluble in acids. On heating with carbon strontium sulfate yields strontium sulfide, SrS, while on boiling with sodium carbonate solution, $SrSO_4$ yields strontium carbonate.

Strontium sulfide, SrS, [CAS: 1314-96-1], grayish-white solid (thermodynamic K_{sp} 500) reactive with water to form strontium hydrosulfide, $Sr(SH)_2$, solution. Strontium hydrosulfide is formed (1) by reaction of strontium sulfide and H_2O, (2) by saturation of strontium hydroxide solution with H_2S. Strontium polysulfides are formed by boiling strontium hydrosulfide with sulfur.

Editor's Note re Strontium Isotope Research

At any given time, the Sr isotope composition in seawater is uniform throughout the ocean because the oceanic residence time of Sr (5 million years) exceeds the mixing time of the oceans (~1000 years). However, over geologic time, the $^{87}Sr/^{86}Sr$ ratio in seawater has varied as the result of fluxes of Sr to the oceans from various sources. These would include submarine hydrothermal activity, fluxes from rivers, and submarine recycling, the latter occurring by limestone recrystallization and erosion of ancient sedimentary carbonate. J. Hess and colleagues (University of Rhode Island) reported in 1986 that the seawater Sr isotope composition appears to be a smoothly varying function of time and can be useful for high-precision correlations of oceanic sediments for certain periods of time. These researchers prepared a detailed record of the Sr isotope ratio during the last 100 million years by measuring this ratio in well over a hundred foraminifera samples. Sample preservation was evaluated from scanning electron microscopy studies, measured Sr/Ca ratios, and pore water Sr isotope ratios. Results show that the marine Sr isotope composition can be used for correlating and dating well-preserved authigenic marine sediments throughout much of the Cenozoic to a precision of ±1 mil years. See also **Cordierite**.

In 1990, R.C. Capo and D.J. DePaolo (University of California, Los Angeles and Berkeley, respectively) reported that "marine carbonate samples indicate that during the past 2.5 million years the $^{87}Sr/^{86}Sr$ ratio of seawater has increased by 14×10^{-7}. The high average rate of increase of this ratio indicates that continental weathering rates were exceptionally high. Nonuniformity in the rate of increase suggests that weathering rates fluctuated by as much as ±30 percent of present-day values. Some of the observed shifts in weathering rate are contemporaneous with climatic changes inferred from records of oxygen isotopes and carbonate preservation in deep sea sediments."

Studies of Metamorphism. As reported by J.N. Christensen, J.L. Rosenfield, and D.J. DePaolo (University of California, Berkeley), "Measurement of the radial variation of the $^{87}Sr/^{86}Sr$ ratio in a single crystal from a metamorphic rock can be used to determine the crystal's growth rate. Such variation records the accumulation of ^{87}Sr from radioactive decay of ^{87}Rb (rubidium) in the rock matrix from which the crystal grew. This method can be used to study the rates of petrological processes associated with mountain building." This methodology has been applied by the researchers mentioned to the study of the rates of tectonometamorphic processes from rubidium and strontium isotopes in garnet."

Isotopic Tests for Upwelling Water. In studies of the Yucca Mountain, Nevada, area as a potential site for a high-level nuclear waste repository, the area has been aggressively scrutinized geologically for possible upwelling of deep-seated waters. Strontium and uranium isotopic compositions of hydrogenic materials were used by scientists J.S. Stuckless, Z.E. Peterman, and D.R. Muhs (U.S. Geological Survey, Denver, Colorado) to assist in confirming other geological methods. Their findings indicated in 1991 that the vein deposits are isotopically distinct from groundwater in the two aquifers that underline Yucca Mountain, thus indicating that the calcite could not have precipitated from groundwater and thus providing evidence against upwelling water at the site.

STYRENE. Styrene, $C_6H_5CH{=}CH_2$, is the simplest and by far the most important member of a series of aromatic monomers. Also known commercially as styrene monomer (SM), styrene is produced in large quantities for polymerization. It is a versatile monomer extensively used for the manufacture of plastics, including crystalline polystyrene, rubber-modified impact polystyrene, expandable polystyrene, acrylonitrile–butadiene–styrene copolymer (ABS), styrene–acrylonitrile resins (SAN), styrene–butadiene latex, styrene–butadiene rubber (SBR), and unsaturated polyester resins. See also **Acrylonitrile Polymers**.

Properties

Styrene is a colorless liquid with an aromatic odor. Important physical properties of styrene are shown in Table 1. Styrene is infinitely soluble in acetone, carbon tetrachloride, benzene, ether, *n*-heptane, and ethanol. Polymerization generally takes place by free-radical reactions initiated thermally or catalytically. Styrene undergoes many reactions of an unsaturated compound, such as addition, and of an aromatic compound, such as substitution.

TABLE 1. PHYSICAL PROPERTIES OF STYRENE MONOMER

Property			Value		
boiling point (at 101.3 kPa = 1 atm, °C)			145.0

Ethylbenzene Manufacture

Styrene is manufactured from ethylbenzene. Ethylbenzene is produced by alkylation of benzene with ethylene. The reaction takes place on acidic catalysts and can be carried out either in the liquid or vapor phase.

Commercial ethylbenzene is manufactured almost exclusively for captive use to produce styrene. Most of the ethylbenzene plants built before 1980 are based on use of aluminum chloride catalysts. Aluminum chloride is an effective alkylation catalyst but is corrosive. The newer plants are based on zeolite catalysts.

Zeolite-Based Alkylation. Zeolites have the advantage of being noncorrosive and environmentally benign. The Mobil-Badger vapor-phase ethylbenzene process was the first zeolite-based process to achieve commercial success. It is based on a synthetic zeolite catalyst, ZSM-5, and has the desirable characteristics of high activity, low oligomerization, and low coke formation. See also **Molecular Sieves**.

In the Mobil-Badger vapor-phase process, fresh and recycled benzene are vaporized and preheated to the desired temperature and fed to a multistage fixed-bed reactor. Ethylene is distributed to the individual stages. Alkylation takes place in the vapor phase. Separately, the polyethylbenzene stream from the distillation section is mixed with benzene, vaporized and heated, and fed to the transalkylator, where polyethylbenzenes react with benzene to form additional ethylbenzene. The combined reactor effluent is distilled in the benzene column. Benzene is condensed in the overhead for recycle to the reactors. The bottoms from the benzene column are distilled in the ethylbenzene column to recover the ethylbenzene product in the overhead. The bottoms stream from the ethylbenzene column is further distilled in the polyethylbenzene column to remove a small quantity of residue. The overhead polyethylbenzene stream is recycled to the reactor section for transalkylation to ethylbenzene.

A liquid-phase process based on an ultraselective Y (USY)-type zeolite catalyst, called the Lummus-UOP process, is similar to the Mobil-Badger vapor-phase process. The differences are primarily in the catalysts, reaction conditions, reactor sizes, yields, and product specifications. The zeolite-based processes require more benzene recycle than the aluminum chloride-based processes. The EBMax technology, based on a Mobil zeolite catalyst called MCM-22, overcomes the oligomerization problem that plagues other liquid-phase alkylation processes. The catalyst is highly active for alkylation but inactive for oligomerization and cracking.

Aluminum Chloride-Based Alkylation. An improved aluminum chloride-based process was developed by Monsanto in the 1970s. Using a presynthesized aluminum chloride complex and operating the reactor at higher temperature and pressure, the catalyst inventory is reduced to below its solubility in the reaction mixture. The reactants and the catalyst complex are mixed in the reactor to form a homogeneous liquid. The transalkylation of polyethylbenzenes is carried out separately. These improvements result in a higher yield.

Other Technologies. Ethylbenzene can be recovered from mixed C_8 aromatics by superfractionation. The Alkar process, commercialized in 1960, uses boron trifluoride on alumina support as the catalyst. It has been used for polymer-grade as well as dilute ethylene feeds.

Styrene Manufacture

Styrene manufacture by dehydrogenation of ethylbenzene is used for nearly 90% of the worldwide styrene production. The rest is obtained from the coproduction of propylene oxide (PO) and styrene (SM).

Dehydrogenation. The dehydrogenation of ethylbenzene to styrene takes

$$C_6H_5CH_2CH_3 \rightleftharpoons C_6H_5CH{=}CH_2 + H_2$$

place on a promoted iron oxide–potassium oxide catalyst in a fixed-bed reactor at the 550–680°C temperature range in the presence of steam. The reaction is limited by thermodynamic equilibrium. Low pressure favors the forward reaction. Dehydrogenation is an endothermic reaction. High temperature favors dehydrogenation both kinetically and thermodynamically but also increases by-products from side reactions and decreases the styrene selectivity.

The main by-products in the dehydrogenation reactor are toluene and benzene. The formation of toluene accounts for the biggest yield loss. Other by-products include carbon dioxide and various hydrocarbons.

Dehydrogenation catalysts usually contain 40–90% Fe_2O_3, 5–30% K_2O, and promoters such as chromium, cerium, molybdenum, calcium, and magnesium oxides. Dehydrogenation is carried out either isothermally or adiabatically. In principle, isothermal dehydrogenation has the dual advantage of avoiding a very high temperature at the reactor inlet and maintaining a sufficiently high temperature at the reactor outlet. In practice, these advantages are negated by formidable heat-transfer problems. In an adiabatic reactor, the endothermic heat of reaction is supplied by the preheated steam that is mixed with ethylbenzene upstream of the reactor. As the reaction progresses, the temperature decreases. To obtain a high conversion of ethylbenzene to styrene, usually two, and occasionally three, reactors are used in series with a reheater between the reactors to raise the temperature of the reaction mixture.

Other than the reactor system, the distillation column that separates the unconverted ethylbenzene from the crude styrene is the most important and expensive equipment in a styrene plant. To minimize yield losses and to prevent equipment fouling by polymer formation, polymerization inhibitors are used in the distillation train, product storage, and in vent gas compressors.

The qualities of the styrene product and toluene by-product depend primarily on three factors: the impurities in the ethylbenzene feed-stock, the catalyst used, and the design and operation of the dehydrogenation and distillation units. Other than benzene and toluene, the presence of which is usually inconsequential, possible impurities in ethylbenzene are C_7–C_{10} nonaromatics and C_8–C_{10} aromatics. The condensed reactor effluent is separated in the settling drum into vent gas (mostly hydrogen), process water, and organic phase. The organic phase with polymerization inhibitor added is pumped to the distillation train.

Benzene and toluene by-products are recovered in the overhead of the benzene–toluene distillation column. The bottoms from the benzene–toluene column are distilled in the ethylbenzene recycle column, where the separation of ethylbenzene and styrene is effected. The bottoms, are pumped to the styrene finishing column. The overhead product from this column is purified styrene. The bottoms are further processed in a residue-finishing system to recover additional styrene from the residue.

PO–SM Coproduction. The coproduction of propylene oxide and styrene includes three reaction steps: (*1*) oxidation of ethylbenzene to ethylbenzene hydroperoxide, (*2*) epoxidation of ethylbenzene hydroperoxide with propylene to form α-phenylethanol and propylene oxide, and (*3*) dehydration of α-phenylethanol to styrene.

$$C_6H_5CH_2CH_3 + O_2 \longrightarrow C_6H_5CH(CH_3)OOH$$

$$C_6H_5CH(CH_3)OOH + CH_2{=}CHCH_3 \longrightarrow C_6H_5CH(CH_3)OH + \underset{\diagdown\, O\, \diagup}{CH_2CHCH_3}$$

$$C_6H_5CH(CH_3)OH \longrightarrow C_6H_5CH{=}CH_2 + H_2O$$

The recovery and purification facilities in such a process are complex. One reason is that oxygenated by-products are made in the reactors. Oxygenates hinder polymerization of styrene and cause color instability. Elaborate purification is required to remove the oxygenates.

Specifications and Analysis

The freezing point measurement, standard method for the determination of styrene assay until the 1970s, has been largely replaced by gas chromatography. Color is measured spectrophotometrically and registered on the APHA or the platinum–cobalt scale.

Health and Safety Factors

Styrene is mildly toxic, flammable, and can be made to polymerize violently under certain conditions. However, handled according to proper procedures, it is a relatively safe organic chemical.

While styrene is not confirmed as a carcinogen, it is considered a suspect carcinogen. Styrene liquid is inflammable and has sufficient vapor pressure at slightly elevated temperatures to form explosive mixtures with air. Properly inhibited and attended, styrene can be stored for an extended period of time.

Uses

Commercial styrene is used almost entirely for the manufacture of polymers.

Common applications for polystyrene include packaging, food containers, and disposable tableware; toys; furniture, appliances, television cabinets, and sports goods; and audio and video cassettes. Expandable polystyrene is widely used in construction for thermal insulation.

Uses for ABS are in sewer pipes, vehicle parts, appliance parts, business machine casings, sports goods, luggage, and toys.

SB latex is used in coatings, carpet backing, paper adhesives, cement additives, and latex paint.

SBR is used primarily in tires, vehicle parts, and electrical components.

The principal uses for UPR are in putty, coatings, and adhesives. Glass-reinforced UPR is used for marine, construction, and vehicle materials, as well as for electrical parts.

Derivatives

A large number of compounds related to styrene have been reported in the literature. Those having the vinyl group $CH_2{=}CH-$attached to the aromatic ring are referred to as styrenic monomers. Several of them have been used for manufacturing small-volume specialty polymers. The specialty styrenic monomers that are manufactured in commercial quantities are vinyltoluene, *para*-methylstyrene, α-methylstyrene, and divinylbenzene. In addition, 4-*tert*-butylstyrene (TBS) is a specialty monomer that is superior to vinyltoluene and *para*-methylstyrene in many applications. Other styrenic monomers produced in small quantities include chlorostyrene and vinylbenzene chloride. With the exception of α-methylstyrene, which is a by-product of the phenol–acetone process, these specialty monomers are more difficult and expensive to manufacture than styrene.

Vinyltoluene. Vinyltoluene (VT) is a mixture of *meta*- and *para*-vinyltoluenes, typically in the ratio of 60:40. This isomer ratio results from the ratio of the corresponding ethyltoluenes in thermodynamic equilibrium. Vinyltoluene is produced for special applications. Its copolymers are more heat-resistant than the corresponding styrene copolymers, and it is used as a specialty monomer for paint, varnish, and polyester applications.

para-Methylstyrene. PMS is the para isomer of vinyltoluene in high purity. PMS is made by alkylation of toluene with ethylene to *p*-ethyltoluene, followed by dehydrogenation of *p*-ethyltoluene.

Divinylbenzene. This is a specialty monomer used primarily to make cross-linked polystyrene resins. The largest use of divinylbenzene (DVB) is in ion-exchange resins for domestic and industrial water softening. Ion-exchange resins are also used as solid acid catalysts for certain reactions, such as esterification. Divinylbenzene is manufactured by dehydrogenation of diethylbenzene, which is an internal product in the alkylation plant for ethylbenzene production.

α-Methylstyrene. This compound is not a styrenic monomer in the strict sense. The methyl substitution on the side chain, rather than the aromatic ring, moderates its reactivity in polymerization. It is used as a specialty monomer in ABS resins, coatings, polyester resins, and hot-melt adhesives. As a copolymer in ABS and polystyrene, it increases the heat-distortion resistance of the product. In coatings and resins, it moderates reaction rates and improves clarity. α-Methylstyrene (AMS) is produced as a by-product in the production of phenol and acetone from cumene.

STYRENE-BUTADIENE RUBBER. Styrene–butadiene rubber (SBR), an elastomer, is a copolymer of three parts 1,3-butadiene and one part styrene. It is a synthetic rubber used mainly in the manufacture of automobile tires.

In the late 1920s Bayer & Company began studies of the emulsion polymerization process of polybutadiene for producing synthetic rubber. Incorporation of styrene as a comonomer produced a superior polymer compared to polybutadiene. The product, Buna S, was the precursor of the single largest-volume polymer produced in the 1990s, emulsion styrene–butadiene rubber (ESBR).

In the mid-1950s, the Nobel Prize-winning work of K. Ziegler and G. Natta introduced anionic initiators which allowed the stereospecific polymerization of isoprene to yield high cis-1,4 structure, much like natural rubber. At almost the same time, another route to stereospecific polymer architecture by organometallic compounds was announced.

In the 1960s, anionic polymerized solution SBR (SSBR) began to challenge emulsion SBR in the automotive tire market. Organolithium compounds allow control of the butadiene microstructure, not possible with ESBR. Because this type of chain polymerization takes place without a termination step, an easy synthesis of block polymers is available, whereby glassy (polystyrene) and rubbery (polybutadiene) segments can be combined in the same molecule. These thermoplastic elastomers (TPE) have found use in nontire applications.

Physical Properties

Desirable properties of elastomers include elasticity, abrasion resistance, tensile strength, elongation, modulus, and processibility. These properties are related to and dependent on the average molecular weight and mol wt distribution, polymer macro- and microstructure, branching, gel (cross-linking), and glass-transition temperature (T_g).

Emulsion polymerization gives SBR polymer of high molecular weight. Because it is a free-radical-initiated process, the composition of the resultant chains is heterogeneous, with units of styrene and butadiene randomly spaced throughout. Unlike natural rubber, which is polyisoprene of essentially all cis-1,4 configuration, giving an ordered structure and hence crystallinity, ESBR is amorphous. Unlike SSBR, the microstructure of which can be modified to change the polymer's T_g, the T_g of ESBR can be changed only by a change in ratio of the monomers. Glass-transition temperature is that temperature where a polymer experiences the onset of segmental motion.

The glass-transition temperatures for solution-polymerized SBR as well as ESBR are routinely determined by nuclear magnetic resonance (nmr), differential thermal analysis (dta), or differential scanning calorimetry (dsc).

For routine analysis of SBR polymers, gpc is widely accepted.

Advantages of natural rubber and isoprene rubber (NR/IR) are high resilience and strength, and abrasion-resistance. BR shows low heat buildup in flexing, good resilience, and abrasion-resistance. Random SBR is low in price, wears well, and bonds easily. Block SBR is easily injection-molded, and is not cross-linked. Applications of NR/IR include tires, tubes, belts, bumpers, tubing, gaskets, seals, foamed mattresses, and padding. BR is used in tire treads and mechanical goods, as is random SBR. Block SBR is used in toys, rubber bands, and mechanical goods.

Raw Materials

The monomers butadiene and styrene, are the most important ingredients in the manufacture of SBR polymers. For ESBR, the largest single material is water; for solution SBR, the solvent.

The quality of the water used in emulsion polymerization affects the manufacture of ESBR. Water hardness and other ionic content can directly affect the chemical and mechanical stability of the polymer emulsion (latex). Solution polymerization can use various solvents, primarily aliphatic and aromatic hydrocarbons. SSBR polymerization depends on recovery and reuse of the solvent for economical operation as well as operation under the air-quality permitting of the local, state, and federal mandates involved.

Styrene. Commercial manufacture of this commodity monomer depends on ethylbenzene, which is converted by several means to a low purity styrene, subsequently distilled to the pure form. A small percentage of styrene is made from the oxidative process, whereby ethylbenzene is oxidized to a hydroperoxide or alcohol and then dehydrated to styrene. A popular commercial route has been the alkylation of benzene to ethylbenzene, with ethylene, after which the crude ethylbenzene is distilled to give high purity ethylbenzene. See also **Styrene**.

Butadiene. Economic considerations favor recovering butadiene from by-products in the manufacture of ethylene. Butadiene is a by-product in the C4 streams from the cracking process. For use in polymerization, the butadiene must be purified to 99 + %. Crude butadiene is separated from C_3 and C_5 components by distillation. Separation of butadiene from other C_4 constituents is accomplished by salt complexing/solvent extraction. See also **Butadiene**.

Soap. A critical ingredient for emulsion polymerization is the soap, which performs a number of key roles, including production of oil (monomer) in water emulsion, provision of the loci for polymerization (micelle), stabilization of the latex particle, and impartation of characteristics to the finished polymer. Both fatty acid and rosin acid soaps, mamly derived from tall oil, are used in ESBR.

Polymerization

ESBR and SSBR are made from two different addition polymerization techniques: one radical and one ionic. ESBR polymerization is based on free radicals that attack the unsaturation of the monomers, causing addition of monomer units to the end of the polymer chain, whereas the basis for SSBR is by use of ionic initiators.

Free-radical initiation of emulsion copolymers produces a random polymerization in which the trans/cis ratio cannot be controlled. The nature of ESBR free-radical polymerization results in the polymer being heterogeneous, with a broad molecular weight distribution and random copolymer composition. The microstructure is not amenable to manipulation, although the temperature of the polymerization affects the ratio of trans to cis somewhat.

In solution-based polymerization, use of the initiating anionic species allows control over the trans/cis microstructure of the diene portion of the copolymer. In solution SBR, the alkyllithium catalyst allows the 1,2 content to be changed with certain modifying agents such as ethers or amines. Anionic initiators are used to control the molecular weight, molecular weight distribution, and the microstructure of the copolymer.

SBR Compounding and Processing

The art of compounding requires extensive experience and knowledge of the many compound ingredients. A typical rubber compound in addition to polymer contains one or more ingredients from the following general classes: vulcanizing agents, accelerators, accelerator activators, antioxidants, pigments, and softeners.

The vulcanizing agent, which supplies the bridge between the polymer chains, is furnished predominantly by the sulfur molecule in commercial formulations. Peroxide vulcanizers that produce carbon-to-carbon cross-links are also important.

Accelerators are chemical compounds that increase the rate of cure and improve the physical properties of the compound. Accelerator activators are chemicals required to initiate the acceleration of the curing process.

Antioxidants are routinely added to the compounds over and above those contained in the polymer at manufacture. Antiozonants prevent or reduce polymer degradation by the active ozone molecule. Some antioxidant compounds, such as the *para*-phenylene-diamines, are excellent as antiozonants.

Pigments improve or change polymer properties as well as lower product costs. Reinforcement of SBR by carbon blacks allows this family of polymers to compete with natural rubber. See also **Carbon Black**. It is the most important attribute of the pigment in SBR processing. Softeners, i.e., plasticizers, reinforcing agents, extenders, lubricants, tackifiers, and dispersing aids, are used as processing aids to enhance mixing of uncured stocks and soften cured compounds.

Economic Aspects and Uses

Styrene–butadiene elastomers, emulsion and solution types combined, are reported to be the largest-volume synthetic rubber. The actual percentage has decreased steadily since 1973. The decline has been attributed to the switch to radial tires (longer milage) and the growth of other synthetic polymers. SBR is forecast to remain the dominant elastomer of all synthetic polymers. In the late 1990s, use of SBR has encompassed the following: tires and tire-related products, including tread rubber, 80%; mechanical goods, 11%; other automotive uses, 6%; and adhesives, chewing gum base, shoe products, flooring, etc, for the remaining 3%.

Health and Safety Factors

Air quality and plant effluent have been monitored and more or less regulated from the inception of SBR manufacture. Most local and state governments have strict discharge permits that limit what kind of chemicals and how much of it can be emitted into the environment. Both styrene and butadiene are considered suspect carcinogens.

There is an industry trend to supply SBR certifiably free of volatile nitrosamines or nitrosatable compounds. Of primary concern to local, state, and federal governments is the growing stockpile of scrap tires. The threat of huge piles of scrap tires catching fire is cited as a principal concern. Such fires pollute the air and threaten groundwater as the large quantities of oil released in the incomplete burning become a serious runoff problem. Although use of scrap tires is projected to increase rapidly, the only economically feasible use has been as a fuel or fuel supplement in utility and industrial applications.

STYRENE-MALEIC ANHYDRIDE. A thermoplastic copolymer made by the copolymerization of styrene and maleic anhydride. Two types of polymers are available—impact-modified SMA terpolymer alloys (*Cadon*®) and SMA copolymers, with and without rubber impact modifiers (*Dylark*®). These products are distinguished by higher heat resistance than the parent styrenic and ABS families. The MA functionality also provides improved adhesion to glass fiber reinforcement systems. Recent developments include terpolymer alloy systems with high-speed impact performance and low-temperature ductile fail characteristics required by automotive instrument panel usage.

Copolymers show chemical resistance generally similar to that of polystyrene and terpolymers similar to that of ABS (acrylonitrile-butadiene-styrene). Neither type is recommended for use in strongly alkaline environments. All impact versions have good natural color and products are available in a wide range of colors. Copolymer crystal grades have good clarity and gloss.

Glass-reinforced SMA polymers are used as electrical connectors, consoles, top pads, and as supports for urethane-padded instrument panels. There are several additional automotive uses. SMA are also found in coffee makers, steam curlers, power tools, audio cassette components, business machines, vacuum cleaners, solar heat collectors, electrical housing, and fan blades, among others.

SUBATOMIC PARTICLES. See **Particles (Subatomic)**.

SUBLIMATION. The direct transition, under suitable conditions, bet ween the vapor and the solid state of a substance. If solid iodine is placed in a tube and slightly warmed, it vaporizes and the vapor reforms into crystals on the cooler parts of the tube. Many crystalline substances, both metallic and nonmetallic, may be similarly sublimated in a vacuum; fairly large crystals of selenium have been thus prepared. The most familiar sublimates are frost and snow. As in the case of other changes of state, sublimation is accompanied by the absorption or evolution of heat, the quantity of which

per unit mass is called the heat of sublimation of the substance. At pressures near the triple point the heat of sublimation is approximately equal to the sum of the heats of fusion and vaporization. In physical and chemical literature, it is customary to regard as sublimation only the transition from solid to vapor, not from vapor to solid; but meteorologists do not make this distinction.

Sublimation plays a major role in the freeze-drying of foods. See also **Freeze-Drying**.

SUBLIMATION (Heat of). The quantity of heat required at constant temperature (and pressure) to evaporate unit mass of a solid. In sublimation, the change is directly from solid to vapor, without appearance of the liquid phase.

SUBSTITUTE NATURAL GAS (SNG). A rather general term for describing an artificially produced relatively-high Btu gas that compares favorably with natural gas as a fuel. SNG also may refer to synthetic natural gas; or, on some occasions, to synthesis gas. The latter generally connotes a specially constituted gas to be used as the raw material for a chemical process, such as an ammonia synthesis—thus ammonia synthesis gas, etc. The Btu value of natural gas typically lies within the range of 975 to 1,180 Btu per standard cubic foot (110–133 Calories/cubic meter). Thus, to substitute for and to compete with natural gas (where available), the artificially-produced gas must have a Btu content within this general range. Substitute or synthetic gases generally fall into two categories: (1) low-Btu-value gases with a Btu content of 400 to 600 Btu per cubic foot (50–67 Calories/cubic meter) or lower, sometimes suitable for combined-cycle power generation schemes or for subsequent enrichment to increase the Btu content; and (2) high-Btu-value gases (sometimes referred to as pipeline gases) which have a Btu content generally within the 950 to 1,050 Btu per cubic foot (107–118 Calories/cubic meter) range. Such gases, properly treated to remove traces of unwanted impurities and corrosives, can be introduced into transcontinental pipelines and handled essentially in the same manner as natural gas.

SNG is derived from coal, various petroleum fractions, and waste products. Gases produced from coal are described under **Coal**.

The most practical and economic source of raw material for producing SNG varies with the proximity to raw materials, the relative cost of raw materials, and by numerous other factors which affect the complex energy balance of a given nation and geographical location. Naphtha may make a logical choice of starting material in one area, whereas coal would be most logical in another area. Also, for some years to come—until SNG processes become better proved on a day-to-day operating basis—a somewhat more costly raw material, if available, may be the only practical answer. With proven processes, waste materials as a source of SNG is a very sensible approach, but in some areas the costs of collecting wastes (or the availability of sufficient waste products) may prohibit this approach. As proponents of various schemes and concepts have found upon undertaking detailed, practical development of concepts, a process will not necessarily be successful even though initial gross statistics "prove" the wisdom of the concept.

Catalytic Rich Gas (CRG) Process

This process was developed from the work of a team at the Gas Council's Midlands Research Station (MRS) (England) led by Dr. F. J. Dent. In the late 1950s, it became apparent that, due to the postwar increase in refining capacity in Europe, naphtha was becoming available as a potential feedstock for gas making and that its use would be more economical than coal carbonization, which was then the major source of fuel gas in the United Kingdom. The first semicommercial plant, producing 4 million standard cubic feet per day of rich gas, was commissioned in 1964. Within the next five years, nearly 40 units were installed in the United Kingdom for production of rich gas and town gas (470–500 Btu per standard cubic foot; 53–56 Calories/cubic meter). Plants were also installed in Japan, Italy, Brazil, and the United States.

The overall reactions which occur in the steam reforming of naphtha are:

(1)	$4C_6H_{14} + 10H_2O \longrightarrow 19CH_4 + 5CO_2$	Exothermic
(2)	$CH_4 + H_2O \rightleftharpoons CO + 3H_2$	Endothermic
(3)	$CO + H_2O \rightleftharpoons CO_2 + H_2$	Slightly Exothermic

At all practical temperatures, reaction (1) proceeds almost to completion; no significant quantities of higher hydrocarbons exist at the outlet of the CRG reactor.

Reactions (2) and (3) are reversible; the concentrations of the five components CH_4, H_2O, CO_2, CO and H_2 which result are governed by thermodynamic equilibrium. Raising the reaction temperature shifts the equilibrium for both reactions to the right. Thus at low temperatures the exothermic reaction (1) predominates, while at high temperatures the overall reaction is endothermic. At approximately 500–550°C the reaction is thermally neutral.

Naphthas boiling up to 185°C can be reformed at pressures up to 600 psig. Naphthas with final boiling point up to 240°C may be reformed at lower pressures. Higher olefin contents may be accepted provided that sufficient hydrogen is available in the recycle gas to saturate the feed in the desulfurization section. Higher aromatic contents may be accepted but the catalyst life will be reduced.

A typical rich gas leaving the CRG reactor has the following composition:

CO_2	23.0 mol.% (dry)
CO	0.7
H_2	12.8
CH_4	63.5
	100.0%
Calorific Value (Btu/standard bic foot)	675

Higher hydrocarbons are present in negligible quantities.

The calorific value of this gas is too high for direct use as town gas (470–500 Btu/standard cubic foot in the United Kingdom) and too low for SNG. However, by removing the CO_2 the calorific value is increased to about 870 Btu/standard cubic foot, which is useful for enriching lean gas (e.g. from an Imperial Chemical Industries (ICI) naphtha reformer) to town gas quality. Long has suggested that by enriching this gas with LPG (liquefied petroleum gas) a satisfactory SNG may be obtained.

Alternatively, the calorific value may be changed by bringing the components to a new equilibrium at a different temperature. In the Series "A" Process, part of the rich gas is further reformed at high temperature and remixed with the remaining rich gas. After water gas shift and partial CO_2 removal a 500 Btu/standard cubic foot product is obtained which is fully interchangeable with the town gas distributed in the United Kingdom.

If the subsequent stage is at a lower temperature, carbon oxides and hydrogen recombine to methane, increasing the calorific value. Following CO_2 removal, very little enrichment is required to achieve a product fully interchangeable with natural gas.

CRG catalyst is deactivated by low concentrations of sulfur and chlorine compounds. To achieve removal of sulfur to very low concentrations (less than 0.2 ppm), British Gas developed their own process which is always used in association with CRG catalyst. Organic sulfur compounds are hydrogenated to H_2S over nickelmolybdenum catalyst at about 380°C. The hydrogen is usually generated by reforming rich gas from the CRG reactor with added steam in a tubular reformer. Alternatively, gas from the reactor may be used directly, while in some plants it is normal to use CO_2-free town gas. The H_2S is then absorbed on zinc oxide or, in the case of many United Kingdom town gas plants, Luxmasse (hydrated ferric oxide).

Because of the large stream sizes involved, many of the SNG plants in the United States incorporate a bulk sulfur removal stage using a hydrofining process. The H_2S produced is commonly recovered as elemental sulfur by a Stretford plant, in which the hydrofiner off gas is washed with an aqueous alkaline solution which is regenerated by oxidation with air.

Chlorine compounds, if present in concentration higher than 1 ppm, not only deactivate the CRG catalyst but also interfere with the absorption of H_2S. Therefore they are removed by hydrogenation to HCl which is absorbed on a proprietary absorbent.

Reforming in the CRG process occurs adiabatically at 450–550°C at pressures up to about 600 psig (41 atmospheres). The reactor is a vertical cylindrical pressure vessel containing a bed of the special high-nickel catalyst which is supported on a grid or on inert ceramic balls. The gas flow is downwards through the bed and distributors are provided at inlet and outlet. A layer of ceramic balls on top of the bed prevents disturbance of the catalyst by the entering gas.

Normal practice is to install two reactors in parallel, of which one is working at any time. The catalyst charge in each vessel is designed for 3–6 months operation at full load. This system avoids unnecessary exposure of catalyst to high temperatures, minimizes the catalyst loss in

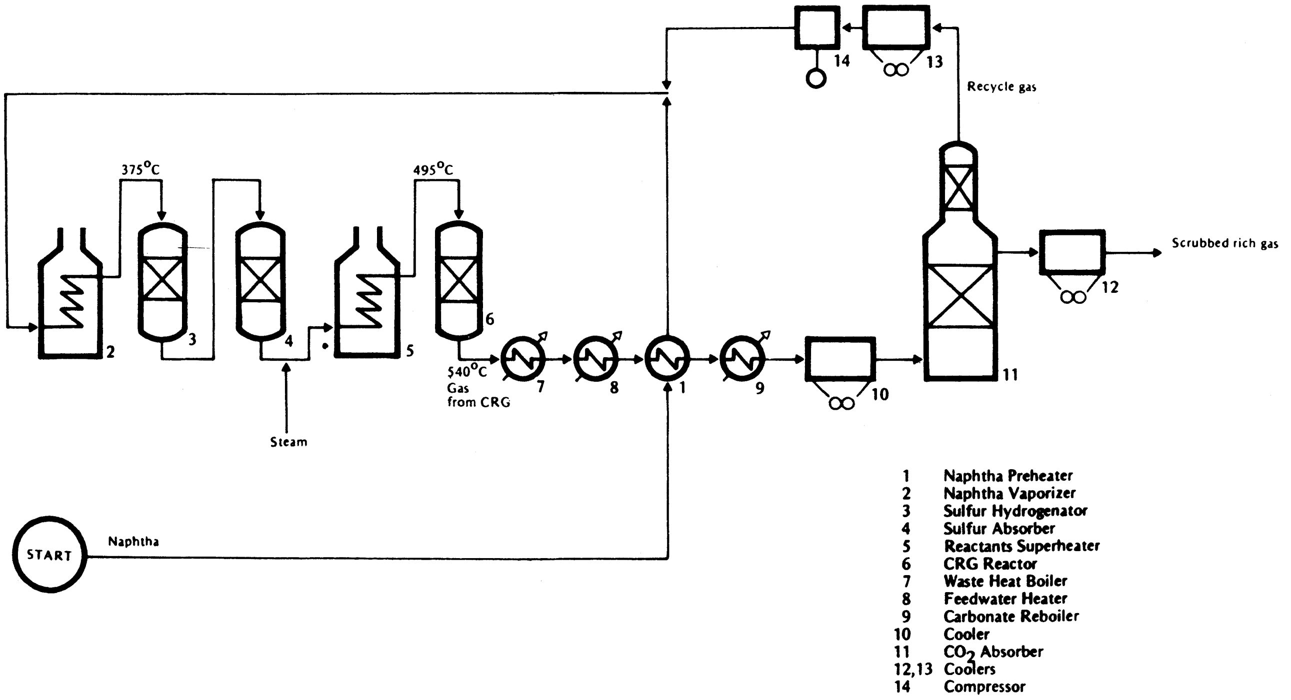

Fig. 1. Typical flowsheet for rich gas plant. (*Woodall-Duckham Limited.*)

the event of damage by maloperation and provides instant standby if such damage occurs.

The flow diagram for a rich gas plant producing gas with a calorific value of 710 Btu/standard cubic foot is shown in Fig. 1. The product is used to enrich lean gas from an ICI (Imperial Chemical Industries) naphtha reformer which has a calorific value of about 320 Btu/standard cubic foot to the town gas standard of 500 Btu/standard cubic foot (56 Calories/cubic meter). Typical gas analyses are given in Table 1.

In what is termed a Series "A" Process, part of the gas from the CRG reactor is reformed with additional steam and the resulting lean gas is reblended with the remaining rich gas. The mixed gas is then subjected to water gas shift and partial carbon dioxide removal, yielding a product with a calorific value of 470–500 Btu/standard cubic foot (53–56 Calories/cubic meter). Typical gas analyses are shown in Table 2. By varying the proportion of gas which flows to the tubular reformer and the degree of CO_2 removal, the characteristics of the product gas can be made interchangeable with any of the different standards employed by the United Kingdom Area Boards and Japanese and European gas companies. A variation of this process has been used in Italy. The calorific value of important Libyan LNG (1395 Btu/standard cubic foot; 157 Calories/cubic meter) was too high for direct use as pipeline gas. The LNG was, therefore, fractionated and the heavy ends (C_2H_6—C_6H_{14}) subjected to processing.

If the rich gas from the CRG reactor is passed over another bed of high-nickel catalyst at a lower temperature, the equilibrium of the five components is reestablished. Carbon oxides react with hydrogen to form methane and the calorific value of the gas is increased. It should be noted that this methanation step differs from that encountered in ammonia synthesis gas production; because of the high steam content the temperature rise is reduced and there is no possibility of temperature "runaway" as the exit temperature can never rise above the temperature corresponding to equilibrium at the inlet composition, i.e. the CRG exit temperature.

In order to minimize cold enrichment and to achieve a very low carbon monoxide content in the product, a second methanation stage is frequently employed. To achieve sufficient "driving force" to make the reaction proceed, the water vapor content is reduced by cooling the gas, rejecting condensate, and reheating to the required reaction temperature.

Table 3 shows the effect of the second methanation stage on product calorific value. While consumption of LPG is minimized, the capital cost is increased and the overall thermal efficiency is slightly reduced.

If part of the purified naphtha vapor from desulfurization is allowed to bypass the CRG reactor, it can be fully gasified by reaction with

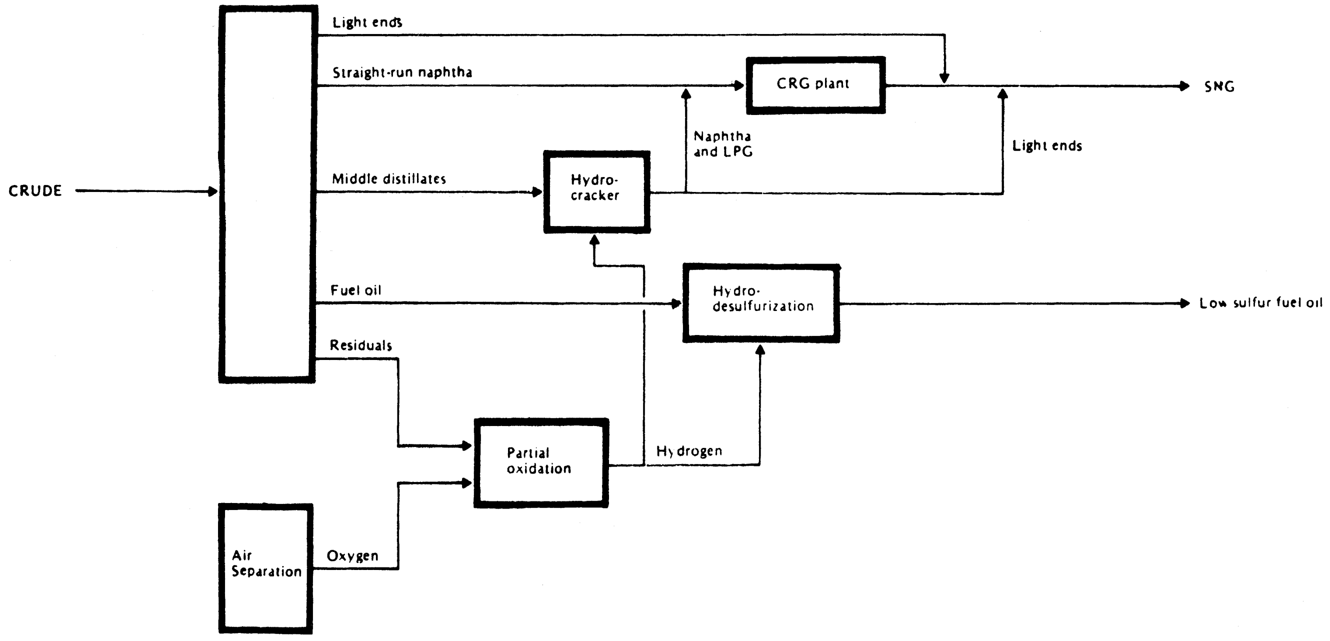

Fig. 3. SNG and low-sulfur fuel oil from crude. (*Woodall-Duckham Limited.*)

the hydrogen and steam in the rich gas. This reaction occurs at lower temperatures than the CRG reaction, and is known as hydrogasification. It has the advantage that the total steam requirement for the process is reduced, although with heavier feedstocks it may be necessary to add a little steam to the hydrogasifier in order to ensure that carbon is not formed by the Boudouard reaction. Since less makeup steam has to be generated from fired boilers, the overall efficiency is improved by 1–2%. The capital cost is slightly lower than that of the methanation route.

The calorific value of the product from hydrogasification is lower than that from single methanation, particularly with high carbon/hydrogen feedstocks because of the additional steam required. However, by adding a final methanator, the calorific value can be increased to that obtained from double methanation, again with increased capital cost and reduced efficiency. This process (Fig. 2) is used in the first operational SNG plant in the United States at Harrison, N.J. Typical gas analyses are given in Table 4.

TABLE 4. GAS ANALYSES—SNG PRODUCTION BY HYDROGASIFICATION

	Recycle gas	1st Stage gas	2nd Stage gas	3rd Stage gas	Scrubbed gas	Product gas
CO_2 (mol %)	0.5	21.8	21.7	21.9	0.5	~0.50

(Btu/standard cubic foot)	395	683	733	772	984	1000
(Calories/cubic meter)	44.4	76.7	82.4	86.7	110.6	112.4

Because of the lower temperature, the catalyst in the hydrogasifier, which is the same as that in the CRG reactor, is slowly deactivated by polymer formation. The activity may be recovered "*in situ*" by heating in hydrogen. Two hydrogasifiers are therefore provided in parallel so that regeneration can be carried out without interrupting production.

The CRG process is one of a range of processes developed by the British Gas Corporation for production of fuel gases. The range and application of these processes and their impact has been described by Hebden, illustrating the effect on capital cost of increasing the carbon/hydrogen ratio of the feedstock.

An alternative method of handling crude oil is the "energy refinery" in which crude is split into a number of fractions which can be treated by proven processes to yield two products, SNG and low sulfur fuel oil.

One such scheme is shown in Fig. 3. The advantages of using the CRG process as the final stage in the production of SNG are high efficiency and low capital cost, the predictable quality of the product gas, and the absence of by-products.

Methane-Rich Gas (MRG) Process. A process which produces methane gas from feedstock hydrocarbons, such as naphtha, liquefied petroleum gases (LPG), and refinery gas, developed by Japan Gasoline Co., Ltd., in collaboration with its affiliate, Nikki Chemical Co., Ltd., for application to town-gas facilities. The MRG process had its origin in the high-temperature hydrocarbon steam reforming technology. First efforts culminated in a successful installation in 1956. In the tendency to employ heavier hydrocarbons as feedstock, carbon formation in the low-temperature range posed a problem. The Japan Gasoline Co. took this up as a main research subject and continued the study of low-temperature-range reaction, concentrating especially on the difference of product gas properties and carbon formation according to reaction conditions and catalyst specifications. As a result, a new catalyst was developed which converts butane or naphtha to a gas consisting mainly of methane, hydrogen, and carbon dioxide, with a negligible amount of carbon monoxide. This was the first stage of development of the present MRG process.

In 1964, while developing practical applications for the town-gas industry, a pilot plant with a daily capacity of 15,000 cubic meters was built. Continuous test runs were conducted over a long term, in cooperation with Osaka Gas Co., Ltd., thus starting commercial production of equipment for the process. Based upon results of the aforementioned test runs, a commercial-size town-gas plant (200,000 cubic meters daily capacity) was constructed at the Hokkoh plant of Osaka Gas Co., Ltd. This was followed by two plants each of 500,000 cubic meters daily capacity in 1967 and 1969. Additional plants followed not only for town-gas uses, but also for petrochemical needs. Late in 1971, an MRG plant incorporating a wet methanation system went into operation at Keiyo Gas Co., Ltd., near Tokyo, with a capacity of 105,000 cubic meters per day. In late 1972, a complete MRG-based SNG plant, consisting of gasification, methanation, and CO_2 removal sections was completed for the same firm, with a capacity of 200,000 cubic meters per day. In early 1974, Boston Gas Co. (U.S.) started up a 1,070,000 cubic meters per day SNG plant which employs a two-stage MRG gasification system.

The basic reactions of the MRG process consist of three stages: (1) hydrodesulfurization of sulfur compounds in the hydrocarbon feedstock; (2) low-temperature steam reforming (gasification) of desulfurized hydrocarbons; and (3) methanation reaction between hydrogen and carbon dioxide in methane gas available by gassification.

Sulfur compounds contained in hydrocarbon feedstock vary, depending on the types of crudes and their boiling points. Naphtha, for example, contains mainly mercaptans, disulfides, and thiophenes. Such sulfur compounds deteriorate the activity of the low-temperature steam-reforming MRG catalyst. They should be removed to some degree before the feedstock enters the system. Major reactions of the hydrodesulfurization step are:

$$RSH + H_2 \longrightarrow RH + H_2S$$

$$R{-}S{-}R' + 2H_2 \longrightarrow RH + R'H + H_2S$$

$$R{-}S{-}S{-}R' + 3H_2 \longrightarrow RH + R'H + 2H_2S$$

$$\text{--R} + 3H_2 \longrightarrow RC_4H_9 + H_2S$$ (alkyl group R not fixed to a specific carbon)

In as much as these are all exothermic reactions, low ambient temperatures are favorable from the standpoint of equilibrium theory, but in consideration of reaction rates, general processes are operated in a range of 350–400°C with the aid of a highly active catalyst (like Co-Mo or Ni-Mo), involving the side reactions:

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O$$

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O$$

The foregoing reactions are highly exothermic and significantly raise reaction temperatures. The MRG process, however, does not involve such adverse side reactions with use of a special, selective hydrodesulfurizing catalyst (developed by Japan Gasoline Co. and Nikki Chemical). The MRG process uses part of product gas for hydrodesulfurization, and even if it contains only 20–25% hydrogen and as high as 20–23% carbon oxides, only the proper hydrodesulfurization reactions take place. The MRG process features a recycle use of product gas for hydrodesulfurization purposes without any special treatment.

To eliminate hydrogen sulfide formed in hydrodesulfurization reactions, two solutions are available: (1) fixation by H_2S contact with an adsorbent (zinc oxide) via the reaction: $ZnO + H_2S \longrightarrow ZnS + H_2O$; and (2) physical removal by stripping. The hydrodesulfurization system is most economically practical with feedstocks containing less than 200 to 500 ppm sulfur. The removal of H_2S by stripping after hydrodesulfurization with an external hydrogen supply may be applied to naphtha stocks contaminated by trace metals as well as those high in sulfur.

Gasification by low-temperature steam-reforming reactions, the heart of the MRG process, is carried out between liquid hydrocarbons and steam over catalyst to form methane, hydrogen, and carbon oxides. In order to increase the calorific value of product gas to the values similar to natural gas, methanation reactions are required. Hydrogen in product gas is reacted with CO_2 and CO to form methane, with only a small portion unconverted. Methanation reactions are:

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O \quad 49.3\ \text{kcal/g-mole at } 25^\circ\text{C}$$

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \quad 9.8\ \text{kcal/g-mole at } 25^\circ\text{C}$$

After methanation, the gas goes to a scrubber to remove CO_2 for further purification.

Because the MRG process is mainly based on steam reforming, the success of the process hinges on the reliable availability of steam. Steam should be controlled at a constant level somewhat above the projected requirements to assure continuous, effective reforming. Adequate steam must be on hand at all times to assure effective control of the steam/naphtha ratio. In summary, for the proper feedstocks and economic situations, the MRG process offers the following: (1) a wide variety of feedstocks can be used; (2) broad selection of calorific value of final product gas. Product gas is available in a range of calorific values from 5,500 to 9,400 kcal/cubic meter; (3) high-pressure operation. Many conventional town-gas plants which operate at near atmospheric pressure require an additional compressor to convey product gas through pipelines. The MRG process does not require any additional compressor, but does permit operation at high pressures—up to approximately 1,140 pounds per square inch gage (77.6 atmospheres), enabling high-pressure, long-distance transportation of product gas. (4) Noncomplex equipment is used. The use of a drum-type reactor makes the reactor design quite simple, resulting in a compact design of the overall system. In terms of product gas calorific value, the MRG reactor requires only $\frac{1}{6}$ to $\frac{1}{8}$ the area of a general coke oven and about $\frac{1}{3}$ that of a conventional high-temperature steam-reforming plant; (5) sulfur-resistant catalyst; and (6) high thermal efficiency. Operation at low temperatures and high pressures permits thermal efficiency as high as 92–96%, depending on desulfurized feedstock used.

Hydrocracking-Hydrogasification Process. In a continuous, two-step process developed by the Institute of Gas Technology, crude oil can be hydrocracked to approximately diesel oil weight and then made to react noncatalytically with hydrogen at elevated pressures (500–1,500 psig; 34–102 atmospheres) and temperatures 593–760°C to produce methane-rich gas containing about 30% (volume) hydrogen and 10% ethane. This gas can be desulfurized and methanated to yield pipeline gas. By adjusting the conditions of hydrocracking, enough heavy fuel oil can be produced to provide feedstock for hydrogen production by partial oxidation, or a low-sulfur fuel oil product can be made if desired.

Interest has centered on plants to produce substitute natural gas from light distillate feedstocks, such as naphtha. However, when naphtha is in

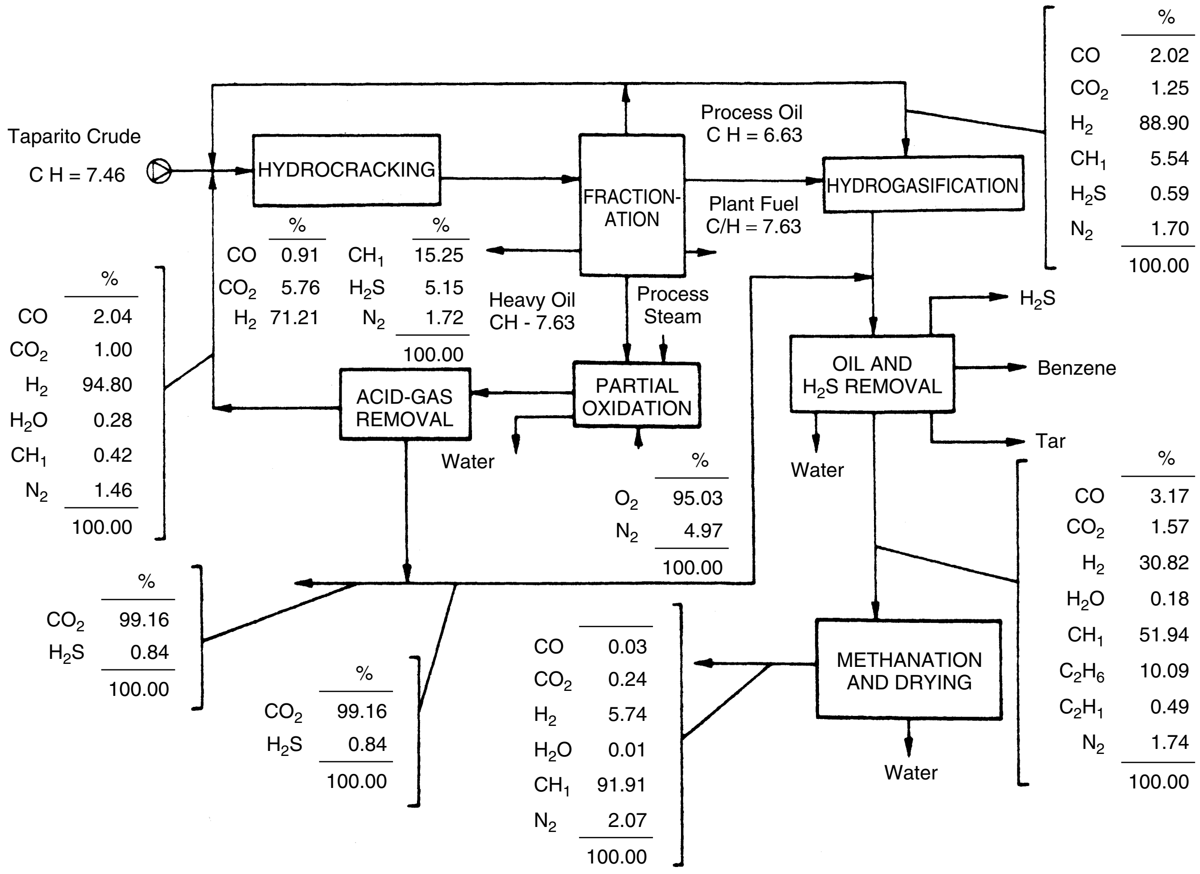

Fig. 4. Block flow diagram for pipeline gas production. (*Institute of Gas Technology.*)

short supply, a process capable of converting the more plentiful crude and residual oils to pipeline gas is needed. A number of processes were developed over 20 years ago to provide supplemental gas in winter periods when demand is high. Because the supplemental gas was required for only 20 to 30 days during the year, only cyclic thermal cracking at atmospheric pressure was used in order to avoid the high capital cost of more complex continuous processes. However, with the need for base-load gas, a continuous process would be feasible.

The major difficulty associated with the production of pipeline gas from crude and residual oils is carbon deposition during the gasification step, which leads to reactor vessel plugging. One approach to this problem has been to conduct pressure gasification with hydrogen in a fluidized bed of coke, allowing carbon to deposit on the coke particles. To avoid accumulation of these deposits, a small amount of coke is continuously withdrawn from the bed. This technique, developed by the British Gas Council, gasifies the oil in a single reaction step. An approach to the problem of carbon deposition taken by the Institute of Gas Technology is to eliminate the carbon-forming materials in the heavy oil prior to hydrogasification by catalytic hydrocracking. In developing this concept, experiments were conducted on both the hydrocracking and the hydrogasification operations for a variety of feedstocks, ranging from kerosine to Bunker-C fuel oil. Distillate feeds required no hydrocracking.

A simplified flowsheet based on this concept (hydrocracking, separation, and hydrogasification) is shown in Fig. 4, where 250 billion Btu/day (63 billion Calories/day) of pipeline-quality gas is produced from 59,350 barrels/day of Taparito crude. The overall fuel efficiency of the process is 67%, allowing for all utility requirements, including oxygen production. The design of hydrogen plants based on partial oxidation of residual oils and the design of hydrocracking operations are well established arts. The only unusual component of the process, therefore, is the hydrogasification reactor itself. Offsites not shown on the flowsheet include an oxygen plant, sulfur-recovery facilities (Claus plant), power and steam generation equipment, and water treatment facilities.

At the hydrogasification conditions used, about 90% of the 360°C endpoint feed oil is gasified, yielding a raw gas containing about 52% methane and 10% ethane, with the remainder principally hydrogen. About 60% of the liquid products is benzene. Total liquid products are removed first by separation in a knockout drum and then by straw oil scrubbing. Benzene, the last traces of which are removed from the gas by activated carbon, is recovered and sold. Very heavy oil is used for plant fuel. Since the excess hydrogen in the gas is to be methanated with carbon dioxide, a small amount of carbon dioxide from the hydrogen plant is added to the gas prior to the removal of hydrogen sulfide. Most of the hydrogen in the gas at this point will react with ethane during methanation. Because carbon dioxide is used for methanation, hydrogen sulfide must be selectively removed from the gas prior to methanation. Approximately 48,400 metric tons/year of elemental sulfur are recovered for disposal from waste gas streams in the plant. The waste gas streams from the acid-gas removal unit upstream of the methanator and from the first stage of the acid-gas removal unit in the hydrogen plant are sent to a Claus plant.

Noncatalytic Partial-Oxidation Gasification. Designed for the partial combustion or oxidation of hydrocarbons, a process of this type is particularly suitable for converting heavy, sulfur-containing residual fuels and heavy crude oils into a mixture of hydrogen and carbon monoxide in inert gases. The process is carried out by injecting oil and air (or oxygen) through a specially-designed burner assembly into a closed combustion vessel, where partial oxidation occurs at about 1,316°C. The term partial oxidation describes the net effect of a number of component reactions that occur in a flame supplied with less than stoichiometric oxygen.

In the fuel injection region of the reactor, hydrocarbons leaving the atomizer at about preheat temperature are intimately mixed with air or oxygen. The atomized hydrocarbon is heated and vaporized by back radiation from the flame and reactor walls. Some cracking of the hydrocarbons to carbon, methane, and hydrocarbon radicals may occur during this brief phase. When the fuel and air or oxygen reach the ignition temperature, part of the hydrocarbons reacts with oxygen in a highly exothermic reaction to produce carbon dioxide and water. Practically all available oxygen is consumed in this phase. The remaining hydrocarbons which have not been oxidized react with steam and the combustion products from reaction to form carbon monoxide and hydrogen. The carbon produced during gasification is recovered as a soot-in-water slurry.

Depending upon the desired heating value of the product gas, either oxygen or air may be used as oxidant. Nitrogen present in the air acts as a moderator for temperature control in the reactor and does not enter

into the reactions. When either oxygen or air enriched with oxygen is used, a quantity of steam must be injected into the reactor for temperature moderation. Air oxidation alone requires no steam. The latter method produces a low heating-value fuel gas (approximately 120 Btu/standard cubic foot; 13.5 Calories/cubic meter) due to the presence of nitrogen. Oxygen feed produces a medium heating-value gas (approximately 300 Btu/standard cubic foot; 33.7 Calories/cubic meter).

The net products of the process are high-pressure steam, clean wastewater, and carbon-free fuel gas. While the high-pressure steam is saturated, pressures over 1,100 psig (74.8 atmospheres) have been commercially demonstrated and increases to substantially higher pressures in commercial practice are anticipated. Under any condition, using superheating, this steam is easily converted into an attractive feed for steam turbines. With appropriate design, oxygen-based oxidation units can be made almost entirely energy self-sufficient.

Gas from Solid Wastes. In one process, municipal refuse is charged at the top of a shaft furnace and is pyrolyzed as it passes downward through the furnace. Oxygen enters the furnace through tuyeres near the furnace bottom and passes upward through a 1,425–1,650°C combustion zone. The products of combustion then pass through a pyrolysis zone and exit at about 93°C. The offgas then passes through an electrostatic precipitator to remove flyash and oil formed during pyrolysis, both of which are recycled to the furnace combustion zone. The gas then passes through an acid absorber and a condenser. The clean fuel gas has a heating value of about 300 Btu/cubic foot (33.7 Calories/cubic meter) and a flame temperature equivalent to that of natural gas. As the solid waste passes downward through the furnace, it contacts the exiting pyrolysis products and traps a portion of the oil and flyash while itself losing moisture. After passing through the pyrolysis and combustion zones, the remaining solid waste is removed as a slag from the furnace bottom. The system has a net thermal efficiency of about 65% in converting solid waste to fuel gas. Process losses include energy losses in the conversion process and energy required for the operation of the onsite cryogenic gas separation unit for production of 95% oxygen needed by the system. The clean fuel gas is low in sulfur (about 15 ppm) and is essentially free of nitrogen oxides.

Another process involves the anaerobic digestion of a solid waste and water or sewage slurry at 60°C for 5 days to produce a methane-rich gas. Solid waste is prepared by shredding and air classification prior to being blended with water or sewage sludge to a 10 to 20% solids concentration. The slurry is heated and placed in a mixed digester for 5 days detention. The digestor gas is drawn off and separated into carbon dioxide and methane. The spent slurry from the digester is pumped through a heat exchanger to partially heat the incoming slurry prior to filtration. The filtrate is returned to the blender and the sludge is used as landfill. Heat addition to the refuse slurry is required to maintain the required digester temperature. This process is suited for use on sewage sludge, animal manures, and other high-moisture-content solid wastes. It is estimated that the process reduces the volume of volatile solids by 75% while producing about 3,000 cubic feet (85 cubic meters) of methane per metric ton of incoming solid waste. The major residue is a sludge that requires landfilling or incineration. About 10% of the methane is consumed in heating the digester feed.

Methanol as Source of SNG. Methanol can be produced from a large range of feedstocks by a variety of processes. Natural gas, liquefied petroleum gas (LPG), naphthas, residual oils, asphalt, oil shale, and coal are in the forefront as feedstocks to produce methanol, with wood and waste products from farms and municipalities possible additional feedstock sources. In order to synthesize methanol, the main feedstocks are converted to a mixture of hydrogen and carbon oxides (synthesis gas) by steam reforming, partial oxidation, or gasification. The hydrogen and carbon oxides are then converted to methanol over a catalyst.

The concept of utilizing associated or natural gas for production of methanol which could be transported more economically than LNG from areas of surplus to areas of shortage was examined in the mid-1960s. At that time, the largest single-stream plant designed had a capacity of 900 metric tons of methanol per day. A fuel plant which might need to produce—say 22,500 metric tons per day of methanol was assessed on the economics basis of 25 times the small plant. It was quickly ascertained that methanol fuel delivered, for example, to the United States from the Middle East could not compete with local natural gas supplies which were than available at low cost within the United States. With shorter local supplies accompanied by much greater costs, the possibilities of economically feasible large-scale fuel methanol production now appear much more promising.

Conversion of natural gas (or other petroleum components) at the source to methanol, shipment as methanol, and reconversion of methanol into pipeline gas at point of use—versus the concept of liquefying natural gas and shipping LNG for regasification at point of use—probably will be a problem of some controversy for a number of years, pending assessment of actual system operating costs for both systems on a large-scale. See also **Natural Gas**.

SUBTRACTIVE COLOR PROCESS. A method of photographic color synthesis using two or more superimposed colorants, which selectively absorb their complementary colors from white light.

Most modern processes of color photography make use of a subtractive synthesis to yield prints or transparencies. In a three-color process, the colorants cyan, magenta, and yellow are used to control the amounts of red, green and blue in a beam of white light. See Fig. 1. This beam of white light may be either that of a projector with its color transparency, or the light reflected from a white support, such as paper, on which the color reproduction is printed. In the first case, the light passes through the colorants once, while in the print viewed by reflection the light must traverse the colorants twice.

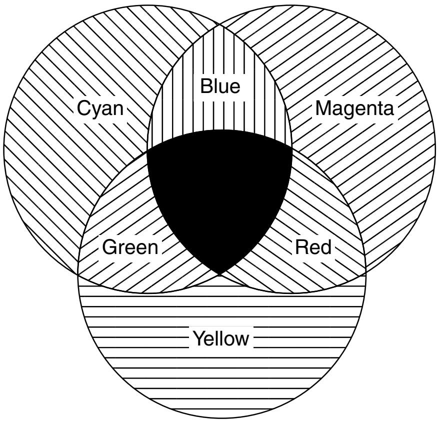

Fig. 1. Superimposed color filters

The colorants are positive or negative images. A cyan positive image (a cyan colorant controls red light), for example, may be prepared from the negative that recorded the red present in the subject. The magenta and yellow colorant images are likewise made from green and blue record negatives. These colorant images are superimposed in register to yield the final reproduction. The three colorants may be in separate removable layers or they may be physically inseparable as in the modern integral tripacks. The contrast of the colorant images must be approximately double for a picture to be viewed by transmitted light as compared to one to be viewed by reflection. The accuracy of color reproduction by a subtractive synthesis as compared to an additive is chiefly dependent on how satisfactorily the three colorants cyan, magenta, and yellow fulfill their role, as red, green and blue absorbers respectively. Color correction is often adopted to improve the accuracy of reproduction when using the colorants generally available.

SUCROSE. See **Carbohydrates**; **Sugar**; and **Sweeteners**.

SUGAR. The two principal sources of sucrose (table sugar, saccharose) are sugarcane, a tropical perennial grass (*Saccharum officinarium*), accounting for slightly over 60% of world sugar production; and the sugar beet, a biennial plant (*Beta vulgaris*), accounting for nearly 40% of world sugar production. Relatively minor commercial sources of saccharose include sorghum and the sugar maple tree (sap). Sucrose also occurs in honey. The basic chemical and physical properties of sucrose, $C_{12}H_{22}O_{11}$, are described in the entry on **Carbohydrates**.

Cane Sugar Manufacture

The amount of sucrose in the natural juice of the cane ranges from 10% to nearly 17% (weight), depending upon the variety, the nature of the growing season, and the time of harvesting. In addition to sucrose, cane juice contains from 1 to 2.5% glucose or reducing sugars. Various nonsugars range from 1 to 3% and are made up of carbohydrate polymers, such

as gums, and polysaccharides, such as pectins—plus a number of other substances in small quantities.

Crushing the Cane. Upon receipt of cane at the mill, the stalks are washed and cut into several smaller pieces, after which they are fed to a series (frequently three) roller mills. Three heavy, serrated roller crushers are used for each of these milling operations. Two of the rollers turn in opposite direction, while a third roller guides the flow of the stalks through the crushing operation. Where three sets of mills are used, the adjustment of the spacing between the crushing rollers will be wider for the first mill than the second mill, with the narrowest spacing for the third set of crushing rollers. The fibers are sprayed during crushing with a small amount of maceration water (from 5 to 20% of the weight of the cane). This facilitates extraction of sucrose. In some installations, the juice from the third mill is returned to the first and second mills as maceration water. The concentration of sucrose in juice from the first mill will usually be about 0.2% greater than that from the second mill; that of the third mill will be about 0.5% less than that of the first mill. However, the juice of the third mill will contain greater concentrations of gummy matter and some of the other impurities. The result of the total macerating action, which fully ruptures the plant cells, is a gray- to dark-green, cloudy juice that must be treated to effect a separation of impurities.

Liming and Clarifying. The ancient sugarmakers heated the raw juice and added ashes, causing a precipitation of many of the impurities, but the final product did not approach the purity of cane sugar marketed today which is one of the most highly purified compounds found in commerce. Over the past few centuries, lime has replaced the ashes and, during the past several decades, sulfur dioxide and phosphoric acid or phosphates also have been added to the total clarifying process. Sulfur dioxide bleach acts as an antimicrobial agent, and assists in the coagulation of such substances as albumin present in the juice. Further, the sulfur dioxide makes it possible to use more lime in the clarifying operation. Lime functions in several ways, forming insoluble compounds with several of the impurities present, neutralizes organic acids present, and when added in sufficient quantity, also reacts with the glucose present, converting it to organic acids. Most of the calcium compounds formed are quite insoluble and thus can be removed by settling or filtration. When phosphoric acid is added, the insoluble tricalcium phosphate is formed. A number of researchers have suggested that phosphates other than phosphoric acid may be preferable. Various sodium, ammonium, potassium, and calcium orthophosphates have been proposed as additives to the sugar solution, along with lime. The control of pH is critical if all lime is to be removed from the juice. Jung (U.S. Patent 3,347,705 issued in 1967) developed the use of polyphosphoric acid in combination with a dicarboxylic acid for the clarification of sugar juices. The primary objection to any excess lime in the solution is later scaling that will be caused in processing equipment.

Upon leaving the crushing mill, the juice is first treated with sulfur dioxide. The design of clarifying equipment has changed much during the past few decades. In earlier installations, the clarifiers were rectangular or circular metal pans, each with a capacity up to 1200 gallons (45 hectoliters).

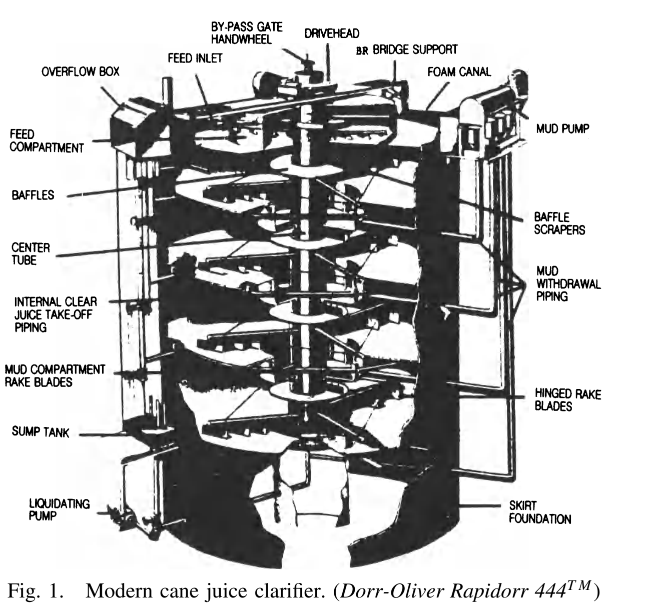

Fig. 1. Modern cane juice clarifier. (*Dorr-Oliver Rapidorr 444*^{TM})

A modern cane juice clarifier or proprietary design is shown in Fig. 1. As shown, the unit is equipped with separate provisions in each compartment for feed, overflow takeoff and mud withdrawal which allows the unit to operate essentially as four totally independent clarifiers enclosed in a common housing. Juice is introduced as the top-center of each compartment through a hollow rotating center tube. This tube is fitted with a series of ports and scalpers that serve as feed introduction points. Located directly below each port, and attached to the center tube, are feed deflection baffles which insure uniform feeding and impede the natural tendency of the incoming juice to mix with the settled muds. Also attached to the center tube are the various sets of rake arms.

As the feed enters each compartment, it first strikes the deflection baffle, then flows outward at a decreasing velocity creating minimum turbulence. The various sets of rotating rake arms move the settled muds to the mud discharge boot located at the center of each tray. The mud is then withdrawn from each compartment separately. Overflow piping removes the clarified juice from each compartment independently at multiple points around the periphery of the clarifier, through a single overflow box where accurate flow distribution is easily maintained and controlled at one point. Standard capacities of the units range from 10,800 gallons (409 hectoliters) and a mud-thickening area of 312 square feet (29 square meters) to 140,800 gallons (5329 hectoliters) and a mud-thickening area of 4068 square feet (378 square meters).

Evaporation. After clarification and filtration, the juice goes to evaporators (vacuum pans), where upon concentration of the solution, small crystals grain out. Continuous evaporation produces a very thick mixture (*masscuite*), which is a mixture of sugar grains that are suspended in thick molasses. This mixture is centrifuged which throws off most of the molasses, leaving raw sugar, sometimes referred to as *centrifugal sugar*. At this point, the sugar is from 96 to 97% pure. The molasses may be reworked 2 or 3 times more to increase the yield of sugar. Although the remaining molasses may contain up to 50% sugar, the impurities present prevent any further formation of crystals. At this point the residue is called blackstrap and is further treated for use in animal feedstuffs. Molasses is described further a bit later.

Cane Sugar Refining. Raw cane sugar mills, as just described, produce the raw sugar. Refiners then further process the raw sugar into the more familiar white crystalline sugar. This 2-stage sugar production process for cane sugar stems from the economics of processing raw sugar in relatively small cane-producing regions and then refining the sugar on a much larger scale, usually thousands of miles closer to the markets. Traditionally, much of the raw sugar was imported from tropical, underdeveloped countries that lacked resources for constructing complete refineries. There are cases, however, where both processing and refining are performed at a single location or where the raw mill and refinery are adjacent and operated under one ownership.

The raw sugar as received at the refinery is mixed with sugar syrup for the purpose of dissolving the molasses residuals which still stick to the crystals. The heavy mixture resulting is sometimes called *magma*. This mix is centrifuged, after which the crystals are steam-treated and at this point are almost white. Again, the sugar crystals are dissolved in sugar syrup and, once again, are treated with lime and phosphoric acid in order to precipitate impurities present. From this operation, the effluent is filtered through bone char to yield a purified solution. Again, the solution is evaporated, crystallized, centrifuged, the final moisture content adjusted, after which the product is packaged.

Beet Sugar Production

The German chemist Marggraf discovered the presence of sugar in beets as early as 1747. Early laboratory methods to extract sugar from the beet proved overwhelmingly costly as contrasted with processing the traditional source, sugar cane. Little progress was made for over a half-century, when in 1802, another German chemist, Achard, found a way to extract sugar from the beet root on a relatively large scale. For a few years, a small manufacturing operation in Silesia prospered, mainly because of political factors that drove up the price of cane sugar. In 1812, Napoleon ordered an establishment of the beet sugar industry in France. Early attempts toward beet sugar extraction were made in the United States (Massachusetts) in 1838, followed by efforts over the subsequent 30 years in Illinois, Wisconsin, and California. The first real success in the United States was achieved in the late 1870s by a factory in Alvardo, California.

The principal operations in sugar beet processing today include thorough washing of the beets, after which whirling knives slice the beets into

thin strips, called *cossettes*. These are immersed in hot water where the sugar is removed from the beets by diffusion. The resulting solution is *raw juice*. This juice is purified in a process (carbonation), wherein lime and carbon dioxide are added to cause undesired impurities in the raw juice to precipitate out of the solution (as in the case of cane sugar previously described). This resulting, purified liquid is *thin juice*. Filtering and settling operations remove solid particles and impurities from the thin juice. This juice is concentrated by boiling off water to form *thick juice*. Further filtering ensures that all solid particles are eliminated. Sugar crystals are formed by boiling the thick juice under vacuum. The resulting mixture of crystals and liquid is known as *fillmass*. This mixture is spun and washed in high-speed centrifugals to separate the sugar crystals from the liquid. These crystals are now pure white sugar (sucrose). After further crystallization of the separated liquid, additional sugar and an important by-product (molasses) is obtained. The white sugar crystals are dried by tumbling in warm air in long rotating drums (granulators), after which the sugar is ready for market. The residue of the beets (*pulp*) is sold for livestock feed in either wet or dried form. Some molasses may be added to the pulp prior to drying.

SULFITE PULP PROCESS. See **Pulp (Wood) Production and Processing**.

SULFONAMIDE DRUGS. In 1935, Domagk, a German researcher, was the first to observe the clinical value of *prontosil*, a red compound derived from azo dyes. Paraaminobenzenesulfonamide was shown to be the effective portion of the prontosil molecule. This substance was given the name *sulfanilamide*. This was the first of a group of related drugs to receive wide clinical trial. It was found to be effective in the treatment of hemolytic streptococcal and staphylococcal infections. Within a short span of years, related drugs were synthesized and given clinical trials. These included *sulfapyridine, sulfathiazole, sulfaguanidine, sulfadiazine*, and *sulfamerazine*. These drugs acted by inhibiting the growth of bacteria rather than by killing organisms.

Even though numerous adverse side effects were observed over a period of time, the sulfonamides played an important role in medicine prior to the advent of the antibiotics. In recent years, the importance of the so-called *sulfa drugs* has diminished considerably, but for certain situations they are still considered important antimicrobials. Presently the sulfonamides are mainly used to treat uncomplicated urinary tract infections, including prostatitis, due to *E. coli*. They are also used to treat a number of noncardial infections. At one time the sulfa drugs were widely used in the treatment of meningococcal meningitis and bacillary dysentery. Unfortunately, the bacilli responsible for these diseases developed, over the years, a resistance to the drugs, severely reducing their efficacy.

Within the last few years, some new sulfa drugs have been introduced, including trimethoprim-sulfamethoxazole. This drug has broadened the scope in treatment of urinary tract infections derived from species in addition to *E. coli*, namely, *Klebsiella, Enterobacter*, and *Porteus* species. This drug also is used for the treatment of acute otitis media in children, particularly those instances where strains of *H. influenzae* and *streptococcus pneumoniae* may be suspected. The drug is also used to treat systemic infections that may arise from chloramphenicol- and ampicillin-resistant *Salmonella*; as well as infections attributed to *Pneumocystis carinii*.

Also, the nature of sulfonamide compounds (relatively short duration of action, capability of entering into synergism with other drugs, poor absorption, and topical effectiveness, not to mention relatively low cost) is taken advantage of in what is sometimes called short-acting sulfonamides. Short-acting sulfonamides include sulfisoxazole, sulfadiazine, and trisulfapyrimidines. An intermediate-acting sulfonamide in current use is sulfamethoxazole. This drug does tend to cause renal damage arising from sulfonamide crystalluria.

Sulfacetamide eyedrops continue to be used for treatment of superficial ocular infections. Sometimes silver-sulfadiazine cream is applied to burn surfaces to minimize or prevent bacterial growth, as well as preventing invasive infection.

The adverse effects of sulfonamides include hypersensitivity reactions, as manifested by rashes, photodermatitis (allergic reaction to light), so-called drug fever, nausea, and vomiting. These reactions occur with some frequency when sulfonamides are administered. Less frequently encountered is crystalluria, previously mentioned, but with the risk lessened in the case of sulfisoxazole. Sulfa drugs also occasionally cause hemolytic anemia, agranulocytosis, and kernicterus (in infants) when the drugs are given to nursing mothers. In rare instances, sulfa drugs may precipitate hepatitis, aplastic anemia, renal tubular necrosis, and certain blood disorders.

SULFONATION AND SULFATION. Sulfonation and sulfation, chemical methods for introducing the SO_3 group into organic entities, are related and usually treated jointly.

In sulfonation, an SO_3 group is introduced into an organic molecule to give a product having a sulfonate, CSO_3, moiety. The compound may be a sulfonic acid, a salt, or a sulfonyl halide requiring subsequent alkaline hydrolysis. Aromatic hydrocarbons are generally directly sulfonated using sulfur trioxide, oleum, or sulfuric acid. Sulfonation of unsaturated hydrocarbons may utilize sulfur trioxide, metal sulfites, or bisulfites. The latter two reagents produce the corresponding hydrocarbon metal sulfonate salts in processes referred to as sulfitation and bisulfitation, respectively. Organic halides react with aqueous sodium sulfite to produce the corresponding organic sodium sulfonate. In instances where the sulfur atom at a lower valance is attached to a carbon atom, the sulfonation process entails oxidation. Thus the reaction of a paraffin hydrocarbon with sulfur dioxide and oxygen is referred to as sulfoxidation; the reaction of sulfur dioxide and chlorine is called chlorosulfonation. The sulfonate group may also be introduced into an organic molecule by indirect methods through a primary reaction, e.g., esterification, with another organic molecule already having an attached sulfonate group.

Sulfation is defined as any process of introducing an SO_3 group into an organic compound to produce the characteristic $C{-}OSO_3$ configuration. Typically, sulfation of alcohols utilizes chlorosulfuric acid or sulfur trioxide reagents. Unlike the sulfonates, which show remarkable stability even after prolonged heat, sulfated products are unstable toward acid hydrolysis. Hence, alcohol sulfuric esters are immediately neutralized after sulfation in order to preserve a high sulfation yield.

In sulfamation, also termed N-sulfonation, compounds of the general structure R_2NSO_3H are formed as well as their corresponding salts, acid halides, and esters. The reagents are sulfamic acid (amido-sulfuric acid), SO_3–pyridine complex, SO_3–tertiary amine complexes, aliphatic amine–SO_3 adducts, and chlorine isocyanate–SO_3 complexes.

Uses for Derived Products and Sulfonation Technology

Sulfonation and sulfation processes are utilized in the production of water-soluble anionic surfactants as principal ingredients in formulated light-duty and heavy-duty detergents, liquid hand cleansers, general household and personal care products, and dental care products. Other commercially significant product applications include emulsifiers, lube additives, sweeteners, pesticides, medicinals, ion-exchange resins, dyes and pigments.

Sulfonation and sulfation processes are important tools for organic synthesis of specific molecules and positional isomers.

Application chemists are most interested in physical and functional properties contributed by the sulfonate moiety, such as solubility, emulsification, wetting, foaming, and detersive properties. Products can be designed to meet various criteria including water solubility, water dispersibility, and oil solubility. The polar SO_3 moiety contributes detersive properties to lube oil sulfonates and dry-cleaning sulfonates.

Process Selection and Options. Because of the diversity of feedstocks, no one process fits all needs. An acceptable sulfonation/sulfation process requires (*1*) the proper reagent for the chemistry involved and the ability to obtain high product yields; (*2*) consistency with environmental regulations such that minimal and disposable byproducts are formed; (*3*) an adequate cooling system to control the reaction and to remove significant heat of reaction; (*4*) intimate mixing or agitation of often highly viscous reactants to provide adequate contact time; (*5*) products of satisfactory yields and marketable quality; and (*6*) acceptable economics. Viscosity constraints may play a significant role not only dictating agitation/mixing requirements but also seriously affecting heat-exchange efficiency.

Reagents

Reagents for direct sulfonation and sulfation reactions are listed in Table 1. Unlike sulfuric acid reactions which usually require 3–4 moles per mole of organic feedstock resulting in substantial "spent acid" requiring disposal, SO_3 generally reacts essentially stoichiometrically thus producing high-purity products directly.

By 1987, sulfur trioxide reagent use in the United States exceeded that of oleum for sulfonation. Sulfur trioxide source is divided between liquid SO_3 and *in situ* sulfur burning. The latter is integrated into sulfonation production facilitates.

Liquid SO_3 is commercially available as both unstabilized and stabilized liquids. Unstabilized liquid SO_3 can be utilized without problem as long as moisture is excluded, and it is maintained at ca 27–32°C. Stabilized liquid SO_3 has an average in that should the liquid freeze (16.8°C), in the absence of moisture pickup, the SO_3 remains in the gamma-isomer form and is readily remeltable. Gaseous SO_3 can also be obtained by stripping 70% oleum (70%SO_3 : 30%H_2SO_4) or by utilizing SO_3 converter gas (6–8% SO_3) from H_2SO_4 production, or by vaporizing liquid SO_3 which is then generally diluted with moisture free air.

Sulfur trioxide is an extremely strong electrophile that rapidly seeks to enter into transient or permanent relationships or reactions with organics containing electron donor elements, such as oxygen, nitrogen, halogen, and phosphorus. In some instances, SO_3 may first form a transient intermediate adduct at some moderate temperature, which at some higher temperature becomes unstable, liberating SO_3. This subsequently may react to produce a stable sulfonated product, often accompanied by a difficult to control strong or violent exotherm. The reactivity of SO_3 can be moderated by the use of solvents (such as liquid SO_2, or halogenated hydrocarbons), or by the use of SO_3 adducts, (such as SO_3–Trimethylamine or SO_3–Pyridine).

Sulfonation

All sulfonation is concerned with generating a carbon sulfur(VI) bond in the most controlled manner possible using some form of the sulfur trioxide moiety. Sulfonation can be carried out in a number of ways using the reagents listed in Table 1. Sulfur trioxide is a much more reactive sulfonating reagent than any of its derivatives. Care should be taken with all sulfonating reagents owing to the general exothermic nature of the reaction.

The variety of reagents available makes possible the conversion of a wide range of aromatics into sulfonic acids. The reactivity of compounds that are activated toward electrophilic attack are so high that often alternative reagents are used in order to minimize undesirable by-products largely formed owing to excessive heating.

Aromatic Compounds. The accepted general mechanism for the reaction of an aromatic compound with sulfur trioxide involves an activated intermediate as shown in equation 1.

$$R{-}C_6H_5 + SO_3 \longrightarrow [R{-}C_6H_5SO_3]^* \longrightarrow R{-}C_6H_4SO_3H \qquad (1)$$

The reaction of sulfur trioxide and benzene in an inert solvent is very fast at low temperatures. Yields of 90% benzenesulfonic acid can be expected. Increased yields of about 95% can be realized when the solvent is sulfur dioxide.

Several thousand different synthetic dyes are known, having a total worldwide consumption of 298 million kg/yr. Many dyes contain some form of sulfonate as $-SO_3H$, $-SO_3Na$, or $-SO_2NH_2$.

The world's largest volume synthetic surfactant is linear alkylbenzene sulfonate (LAS), which was developed as a biodegradable replacement for nonlinear alkylbenzene sulfonates (BAB). LAS is derived from the sulfonation of linear alkylbenzene (LAB). Detergent sulfonates use LAB in the 236 to 262 molecular weight range, having a C_{11}–C_{13} alkyl group. The simplest sulfonation route uses 100% sulfuric acid. Continuous falling film SO_3 sulfonation systems utilizing either vaporized and dry air diluted gaseous SO_3 (3–8% SO_3) or *in-situ* sulfur burning integrated air diluted SO_3 generating systems (3–8% SO_3) have become the method of choice for the sulfonation of most aromatics, as well as for the sulfation of alcohols.

Sulfonated toluene, xylene, and cumene, neutralized to the corresponding ammonium or sodium salts, are important industrially as hydrotropes or coupling agents in the manufacture of liquid cleaners and other surfactant compositions.

Sulfitation and Bisulfitation of Unsaturated Hydrocarbons. Sulfites and bisulfites react with compounds such as olefins, epoxides, aldehydes, ketones, alkynes, aziridines, and episulfides to give aliphatic sulfonates or hydroxysulfonates.

Sulfosuccinates and Sulfosuccinamates. The principal sulfonating reagent in these cases is the bisulfite molecule which readily attacks electron-deficient carbon centers. Variations in the choice of starting material can give a broad spectrum of products of widely varying chemical and physical properties.

TABLE 1. REAGENTS FOR DIRECT SULFONATION AND SULFATION REACTIONS[a]

Reagent	Formula	Physical form	Advantages	Disadvantages	Applications
sulfur trioxide liquid	SO_3	liquid	low cost, concentrated reagent	extremely reactive; charring	very few
gas	SO_3	gas, 3–8% SO_3	low cost, stoichiometric reactions; preferred reagent	requires significant dry diluent gas; mole ratio sensitive; liquid storage	most every sulfonation and sulfation reaction
sulfur burning	SO_3	gas *in situ*, 3–8% SO_3	lowest cost SO_3 produced *in situ*; preferred reagent	catalyst requires startup time; higher investment cost	most every sulfonation and sulfation reaction
chlorosulfuric acid	$ClSO_3H$	liquid	stoichiometric reactions	expensive; produces HCl gas, disposal problem	alcohol sulfation, dyes, etc.
oleum	$H_2SO_4 \cdot SO_3$	liquid	low cost	reactions not stoichiometric; 3–4 mol generally required	dyes, alkylated aromatic sulfonation; continuous sulfation of alcohols
sulfuric acid	H_2SO_4[b]	liquid	low cost, easily handable	reactions not stoichiometric; generally requires 3–4 mol	hydrotrope sulfonation of aromatics using azeotropic water removal, etc.
sodium bisulfite	$NaHSO_3$	solid, 38% liquid	simple processing	higher cost, except for sulfur burning	sulfosuccinates, lignin, olefins, Streker reaction
sodium sulfite	Na_2SO_3	solid, 38% liquid	simple processing	higher cost	Streker reaction, etc.
sodium bisulfite, hydroperoxide catalyst	$NaHSO_3$, O_2	solid, 38% liquid	sulfonation of olefins	requires hydroperoxide catalyst; costly	sulfonation of olefinic hydrocarbons producing primary paraffin sulfonation
sulfamic acid	H_2NSO_3H	solid	stoichiometric reaction, mild, simple	high cost; limited to NH_4 salt; heating to ca 150°C	small specialties, sulfations
sulfuryl chloride	SO_2Cl_2	liquid	few	expensive, usually required catalyst	chlorosulfonation reactions; mostly research
sulfur dioxide and chlorine	SO_2, Cl_2	gases	few, relatively inexpensive	not generally stoichiometric; need catalyst	chlorosulfonation of paraffins, produces HCl
sulfur dioxide and oxygen	SO_2, O_2	gases	few, inexpensive	not stoichiometric; requires catalyst	sulfoxidation of paraffins

[a] In order of descending reactivity.
[b] 93–100%.

Unsaturated Hydrocarbons. The reaction of long-chain, i.e., $C_{12}-C_{18}$, α-olefins with strong sulfonating agents leads to surface-active materials. The overall product of continuous falling film SO_3 sulfonation of α-olefins, termed α-olefin sulfonate (AOS), is really a mixture containing both alkenesulfonates (65–70%) and hydroxyalkanesulfonates (20–25%), along with small amounts of disulfonated products (7–10%). The composition of the final product varies as a result of manufacturing conditions.

AOS prepared from α-olefins in the $C_{12}-C_{18}$ range are most suitable for detergent applications.

Fatty Acid Esters. Fatty acid ester sulfonates are manufactured by reaction of the corresponding hydrogenated (usually methyl) ester and a strong sulfonating agent, such as sulfur trioxide, in order to sulfonate on the alpha-position of the ester. The procedure for the reaction and equipment requirements are very similar to those for the production of LAS. Sodium fatty acid ester sulfonates are known to be highly attractive as surfactants, because they are produced from renewable natural resources and their biodegradability is almost as good as alkyl sulfates.

Petroleum and Related Feedstocks. Petroleum sulfonate by-products were the first petrochemical product. Since that time, By-product petroleum sulfonates have gradually found utilization in a great many applications, including as lubricant additives for high performance engines; as emulsifiers, flotation agents, and corrosion inhibitors; and for enhanced oil recovery. The importance of petroleum sulfonates has grown to the point where these compounds are produced as coproducts, or even as primary petrochemicals.

Factors impacting petroleum sulfonation operations since the late 1970s include the many significant changes and modernizations petroleum refineries have undergone leading to the closing of many refineries practicing oil sulfonation processes; white oil manufacturing technology has eliminated sulfonation and thus sludge disposal to utilize the more cost-efficient hydrogenation process; a principal shift has developed in the use of first-intent oil-soluble synthetic alkylated aromatic sulfonates in place of the traditional petroleum sulfonates for lube additives, and the synthetic sulfonates are made by continuous SO_3 sulfonation processes; and the large projected need for petroleum sulfonates for enhanced oil recovery processes has ceased owing to a significant and prolonged drop in crude oil market prices. Hence there has been a significant drop in the production of natural petroleum sulfonates.

Lignin. Lignosulfonates are complex polymeric materials obtained as by-products of wood pulping where lignin is treated with sulfite reagents under various conditions See also **Pulp (Wood) Production and Processing**. Lignin polymers contain substantial amounts of guaiacyl units, followed by *p*-hydroxyphenyl and syringyl units. Two principal wood pulping processes are utilized: the sulfite process and the kraft process. Sulfonation of lignin mainly occurs on the substituted phenyl–propene precursors at the alphacarbon next to the aromatic ring.

Styrene and Vinyl Monomer, Polymer, and Copolymer Sulfonates. The incorporation of sulfonates into polymeric material can occur either after polymerization or at the monomer stage. The sulfonic acid group is strongly acidic and can therefore be used to functionalize the polymer backbone to the desired degree. The ability of sulfonic acids to exchange counterions has made these polymers prominent in industrial water treatment applications, separators in electrochemical cells, and selective membranes of many types.

The simplest monomer, ethylenesulfonic acid, is made by elimination from sodium hydroxyethyl sulfonate and polyphosphoric acid. Ethylenesulfonic acid is readily polymerized alone or can be incorporated as a copolymer using such monomers as acrylamide, allyl acrylamide, sodium acrylate, acrylonitrile, methylacrylic acid, and vinyl acetate. Styrene and isobutene fail to copolymerize with ethylene sulfonic acid.

Sulfation

Sulfation is the generation of an oxygen sulfur(IV) bond, where the oxygen is attached to the carbon backbone, in the most controlled manner possible, using some form of sulfur trioxide moiety. When sulfating alcohols, the reaction is strongly exothermic. Examples of feedstocks for such a process include alkenes, alcohols, or phenols. Unlike the sulfonates, which exhibit excellent stability to hydrolysis, the alcohol sulfates are readily susceptible to hydrolysis in acidic media. The sulfation of fatty alcohols and fatty polyalkoxylates has produced a substantial body of commercial detergents and emulsifiers.

Linear ethoxylates are the preferred raw materials for production of ether sulfates used in detergent formulations because of uniformity, high purity, and biodegradability. The alkyl chain is usually in the C_{12} to C_{13} range having a molar ethylene oxide: alcohol ratio of anywhere from 1:1 to 7:1. Propoxylates, ethoxylates, and mixed alkoxylates of aliphatic alcohols or alkyl phenols are sulfated for use in specialty applications.

Alcohols and Alkoxylates. The preferred method of sulfation uses some form of a continuous thin-film SO_3 reactor.

Sulfamation

Sulfamation is the formation of a nitrogen sulfur(VI) bond by the reaction of an amine and sulfur trioxide, or one of the many adduct forms of SO_3. Heating an amine with sulfamic acid is an alternative method. A practical example of sulfamation is the artificial sweetener sodium cyclohexylsulfamate, produced from the reaction of cyclohexylamine and sulfur trioxide See also **Sweeteners**. Sulfamic acid is prepared from urea and oleum. Whereas sulfamation is not greatly used commercially, sulfamic acid has various applications.

Industrial Processes

A wide array of industrial processes is suitable for the manufacture of sulfated and sulfonated products. Process selection is dependent on the specific chemistry involved, choice and cost of reagents, physical properties of feedstocks and derived products, product volume requirements, operational mode (batch, continuous), quality of derived products, and possible generation and disposal of by-products as well as operating and equipment investment costs. Another important consideration is the location of the sulfonation plant relative to raw material suppliers, particularly for the more limited liquid SO_3 supplier's plants. On the other hand, molten sulfur used for *in situ* sulfur burning and gaseous SO_3 generation is readily available throughout the United States and worldwide. Another consideration for process selection is plant versatility in sulfonating a variety of feedstocks.

The handling of highly acidic sulfonation reagents and the actual sulfonation processing conditions for the production of acidic reaction products and by-products present a number of corrosion problems which must be carefully addressed. Special stainless steel alloys or glass-lined equipment are often used, although the latter generally has poorer heat-exchange properties. All environment regulations or restrictions must also be met. For example, in utilizing $ClSO_3H$ reagent, HCl gaseous by-product is generated requiring its recovery by adsorption or neutralization.

The viscosity of sulfonation and sulfation reaction mixtures increases with conversion, often producing extremely high viscosities. Sulfonation process design must accommodate such viscosities.

Batch processes are currently used for the manufacture of small volume specialty sulfonates based on H_2SO_4, oleum, $ClSO_3H$, sulfite, or SO_3 reagents. Production of large volume sulfonates or alcohol sulfates generally utilize continuous SO_3 falling-film processes based on multitubular or concentric designed reactor systems.

SULFONE POLYMERS. Polysulfone is a transparent, heat-resistant, ultrastable and high-performance engineering thermoplastic. It is amorphous and has low flammability and smoke emission. Electrical properties are good; the material remains essentially unchanged up to near its glass transition temperature, 190°C (374°F). The molecular structure of polysulfone features the diaryl sulfone group, a group that tends to attract electrons from the phenyl rings. Oxygen atoms para to the sulfone group enhance resonance and produce oxidation resistance. High resonance also strengthens the bonds spatially, fixing the grouping into a planar configuration. Thus, the polymer has good thermal stability and rigidity at high

temperatures. Ether linkages provide chain flexibility, thus imparting good impact strength.

The resistance to acids, alkalies, and salt solutions is high and also good in terms of detergents, oils, and alcohols even at elevated temperatures under moderate stress. Polysulfones, however, are attacked by polar organic solvents, such as ketones, chlorinated hydrocarbons, and aromatic hydrocarbons. The material can be used continuously in steam up to temperatures of 93°C (300°F). Maximum stress in water at about 82°C (180°F) is 2000 psi (steady loads) and 2500 psi (intermittent loads). In long-term performance at 150°C (300°F), polysulfone increases about 10% in strength and modulus values, retaining 90% of its dielectric strength and 70% of its impact strength.

Polysulfone is widely used in medical instrumentation and trays for holding instruments during sterilization. Food processing applications, such as piping, scraper blades, steam tables, microwave oven cookware, and beverage dispensing tanks, are numerous. Electrical/electronic applications include connectors, automotive fuses and switch housings, soil bobbins and cores, television components, capacitor film, and structural circuit boards. In chemical processing equipment, uses include corrosion-resistant piping, tower packing, pump parts, filter modules, and membranes. Polysulfone is available in both molding and extrusion grades. A special medical grade is available. Also available are polysulfone compounds with glass fiber or beads, as well as fillers, such as Teflon®.

SULFONIC ACIDS. Sulfonic acids are classically defined as a group of organic acids which contain one or more sulfonic, $-SO_3H$, groups, The general formula of organic sulfonic acids RSO_3H, where the R-group may be derived from many different sources. Typical R-groups are alkane, alkene, alkyne, and arene. The R-group may contain a wide variety of secondary functionalities such as amine, amide, carboxylic acid, ester, ether, ketone, nitrile, phenol, etc. Sulfonic acid derivatives, where the R-group is derived from an inorganic source such as a halide, oxygen (i.e., sulfate), or amine (i.e., sulfamic acid), are often referred to as sulfuric acid derivatives.

Physical Properties

The physical properties of sulfonic acids vary greatly depending on the nature of the R-group. Sulfonic acids can be described as having similar acidity characteristics to sulfuric acid. Sulfonic acids are prone to thermal decomposition, i.e., desulfonation, at elevated temperatures. However, several of the alkane-derived sulfonic acids show excellent thermal stability, as shown in Table 1. Arene-based sulfonic acids are thermally unstable.

Sulfonic acids are such strong acids that in general they can be considered greater than 99% ionized.

Chemical Properties

Sulfonic acids are prepared on a commercial scale by the sulfonation of organic substrates using a variety of sulfonating agents, including sulfur trioxide (diluted in air), sulfur trioxide (in sulfur dioxide), sulfuric acid, oleum (fuming sulfuric acid), chlorosulfuric acid, sulfamic acid, trialkylamine–sulfur trioxide complexes, and sulfite ions. Other methods of sulfonic acid production, practiced on an industrial scale, include the oxidation of thiols, sulfide, disulfides, sulfoxides, sulfones, and sulfinic acids. See also **Sulfonation and Sulfation**.

[b] At 13.3 Pa (0.1 mm Hg).
[c] At 101.3 kPa = 760 mm Hg.

General Reaction Chemistry of Sulfonic Acids. Sulfonic acids may be used to produce sulfonic acid esters, which are derived from epoxides, olefins, alkynes, allenes, and ketenes, as shown in Figure 1. Phosphorus pentachloride and phosphorus pentabromide can be used to convert sulfonic acids to the corresponding sulfonyl halides.

Halogenation of sulfonic acids, which avoids production of a sulfonyl halide, can be achieved under oxidative halogenation conditions.

Sulfonic acids may be subjected to a variety of transformation conditions. Sulfonic acids may be hydrolytically cleaved, using high temperatures and pressures, to drive the reaction to completion.

Aromatic sulfonic acid derivatives can be nitrated using nitric acid, in H_2SO_4. Sulfones may be treated with hydrazine derivatives to give the corresponding ring-opened sulfonic acid.

Production

At the end of the 1990s, there were four primary methods of sulfonic acid production in the United States: falling film sulfonation; oleum sulfonation; chlorosulfuric acid sulfonation; and SO_3 solvent-based sulfonation.

The vast majority of sulfonic acids were produced using continuous falling film sulfonation technology, which utilizes vaporized SO_3 mixed with air. This technology dominates the sulfonation industry owing to the capability of high product throughput and low by-product waste streams.

Analytical and Test Methods

Modern analytical techniques have been developed for complete characterization and evaluation of a wide variety of sulfonic acids and sulfonates. Titration is the most straightforward method of evaluating sulfonic acids. Spectroscopic methods for sulfonic acid analysis include ultraviolet spectroscopy, infrared spectroscopy, and ^{1}H and ^{13}C nmr spectroscopy. Modern separation techniques of sulfonates include liquid chromatography and ion chromatography. See also **Chromatography**.

Health and Safety Factors

In general, unneutralized sulfonic acids are regarded as moderate to highly toxic substances. However, slight detoxification, via the introduction of a sulfonic acid moiety, is observed for nitrobenzene and aminobenzene. Sulfonic acids emit toxic SO_x fumes upon heating to decomposition. Halogenated sulfonic acids, such as trifluoromethane sulfonic acid, also release toxic halogen-containing fumes when heated to decomposition.

Sulfonic acids have essentially the same corrosive characteristics as does concentrated sulfuric acid. Detergent-based sulfonic acids pose a contact hazard, as they are very corrosive to the skin.

When sulfonic acids are neutralized to sulfonic acid salts, the materials become relatively innocuous and low in toxicity, as compared to the parent sulfonic acid.

Environmental Issues

Linear alkylbenzenesulfonic acid is the largest intermediate used for surfactant production in the world. Owing to the large volumes of production and consumption of linear alkylbenzenesulfonate, much attention has been paid to its biodegradation and a series of evaluations have been performed to thoroughly study its behavior in the environment. Much less

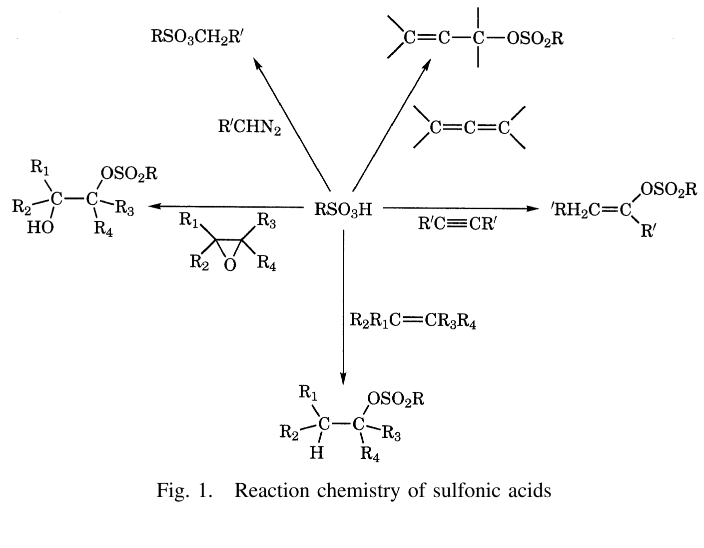

Fig. 1. Reaction chemistry of sulfonic acids

attention has been paid to the environmental impact of other sulfonic acid-based materials.

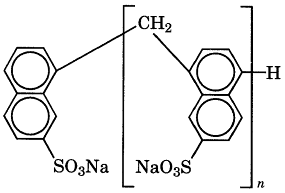
Linear alkylbenzenesulfonate showed no deleterious effect on agricultural crops exposed to this material. Kinetics of biodegradation have been studied in both wastewater treatment systems and natural degradation systems. Studies have concluded that linear alkylbenzenesulfonate does not pose a risk to the environment. Linear alkylbenzenesulfonate has a half-life of approximately one day in sewage sludge and natural water sources and a half-life of one to three weeks in soils. Aquatic environmental safety assessment has also shown that the material does not pose a hazard to the aquatic environment.

Uses

Surfactants and Detergents Uses. Perhaps the largest use of sulfonic acids is the manufacture of surfactants and surfactant formulations. In almost all cases, the parent sulfonic acid is an intermediate which is converted to a sulfonate prior to use. The largest volume uses for sulfonic acid intermediates are the manufacture of heavy-duty liquid and powder detergents, light-duty liquid detergents, hand soaps (see **Soaps**), and shampoos.

Lignosulfates, a complex mixture containing sulfonated lignin, are used as dispersing agents, wetting agents, binding agents, and sequestering agents. Dry forms of the materials are used as road binders, concrete additives, animal feed additives, and in vanillin production.

Naphthalenic, lignin, and melamine-based sulfonic acids are used as dispersion and wetting agents in industry. The sulfonate (**1**) is also widely used as a dispersing agent in dyestuff manufacture and high temperature dyeing of polyester fibers. A derivative of (**1**) based on 4-aminobenzene sulfonic acid has also been produced.



(**1**)

Other commercial naphthalene-based sulfonic acids, such as dinonylnaphthalene sulfonic acid, are used as phase-transfer catalysts and acid reaction catalysts in organic solvents.

Sulfonic Acid-Based Dyestuffs. Sulfonic acid-derived dyes are utilized industrially in the areas of textiles, paper, cosmetics, foods, detergents, soaps, leather, and inks, both as reactive and disperse dyes. Of the principal classes of dyes, sulfonic acid derivatives find utility in the areas of acid, azoic, direct, disperse, and fiber-reactive dyes. Sulfonic acid-based azo dyes and intermediates are characterized by the presence of one or more azo, RN=NR, groups.

Amide-Based Sulfonic Acids. The most important amide-based sulfonic acids are the alkenylamidoalkanesulfonic acids. These include 2-acrylamidopropanesulfonic acid, 2-acrylamido-2-methylpropanesulfonic acid, 3-acrylamido-2,4,4-trimethylpentanesulfonic acid, 2-acrylamido-2-(*p*-tolyl)ethanesulfonic acid, and 2-acrylamido-2-pyridylethanesulfonic acid.

Biological Uses

Taurine (2-aminoethanesulfonic acid), is the only known naturally occurring sulfonic acid. The material is an essential amino acid for cats and is used extensively by Ralston Purina Company as a food supplement in cat food manufacture.

Sulfonic acids have found greatly expanded usage in biological applications. Whereas the toxicity of sulfonic acids is in general rather high, several sulfonic acids are beneficially utilized *in vivo*. Taurocholic acid is an important bile component, aiding in the digestion of fat.

Potent inhibition of the herpes simplex virus has been observed using biphenyl disulfonic acid urea copolymers. Sulfonic acid derivatives have been shown to be potent antihuman immunodeficiency virus (anti-HIV) agents.

Other Applications. Hydroxylamine-*O*-sulfonic acid has many applications in the area of organic synthesis. The acid has found application in the preparation of hydrazines from amines, aliphatic amines from activated methylene compounds, aromatic amines from activated aromatic compounds, amides from esters, and oximes.

Petroleum sulfonates have found wide usage in enhanced oil recovery technology.

A variety of barium sulfonates have found use in antifriction lubricants for high speed bearing applications. Calcium and sodium salts of sulfonated olefins, esters, or oils are used for the enhancement of extreme pressure properties of grease and gear lubricants.

SULFOXIDES. Sulfoxides are compounds that contain a sulfinyl group covalently bonded at the sulfur atom to two carbon atoms. They have the general formula RS(O)R′, ArS(O)Ar′, and ArS(O)R, where Ar and Ar′ = aryl. Sulfoxides represent an intermediate oxidation level between sulfides and sulfones. The naturally occurring sulfoxides often are accompanied by the corresponding sulfides or sulfones. The only commercially important sulfoxide is the simplest member, dimethyl sulfoxide (DMSO) or sulfinylbismethane.

Sulfoxides occur widely in small concentrations in plant and animal tissues.

Properties

For the most part, sulfoxides are crystalline, colorless substances, although the lower aliphatic sulfoxides melt at relatively low temperatures. The lower aliphatic sulfoxides are water soluble; but as a class the sulfoxides are not soluble in water. They are soluble in dilute acids and a few are soluble in alkaline solution. DMSO is a colorless liquid; selected properties are listed in Table 1. Dimethyl sulfoxide generally undergoes typical sulfoxide reactions. It is used herein as an illustrative example.

Thermal Stability. Dimethyl sulfoxide decomposes slowly at 189°C to a mixture of products that includes methanethiol, formaldehyde, water, bis(methylthio)methane, dimethyl disulfide, dimethyl sulfone, and dimethyl sulfide. The decomposition is accelerated by acids, glycols, or amides. Sulfoxides undergo oxidation, reduction, carbonsulfide cleavage, and Pummerer reactions.

Methylsulfinyl Carbanion. Strong bases, e.g., sodium hydride or sodium amide, react with DMSO producing solutions of methylsulfinyl carbanion, known as the dimsyl ion, which are synthetically useful. The solutions also provide a strongly basic reagent for generating other carbanions.

[b] To convert J to cal, divide by 4.184.

Methoxydimethylsulfonium and Trimethylsulfoxonium Salts. Alkylating agents react with DMSO at the oxygen. For example, methyl iodide gives methoxydimethylsulfonium iodide as the initial product. The alkoxysulfonium salts are quite reactive and, upon continued heating, either decompose to give carbonyl compounds or rearrange to the more stable trimethylsulfoxonium salts.

Complexes. The sulfoxides have a high (ca 4) dipole moment, which is characteristic of the sulfinyl group, and a basicity about the same as that of alcohols. They are strong hydrogen-bond acceptors. They would be expected, therefore, to solvate ions with electrophilic character, and a large number of DMSO complexes of metal ions have been reported.

Synthesis and Manufacture

The sulfoxides are most frequently synthesized by oxidation of the sulfides.

Dimethyl Sulfoxide. Dimethyl sulfoxide is manufactured from dimethyl sulfide (DMS), which is obtained either by processing spent liquors from the kraft pulping process or by the reaction of methanol or dimethyl ether with hydrogen sulfide.

Health and Safety Factors

Dimethyl sulfoxide is a relatively stable solvent of low toxicity. However, DMSO can penetrate the skin and may carry with it certain chemicals with which it is combined under certain conditions. Dimethyl sulfoxide has received considerable attention as a useful agent in medicine. In veterinary medicine, DMSO is used for horses and dogs as a topical application to reduce swelling resulting from injury or trauma.

Uses of Dimethyl Sulfoxide

Polymerization and Spinning Solvent. Dimethyl sulfoxide is used as a solvent for the polymerization of acrylonitrile and other vinyl monomers, and as a reaction solvent for other polymerizations. It is also used as a solvent for displacement reactions, solvent for base-catalyzed reactions, extraction solvent, solvent for electrolytic reactions, cellulose solvent, pesticide solvent, and clean-up solvent.

SULFUR. [CAS: 7704-34-9]. Chemical element, symbol S, at. no. 16, at. wt. 32.064, periodic table group 16, mp 112.8°C (rhombic), 119.0°C (monoclinic), 120.0°C (amorphous), bp 444.7°C (all forms), sp gr 2.07 (rhombic), 1.96 (monoclinic), 2.046 (amorphous). Atomic weight varies slightly because of naturally occurring isotopes 32, 33, 34, and 36, the total possible variation amounting to ±0.003.

The stable isotopes of sulfur are ^{32}S, ^{33}S, ^{34}S, and ^{36}S. There are three known radioactive isotopes, ^{31}S, ^{35}S, and ^{37}S, with ^{35}S having the longest half-life (87.1 days). See also **Radioactivity**. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^4$. Ionic radius S^{2-} 1.855 Å, S^{6+} 0.29 Å (Pauling). Covalent radius 1.07 Å. In terms of abundance, sulfur ranks fourteenth among the elements occurring in the earth's crust, with an estimated 520 grams per metric ton. In seawater, the element ranks fifth, with an estimated 894 grams per metric ton.

First ionization potential 10.357 eV; second, 23.3 eV; third, 34.9 eV; fourth, 47.08 eV; fifth, 63.0 eV; sixth 87.67 eV. Oxidation potentials $H_2S(aq) \longrightarrow S + 2H^+ + 2e^-$, -0.141 V; $H_2SO_3 + H_2O \longrightarrow SO_4^{2-} + 4H^+ + 2e^-$, -0.20 V; $S + 3H_2O \longrightarrow H_2SO_3 + 4H^+ + 4e^-$, -0.45 V; $SO_3^{2-} + 2OH^- \longrightarrow SO_4^{2-} + H_2O + 2e^-$, 0.90 V; $S^{2-} \longrightarrow S + 2e^-$, 0.508 V; $HS^- + OH^- \longrightarrow S + H_2O + 2e^-$, 0.478 V. Other important phy sical properties of sulfur are given under **Chemical Elements**.

Sulfur has a large number of allotropes. The ordinary form, α-sulfur, is rhombic having a crystal unit cell composed of sixteen S_8 molecules. At 95.5°C it undergoes transition to β-sulfur, which is monoclinic and also has a molecular weight (in solution in carbon disulfide) corresponding to S_8. Four other monoclinic forms have been identified microscopically: γ-sulfur, prepared by heating α-sulfur to 150°C, cooling to 90°C, and inducing crystallization by friction, ρ-sulfur, S_6, prepared by extracting an acidulated sodium thiosulfate solution with toluene, as well as δ-sulfur, and λ-sulfur. There is also a tetrahedral form, θ-sulfur, crystallized from a carbon disulfide solution of rhombic sulfur treated with balsam. The first liquid form to appear is λ-sulfur, a pale yellow liquid, obtained on heating sulfur to 120°C. Above 160°C, this form changes to a viscous, dark-brown liquid consisting mainly of μ-sulfur. A third liquid allotrope, π-sulfur is considered to exist in molten sulfur, in equilibrium with the other two forms, having its greatest concentration at about 180°C. Sulfur vapor has been shown to contain S_8, S_6, S_4, and S_2 molecules. Several other allotropes of sulfur have been produced, including two paramagnetic forms, purple and green in color, by low-temperature processing.

Sulfur occurs as free sulfur in many volcanic districts, and may have been formed in part by sublimation, by decomposition of hydrogen sulfide, or metallic sulfides, or by organic agencies. It is often associated with limestones and gypsum. Sulfur is found in Spain, Iceland, Japan, Mexico, and Italy. It occurs especially in Sicily, which was the producer for the world until about the beginning of the twentieth century, when Herman Frasch, by inventing the superheated-water method of mining sulfur, made available the great Louisiana and Texas deposits. This method of mining is at the same time a method of purifying sulfur, because in the process of heating, accompanying materials remain unmelted at the temperature at which sulfur melts and is drawn off. In the Louisiana and Texas deposits the sulfur is associated with gypsum, occurring in the caprock overlying the salt plugs that have pierced the strata underlying the Gulf coastal plain. In the United States, sulfur is also found in California, Colorado, Nevada, and Wyoming. Sulfur also occurs as (1) sulfides, e.g. cobaltite, iron disulfide, pyrite, FeS_2, lead sulfide, galenite, PbS, copper iron sulfide, copper pyrite, $CuFeS_2$, zinc sulfide, zinc blende, ZnS, mercury sulfide, cinnabar, HgS; and (2) as sulfates, e.g., calcium sulfate, gypsum, $CaSO_4 \cdot 2H_2O$, barium sulfate, barite, $BaSO_4$. Several of these minerals are described under separate alphabetical entries.

Sulfur Production and Use

The manufacture of H_2SO_4 accounts for nearly 90% of all sulfur consumed. Of this, about 50% of the H_2SO_4 goes into fertilizer production, nearly 20% into chemical manufacture, 5% into pigments, about 3% each for iron and steel production and the manufacture of rayon and synthetic films, and about 2% for various petroleum processes. The balance of over 15% of H_2SO_4 is consumed by a large number of other industries, this all giving credence to the use of H_2SO_4 production figures as an overall economic index. The 10% of the sulfur not going into H_2SO_4 is converted into numerous chemicals that are consumed by a variety of industries, the largest among these being pulp and paper production and the manufacture of carbon disulfide.

Sulfur Compounds

In addition to the compounds described in the following paragraphs, see also **Hydrogen Sulfide**; **Mercaptans**; **Sodium Thiosulfate**; **Sulfuric Acid**; **Sulfurous Acid**; **Thiocyanic Acid**; **Thioethers**; **Thiophene**; and **Thiourea**.
